A Unifying Mechanistic Model of Mild Steel Corrosion in Weak Acid Aqueous Solutions

Srdjan Nesic, Aria Kahyarian, Bruce Brown
Institute for Corrosion and Multiphase Flow Technology, Ohio University, Athens, OH, USA
nesic@ohio.edu

Recent advaces in understanding of the mechanism of mild steel corrosion in the presence of carboxylic acids, dissolved carbon dioxide, and hydrogen sulfide has challenged the conventional views of aqueous corrosion in anoxic weak acid solutions. Conventionally, the high corrosivity of such environments was associated with the direct reduction of these weak acids. Within the last few years, experimental and theoretical investigations of the electrochemical behavior of these corrosive environments suggest that the buffering effect arising from the dissociation of weak acids in the vicinity of metal surface is the main cause for the observed high corrosivity. These findings suggest that neither carboxylic acids, nor the dissolved carbon dioxide, nor hydrogen sulfide are themselves corrosive, and that they merely exacerbate an existing acidic corrosion process. In this study, the buffering effect, being an inherent property of any weak acid, is shown to account for all characteristic behaviors observed in cathodic currents, in all of the cases considered. In order to further elucidate this general behavior, a comprehensive mathematical model was developed and used to simulate the behavior of a hypothetical weak acid, as a function of the kinetic and thermodynamic properties of its dissociation reaction. The mechanistic findings in the present study are framed in terms of a generic mechanistic view of corrosion in weak acid solutions. That enables a simple and generic categorization of weak acids based on their pKa values to serve as a basis to assess the detrimental effect of any weak acid on mild steel corrosion in acidic solutions.

Electrochemical Zero-Mode Waveguide Studies of Single Redox Molecules in Nanopore Electrode Arrays

Paul W. Bohn, Vignesh Sundaresan, Seol Baek
Departments of Chemical and Biomolecular Engineering and Chemistry and Biochemistry
318 Stinson Remick Hall, Notre Dame IN 46556 USA
pbohn@nd.edu

It is critically important to understand the relationship between functional states of individual redox enzymes and the macroscopically observed phenotype, which results from averaging over all copies of the same enzyme. Optimally, single enzyme molecules would be studied one-molecule-at-a-time and combined to characterize population behavior. However, studying single electron transfer events in biological systems is quite challenging, principally because the generated currents are below, the noise floor of electrical measurements at accessible gain-bandwidth products. However, the Johnson noise floor can be circumvented by converting redox processes to photon emission events, *i.e.* luminescence, thereby converting the measurements into the shot noise limited regime. Fortunately, flavoenzymes, *i.e.* enzymes with a flavin-based cofactor, exhibit electrofluorogenic behavior, in which the oxidized state of the isoalloxazine chromophore in either flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD) is strongly emissive in the oxidized, but almost completely non-emissive in the reduced state. However, in order to take advantage of this, it is necessary to isolate single enzyme molecules. To address this problem, we have developed a bifunctional nanoelectrochemical-nanophotonic architecture - the electrochemical zero mode waveguide (E-ZMW) - that can couple biological electron transfer reactions to luminescence, making it possible to observe single electron transfer events in redox enzymes.

Although E-ZMWs may be realized as single nanopores, we utilize parallel arrays of cylindrical nanopores containing either 1 or 2 embedded annular nanoband electrodes. These architectures exhibit several advantages, including: (1) the average occupancy of individual pores may be controlled by concentration, (2) the electrodes in each individual pore are connected to those in all the other pores, so they can all be controlled at the same potential, E_{appl}, and (3) the electrochemical behavior is integrated over the entire array. Thus, single molecule spectroscopic and electrochemical data can be acquired simultaneously. We have used these E-ZMW nanopore electrode arrays to demonstrate strongly correlated single molecule population fluctuations both by correlating the electrochemical currents at top and bottom electrodes and by cross-correlating the electrochemical signals with luminescence signals at the bottom electrode, which also serves as the optical cladding layer of the E-ZMW.[1]

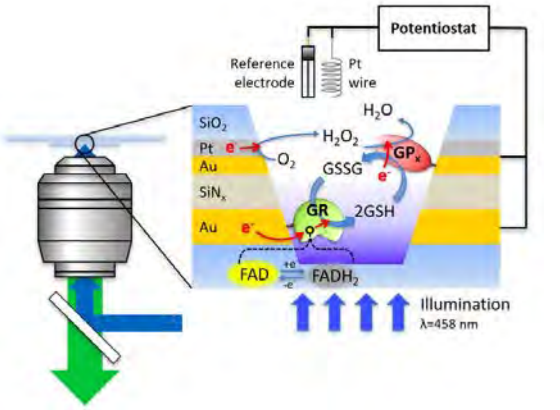

Figure 1. Schematic diagram illustrating the conceptual approach to single electron transfer event observations in the GR-GSSG-GSH system.

Currently, dual-electrode E-ZMWs are being used to carry out single enzyme reduction experiments using the scheme, employing glutathione reductase, GR, as shown in **Figure 1**. The top electrode is used to produce reactive oxygen species in the zeptoliter volume nanopore, for example by the $1e^-$ reduction of O_2 to superoxide, $O_2^{-\bullet}$, which then dismutates into H_2O_2 and O_2. The resulting perturbation of the glutathione redox speciation is then monitored by transients in the single molecule emission of GR.

From Bioelectrochemistry to Bioelectronics, Biocomputing and “Smart” Materials

Evgeny Katz
Department of Chemistry and Biomolecular Science, Clarkson University
8 Clarkson Ave., Potsdam, NY 13699, USA
ekatz@clarkson.edu

The original goal of bioelectrochemistry has been in the fundamental study of biomolecules, particularly enzymes, communicating with electrically conducting/semiconducting interfaces (electrodes and semiconducting devices). Following the impressive achievements in bioelectrochemistry, especially in mediated and direct electron transfer between proteins/enzymes and electrodes, numerous bioelectrochemical systems have been designed resulting in various biosensors and biofuel cells. Later, more sophisticated systems have been approached, resulting in implantable and wearable bioelectronic devices for sensing and power generation. Novel research directions have been formulated including bioelectrochemical information processing (biocomputing) systems, signal-triggered bioelectrochemical systems, “smart” bioelectrochemical interfaces switchable/tunable by various external signals and capable of electronically stimulated biomolecular release. Studies progressing from conventional electrochemistry to novel multidisciplinary research areas mostly named “bioelectronics” rather than “bioelectrochemistry”, resulted in very impressive scientific results and practical applications. The lecture will briefly address general progress in the research areas of bioelectrochemistry and bioelectronics, concentrating on the author’s personal contribution to the areas. Additional information related to the lecture can be found in the recently published books [1-3].

Bioelectrochemical Approaches towards the Detection and Quantification of Drug Resistance in Bacteria and Cancer

Sabine Kuss
University of Manitoba, Department of Chemistry
144 Dysart Road, Winnipeg, Canada, R3T2N2
sabine.kuss@umanitoba.ca

Drug resistance in bacteria and cancer is a growing problem that severely increases the number of deaths from bacterial infections and cancer.[1,2] According to the World Health Organization, drug resistance is present in every country, and various national and international health organizations have called for the urgent development of new treatment and diagnostic strategies.[3] Cellular resistance mechanisms are at the root of drug resistance, which include cell membrane protein modifications, intracellular drug target alterations, and the over expression of efflux pumps.[4]

This presentation outlines innovative and interdisciplinary approaches to recognize and quantify drug resistance in bacteria and cancer cells by electrochemistry. Electroanalytical techniques are cost efficient, sensitive and the transparency of a liquid sample is irrelevant, allowing direct in vitro analysis of blood, urine, and saliva samples. This presentation covers the characterization of some of the most important commercial drugs, and new investigational antibiotic hybrids by electrochemistry.[5] Building on this exploration of drug electrochemistry, the quantification of drug influx and retention in biological cells will be presented. This research forms the basis for the development of a point-of-care biosensor to identify drug resistance in patient samples. Such technology would advance clinical treatment from the current trial-and-error approach to the prescription of evidence-based personalized drug regimens.

Soft interfaces polarisation: The Helmholtz model strikes back!

Hubert H. Girault, Grégoire Gschwend
Laboratoire d'Electrochimie Physique et Analytique,
Ecole Polytechnique Fédérale de Lausanne
Rue de l'Industre 17, CH-1951 SION- Switzerland
Hubert.girault@epfl.ch

When considering the polarisation of soft interfaces, such as at ion-selective electrode polymer membranes, liquid-liquid interfaces, biological membranes, most textbooks present the polarisation of the interface within the framework of the Gouy-Chapman diffuse layer model.
At a metal-electrolyte interface, the electronic charge distribution is homogeneous at the electrode surface and is described by a homogeneous charge density. On the electrolyte side, the ions compensating the electronic charges are either specifically adsorbed or distributed in what is known as the Gouy-Chapman diffuse layer. Many years of studies at the mercury-electrolyte interface have validated this model.

By extension, the Gouy-Chapman model is used to describe the polarization at liquid-liquid interfaces in what is often referred to as the back-to-back diffuse layers model, where a positively charged diffuse layer in one phase is facing another negatively charged diffuse layer in the adjacent phase. As a result, it is thought that the potential drop between the two phases occurs across a couple of nanometers.

In this talk, we wish to show the limits of this model.

Using different experimental techniques such as impedance measurements, electrocapillary curves, and non-linear spectroscopic techniques together with molecular dynamics simulations, we wish to propose another vision where the polarisation of the interface occurs across a bilayer of interfacial "ion-pairs" (more precisely interacting ions) in what could be called a "discrete Helmholtz" model by reference to the very early work of Helmholtz.

Here, we show that the ion-ion interactions are such that ionic charges do not distribute themselves in a diffuse layer, but by direct formation of interfacial "ion pairs". In this way, all the potential drop occurs across this interfacial ionic bilayer in a stepwise manner. Also, the capacitance of the interface is found to be potential independent for a given "ion pair" and the amount of interfacial "ion pairs" is proportional to the potential difference between the two phases.

We shall illustrate the model to explain the distribution potential of a salt and the electrocapillary phenomena observed with polarised interfaces.

This view of the interfacial polarization of the interface allows us to solve the old dilemma of the potential dependence of electron transfer reactions at liquid-liquid interfaces.

Finally, we shall discuss the extension of the so-called "discrete Helmholtz" model to other interfaces where the charge distribution is not evenly distributed but localized for example in nanostructured solid interfaces as in supercapacitors,

Single-particle microscopy of photoelectrodes

Peng Chen
Department of Chemistry and Chemical Biology, Cornell University
Baker Laboratory, Ithaca, NY 14853, USA
pc252@cornell.edu

This presentation will describe our single-molecule fluorescence and photoelectrochemical imaging work on individual semiconductor nanorods under photoelectrochemical water oxidation conditions. I will describe the insights we gained into the charge carrier activities on these semiconductor particle surfaces, how they are related to the photocurrent generation, how deposition of cocatalysts at specific surface sites alters their behaviors, and the efficiency losses from individual particle-particle interfaces.

Reduced Graphene Oxide: Electrochemical Sensing and Therapy

Sabine SZUNERITS
Institut d'Electronique, de Microélectronique et de Nanotechnologie (IEMN), UMR CNRS 8520, University of Lille,
Avenue Poincaré-BP 60069, 59652 Villeneuve d'Ascq, France,
e-mail address: sabine.szunerits@univ-lille.fr

Graphene and its derivatives (graphene oxide, reduced graphene oxide) have drawn tremendous attention from the scientific community as a promising nanomaterial with applications ranging from optoelectronics, high-energy physics, to material science and biomedicine. Different methods have been reported for the preparation of the different graphene-based matrixes. In this presentation, some of your work on the fabrication and interest of reduced graphene oxide (rGO) and rGO-based composite materials for electrochemical sensing and therapeutic applications will be discussed. In the sensing area, the choice of the way graphene is obtained is crucial and will influence strongly electron transfer rates and impact on sensitivity and selectivity to solution analytes. A special focus will be on the use of electrophoretic based approaches for the deposition of rGO and hybrid materials. On the other hand, rGO loaded hydrogels have proven to be versatile controlled-release systems. Some examples on the formation of metformin hydrochloride and insulin loaded bandages for transdermal delivery will be discussed in addition.

Novel Phosphates and Fluoride-Phosphates Electrode Materials for Me-ion Batteries

Evgeny V. Antipov
Lomonosov Moscow State University, Moscow, 119991, Russia
Skolkovo Institute of Science and Technology (Skoltech), Moscow 121205, Russia
e-mail: evgeny.antipov@gmail.com

The rapid progress in mass-market applications of metal-ion batteries intensifies the research on electrode materials for Na-ion and K-ion batteries as viable alternatives to the already mature Li-ion technology. Similar to the Li-ion intercalation systems, the Na and K-based mixed oxides and polyanion materials are thoroughly scrutinized as potential cathodes aiming to enhance the specific energy, durability and rate capability. Whereas the layered oxides display greater volumetric energy density, the polyanion materials usually exhibit better cycling and thermal stability and higher C-rate capabilities due to covalently bonded structural frameworks. At the same time compared to the oxide structures based on a close-packed arrangement of oxygen atoms, the polyanion compounds reveal an extra dimension in their crystal chemistry, which significantly extends the playground for designing materials with superior electrochemical performance. Further advantages are expected from the synergistic effect of combining different anions (such as $(XO_4)^{p-}$ and F^-) in the anion sublattice.

An overview of the research on novel transition metal phosphates, pyrophosphates, and fluoride-phosphates as prospective electrode materials for the Na-ion and K-ion batteries will be presented with a special emphasis on the interrelation between chemical composition, synthesis conditions, crystal structure peculiarities and electrochemical properties of the materials intended for practical applications.

The intense interest in quantifying levels of microRNA is because of its importance as a blood-borne biomarker. The challenge has been to develop methods that can monitor microRNA expression both over broad concentration ranges and ultralow amounts directly in a patient's blood. Here, we show using gold-coated magnetic nanoparticles modified by probe DNA (DNA-Au@MNPs) that possess a redox label. The DNA-Au@MNPs diffuse through the sample for analysis and collect the majority of miRNA in a sample before being brought back to the electrode. The resultant microRNA sensor is able to detect concentrations of microRNA from as low as 10 aM to 1 nM in unprocessed blood samples. The exceptionally low detection limits are a result of an unexpected amplification process where hybridisation of a single DNA-microRNA duplex switches off the electrochemistry from hundreds of DNA-Au@MNPs. This amplification system appears to be *via* an electric-field-induced reconfiguration of a network of DNA-Au@MNPs. The highly-sensitive biosensor is capable of direct analysis of nucleic acids in samples as complex as whole blood. It can distinguish small variations in microRNA concentrations in blood samples of animal models that occur due to the presence of a tumour with changes in miRNA levels detected by the biosensor correlated with real-time polymerase chain reaction (qRT-PCR) analysis of the same blood samples. The ultrasensitive and direct detection of microRNA using electrically-reconfigurable DNA-Au@MNPs network makes the reported device a promising tool for cancer diagnostics.

Bipolar Electrochemistry: A Powerful Tool for Organic Redox Reactions

Shinsuke Inagi
School of Materials and Chemical Technology, Tokyo Institute of Technology
4259 Nagatsuta-cho, Midori-ku, Yokohama 226-8502, Japan
inagi@cap.mac.titech.ac.jp

Electrosynthesis is a powerful method for the synthesis of organic, inorganic and polymeric materials based on electron transfer-driven reactions at the substrate/electrode interface. The use of electricity for synthetic reactions without the need for hazardous chemical oxidants and reductants is recognized as a green and sustainable method. A different mode for driving electrochemical reactions has recently been proposed, in which bipolar electrodes (BPEs) are available as wireless electrodes that undergo anodic and cathodic reactions simultaneously. Bipolar electrochemistry is an old technology that has recently attracted attention again due to the interesting features of BPEs because (i) the wireless nature of a BPE is useful for sensors and material synthesis, (ii) the gradient potential distribution on BPEs is a powerful tool for the preparation of gradient surfaces and materials, and (iii) electrophoresis is available for effective electrolysis (Figure 1).[1] In addition to these unique features, a BPE system only requires a small amount of supporting electrolyte in principle, whereas a large amount of electrolyte is necessary in conventional electrochemistry. Hence, bipolar electrochemistry is an inherently green and sustainable chemical process for redox reactions.

In this study, recent progress in bipolar electrochemistry for the electrosynthesis of organic functional materials is summarized. Potential gradients on a BPE interface have been successfully used as controllable templates to form molecular or polymeric gradient materials, which are potentially applicable for high throughput analytical equipment or as biomimetic materials. The wireless nature of BPEs was utilized for symmetry-breaking to produce anisotropic materials based on the site-selective modification of conductive objects by redox reactions including electropolymerization. The electric field necessary to drive BPEs is also potentially useful to induce the directed migration of charged species. The synergetic effects of electrophoresis and electrolysis were also successfully demonstrated to obtain various functional materials. These features of bipolar electrochemistry and the various combinations of techniques have the potential to change the methodologies of material synthesis.

Cyclic Voltammetry: New Theoretical Challenges for Bringing a Famed Electrochemical Lady up to Date

Christian Amatore,[1,2] Irina Svir,[2] Alexander Oleinick[2]
Xiamen University, CNRS, Sorbonne University and PSL University
[1]*State Key Laboratory PCOSS, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, 361005, China*

christian.amatore@ens.psl.eu

Cyclic voltammetry has proven its large popularity compared to most other electroanalytical methods owing to its versatility for investigating electrochemical mechanisms and their kinetics. Many textbooks provide clues and laws for understanding and quantifying the main features displayed by a voltammogram. However, this is unfortunately not often useful when confronted to complicated mechanisms as those investigated today. Indeed, most mechanistic situations encountered in molecular electrochemistry at the present time involve complex competitive and entangled reactions that occur indifferently in solutions and onto the surface of electrodes, quite often mixing a series of entwined surface-solution sequences. When confronted to such intricate problems, the classical voltammetric dogma prove helpless and even possibly misleading.

For example, we recently introduced and investigated what is now cited as the "Laviron-Amatore paradox" [1,2] to solve the case of the electrocatalyzed reduction of benzyl chloride at silver cathodes [3]. Although the critical steps were demonstrated to be essentially heterogeneous, involving adsorbed and chemisorbed intermediates, the voltammetric traces displayed none of the expected corresponding features. Conversely, they seemed fully coherent with diffusion/reaction solution processes as if the silver cathodes were playing a strict outer-sphere role. Beyond their favorable catalytic consequences, the same type of essential but hardly detectable surface components present in a mechanism may result in self-inhibitory effects whose drawbacks cannot be rationalized or predicted within classical frameworks [2]. It is presumable that many of such competitive reactions involving exchanges of intermediates between an electrode surface and the solution which feeds the overall process have remained unnoticed due to the lack of dynamic theoretical models and computational approaches prone to detect and apprehend their curious behavior. This is in particular with the objective of allowing the investigations of such finely intertwined heterogeneous and homogeneous steps that we developed our multi-purpose simulation program KISSA$^{©}$ [4].

In this conference, aimed to thank ISE and its Division 6 for the attribution of the Jaroslav Heyrovsky Prize in molecular electrochemistry to one of us, we will present some specific cases of complex voltammetric situations from two first examples studied in the past [5,6].

How Does a Polycrystalline Electrodeposited Film Grow? Insights from High-Speed AFM

Walther Schwarzacher*, Aswathi Koorikkat, Oliver Payton, Loren Picco#
H.H Wills Physics Laboratory , University of Bristol, Bristol BS8 1TL, UK
 # Virginia Commonwealth University, Richmond, USA
**w.schwarzacher@bristol.ac.uk*

The problem of how the microstructure and surface topography of a polycrystalline electrodeposited film develop as the film thickness increases is a longstanding one. For example, although ex-situ measurements have shown that both the grain size and the surface roughness of electrodeposited films can increase with film thickness, the details of this process remain unclear[1].

We have used high-speed atomic force microscopy to monitor the surface topography of a Cu film electrodeposited on to a lithographically patterned gold microelectrode from an organic additive-free acid sulfate electrolyte. Measurements are made in real time during growth. The high-speed flexure sample stage of HS-AFM can provide a scan rate 1000 times greater than a conventional AFM, which is key to enabling us to probe much higher deposition rates than previous in-situ studies (currently around 90 nm/s).

The data reveal a number of interesting phenomena. The lateral correlation length appears to increase because different grains grow at different rates. This is accompanied by an increase in local slope, which is also revealed by scaling analysis because surface roughness as a function of deposition time exhibits anomalous scaling[2]. Also, in some cases we clearly observe one grain overgrowing another. A further interesting observation is that, rather than the tip screening the substrate and reducing the deposition rate, tip movement enhanced mass transport significantly during growth: there was accelerated growth where scanning took place compared to other regions of the sample.

Li-ion batteries: from High Energy to Sustainability

Stefano Passerini[a,b], Matthias Kuenzel[a,b], Dominic Bresser[a,b]
[a] *Helmholtz Institute Ulm (HIU), Helmholtzstrasse 11, 89081 Ulm, Germany*
[b] *Karlsruhe Institute of Technology (KIT), P.O. Box 3640, 76021 Karlsruhe, Germany*
stefano.passerini@kit.edu

The announcement of major car manufacturers worldwide to electrify their product line within less than a decade has triggered the large increase of battery cell manufacturing. This will gain even greater momentum once other OEMs will be following this ambition. Lithium-ion batteries are the energy storage technology of choice to enable the deployment of electric vehicles avoiding the use of fossil fuels. However, a transition to a more sustainable production of these cells is required. Consequently, efforts are being invested to develop non-toxic and abundant active materials, for instance, by reducing (if not excluding) the use of cobalt and nickel. Implementing aqueous processing for lithium-ion positive electrodes is another key step towards the achievement of environmentally benign battery production.

Targeting these urgent necessities, we have developed along the years a simple approach leading to the aqueous processing of the high-voltage LiNi0.5Mn1.5O4 (LNMO). This active material is, in fact, considered the most promising for the realization of cobalt-free next generation lithium-ion batteries. First, we demonstrated the feasible use of bio-derived polymers, e.g., sodium carboxymethylcellulose, guar gum and chitosan [1-3], as electrode binders in combination with phosphoric acid, for active material particles and current collector protection, and citric acid, for polymers cross-linking. Thus, to achieve positive electrode tapes readily available for large-scale, high-energy lithium-ion batteries, the use of carbon-coated current collector was introduced, which provides functional groups to crosslink the electrode coating layer to the underlying aluminum foil. The resulting electrodes demonstrate significant improvements concerning the electrode to current collector adhesion and their capacity retention. Through the further optimization of the initial formation cycles, these electrodes offer an electrochemical performance exceeding that of LNMO-based reference electrodes, comprising state-of-the-art poly(vinylidene difluoride) (PVdF) as binder.

Catalyst Design and Operando Structure-Composition-Reactivity Correlations during CO_2 Electroreduction

Beatriz Roldan Cuenya

Department of Interface Science, Fritz Haber Institute of the Max Planck Society
Faradayweg 4-6, 14195 Berlin, Germany
roldan@fhi-berlin.mpg.de

The utilization of fossil fuels as the main energy source gives rise to serious environmental issues, including global warming caused by the continuously increasing level of atmospheric CO_2. Recently, the electrochemical conversion of CO_2 (CO_2RR) to chemicals and fuels driven by electricity derived from renewable energy has been recognized as a promising strategy towards sustainable energy.

In my talk I will describe the challenges but also provide examples of recent advances in the development of highly active and selective catalysts for the electrochemical reduction of CO_2. The new materials include well-oriented Cu single crystals, plasma-modified nanostructured films, and nanoparticle (NP) electrocatalysts (Cu, Ag, Zn, CuZn and AgSn). Selectivity control in CO_2RR will be achieved through the rational design of the electrocatalyst structure (crystal orientation, atomic arrangement, size, shape, defects), oxidation state and composition. Furthermore, I will also demonstrate how important morphological motives and chemical species can be created and regenerated in pulsed electrolysis experiments.

Finally, the determining role of the electrolyte in the surface restructuring, reaction activity and selectivity will be illustrated. Throughout my talk, the importance of *in situ* and *operando* microscopy and spectroscopy characterization methods to gain in depth understanding on the structure- and electrolyte-sensitivity of real CO_2RR catalysts under working conditions will be highlighted. Our results are expected to open up new routes for the reutilization of CO_2 through its direct selective conversion into higher value products such as ethylene and ethanol.

Towards a Comprehensive Understanding of Platinum-based Electrocatalysis

Federico Calle-Vallejo
Universitat de Barcelona
Carrer de Martí i Franquès 1, 08028, Barcelona, Spain
f.calle.vallejo@ub.edu

Platinum is at the same time one of the most versatile and scarce electrocatalysts. While considerable research efforts have been directed to its replacement in many applications, another plausible strategy is the design of optimal Pt electrocatalysts. In the latter case, the most active sites for each Pt-catalyzed reaction need to be unambiguously determined and fully exploited. A tool for that purpose are "generalized coordination numbers" (GCNs).

In this talk, I will show that GCNs accurately describe adsorption-energy trends for unstrained as well as strained Pt sites on nanoparticles of different shapes and sizes and extended surfaces [1, 2].

Moreover, I will briefly show that "coordination-activity plots" based on GCNs outline the geometric configuration of optimal Pt sites for three important electrocatalytic reactions: O_2 reduction [3, 4], H_2 evolution [5], and CO oxidation [6].

Finally, I will show that GCNs can be used to shed light into two important topics in electrocatalysis, namely adsorbate solvation [7] and the intricate selectivity of organic reactions [8].

Probing the Solvated Electron at the Electrochemical Interface with a Novel Optoelectronic Method

Yujin Tong

Fritz Haber Institute of the Max Planck Society, Faradayweg 4-6, 14195 Berlin, Germany

Faculty of Physics, University of Duisburg-Essen, Lotharstrasse 1, 47057 Duisburg, Germany

e-mail: tong@fhi-berlin.mpg.de

The solvated electron has fundamental and practical significance in radiation and radical chemistry, catalysis and radiobiology. While its bulk properties have been extensively studied, its behavior at electrochemical interfaces is still unclear due to the lack of effective tools to characterize this short-lived species at the condensed matter interfaces. To solve this problem, our group developed a new technology based on ultrashort laser and electrochemical detection (two-photon pump electrochemical probe technique). As shown in in the scheme, here we introduce ultra-short pulse lasers in the traditional electrochemical detection system. One of the lasers is used to excite charge transfer or dipole inversion, and the other laser is used to track the relaxation of the excited state that was trigged by the first laser, while detecting photocurrent or photovoltage in both processes. By adjusting the photon energy of two pulsed lasers and their time difference, we can both obtain the spectral information of the surface species and track ultrafast dynamic processes. In this report, I will use the example of the solvation process of hot electrons at the gold/water interface to show you how this new technique works[1]. This technology will play an important role in the tracking and analysis of various processes in energy and environmental transition in chemistry.

Atomic Scale Electro-Catalysis

Jan Rossmeisl
Department of Chemistry, University of Copenhagen
Universitetsparken 5, 2100, København Ø, Denmark
Jan.rossmeisl@chem.ku.dk

The chemical industry should in the future be based on renewable energy. Therefore, material development for environmentally friendly, electrocatalytic production of valuable chemicals is needed.

Chemicals could be produced using safe, cheap, more environmentally friendly and more abundant reactants than today. The products could be provided on demand at the place where they are needed, reducing expensive and hazardous transport of chemicals. However, stable, efficient and selective catalysts have to be discovered. This requires insight into the surface chemistry at the atomic scale.

The challenge of discovering new catalyst materials is twofold: Firstly, the properties or descriptors of the wanted catalyst have to be identified. Secondly, real materials with the wanted properties should be found.

I will give examples of determining descriptors for different reactions and a method for identify promising catalyst materials based on high entropy alloy, which is a new class of materials with the promise to change the way we discover interesting catalyst materials.

Electronic Interactions within Mixed Valent Compounds:
- The Influence of Anions, Solvents and Electrostatic Properties -

Alexander Hildebrandt
Technische Universität Chemnitz, Faculty of Natural Sciences, Institute of Chemistry, Inorganic Chemistry , D-09107 Chemnitz, Germany
alexander.hildebrandt@chemie.tu-chemnitz.de

The electrochemical properties of bi- and multi-metallic compounds are a convolution of several factors, among which through-bond electron transfer and through-space electrostatic features are the most prominent.[1,2] Besides intrinsic molecular properties, the measurement conditions have a considerable impact on the electronic interactions of mixed valent compounds.[2]

Within this presentation the dependency of inter valence charge transfer (IVCT) on the electrolytes and solvents will be discussed for analytes of different coupling strength. It can be shown that especially for weakly coupled systems the applied measurement conditions have a distinct impact on the energy and shape of the IVCT band while with an increase of the coupling strength the influence of the measurement media diminishes (Figure 1).

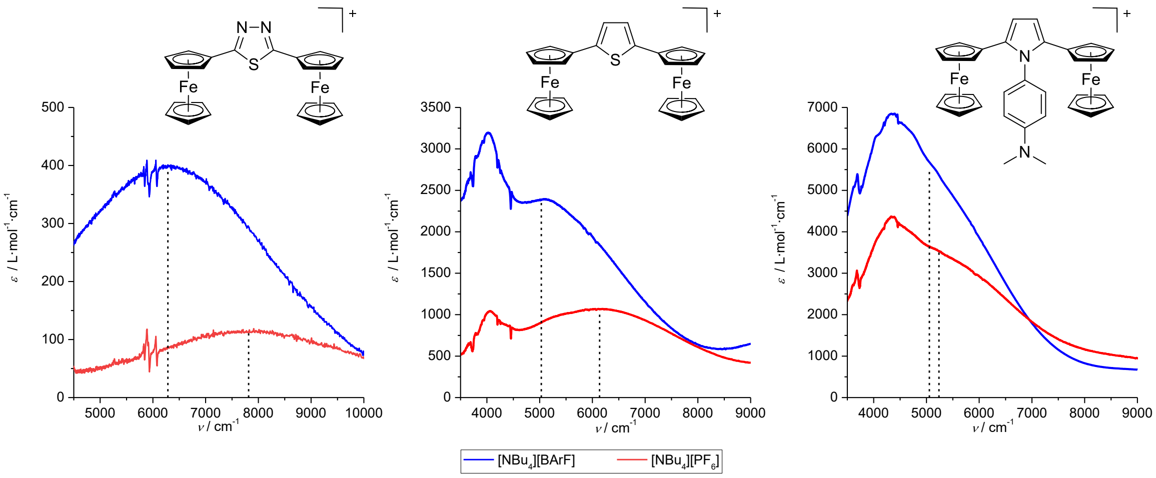

Figure 1. Electrolyte (blue = [NBu4][BArF]; red = [NBu4][PF$_6$]) dependent shift of the IVCT bands of different mixed valent compounds in dichloromethane (BArF$^-$ = B(C$_6$F$_5$)$_4^-$).

In addition, methods that can be used to identify and assess the often less well explored electrostatic contributions to the electrochemical behavior are highlighted. Advances in finding reliable models for intramolecular electrostatic interactions, inter- and intra-molecular influences on the electrostatic properties as well as the exploitation of different ion-pairing capabilities of various electrolytes in order to gain information on electrostatic repulsion energies are discussed.

xuzc@ntu.edu.sg

The oxygen evolution reaction (OER) is the bottleneck that limits the energy efficiency of water-splitting. The process involves four electrons' transfer and the generation of triplet state O_2 from singlet state species (OH- or H_2O). Recently, the OER reactants and products differing in their spin configurations have been thought to cause slow reaction kinetics. Catalysts with magnetically polarized channels could selectively remove electrons with opposite magnetic moment and conserve overall spin during OER, enhancing triplet state oxygen molecule evolution. This talk discuss our recent progress about using ferromagnetic ordered catalysts as the spin polarizer for spin selection under a constant magnetic field to enhance the OER. At the same condition, it does not applicable to non-ferromagnetic catalysts. On the other hand, one example of antiferromagnetic oxides, an inverse spinel structure oxide $LiCoVO_4$, is discussed. It contains d7 Co^{2+} ions that can be stabilized under active octahedral sites, possessing high spin states S=3/2 ($t_{2g}5e_g2$). With high spin configuration, each Co^{2+} ion has an ideal magnetic moment of 3μB, allowing the edge-shared Co^{2+} octahedra in spinel to be magnetically polarized, giving magnetically polarized channels. The average magnetic moment (μ_{ave}) per transition-metal atom in the spin conduction channel is around 2.66μB. Such channels are able to enhance the selective removal of spin-oriented electrons from the reactants during the OER, which facilitates the accumulation of appropriate magnetic moments for triplet oxygen molecule evolution.

Biomolecular Wires of Electric Bacteria: Themes and Variations

Julea Butt
School of Chemistry and School of Biological Sciences,
University of East Anglia, Norwich Research Park, Norwich, NR4 7J, U.K.
j.butt@uea.ac.uk

Electric bacteria are naturally able to exchange electrons between internal enzymes and electrodes [1-4]. As a consequence there is much interest in the electrochemistry of these fascinating microorganisms. They can produce clean electricity in microbial fuel cells and value-added chemicals by microbial electrosynthesis. These processes require electron transfer across cell wall lipid bilayers and along extracellular 'nanowire' structures of several microns. Molecular structures of the conductive proteins allowing this electron transfer have recently been revealed for species of *Shewanella* and *Geobacter* [5-7]. The proteins are multiheme cytochromes spanned by chains of close packed heme cofactors. This contribution will review the structures of these proteins and rates of electron transfer across them [e.g. 8-10] to inspire future engineering of such biomolecular wires for disruptive biotechnology operating at both the cellular and single protein levels.

A Study of Charge Storage in Polyaniline by Electrochemical Means and in situ Electron Spin Resonance Spectroscopy

George Zheng Chen
Department of Chemical and Environmental Engineering,
[1] Faculty of Science and Engineering, University of Nottingham Ningbo China, Ningbo 315100 China
[2] Faculty of Engineering, University of Nottingham, Nottingham NG7 2RD, UK
e-mail address: george.chen@nottingham.ac.uk

Polyaniline is well known for its high reversibility and durability in redox chemistry and related changes in structure, conductivity and chromism. In the past two decades when supercapacitor research has been fast growing, polyaniline, as a model member of the family of conducting polymers, has been widely recognized as a representative of pseudocapacitance [1-4]. During the Covid-19 pandemic lockdown period, the author has paid a re-visit to his own past work that has collected results from experimental and theoretical analyses of electrochemically grown polyaniline coatings [5-7]. Of particular interest to the ongoing effort to differentiate between electric double layer capacitance and pseudocapacitance [7] is the simultaneously recorded electrochemical and electron spin resonance (ESR) signals. This is because double layer charging does not invoke redox chemistry and hence causes no ESR signal change, but electron transfer reactions associated with pseudocapacitance are more likely to generate or eliminate spins. It was revealed that the ESR spectra of polyaniline depended strongly on the electrode potential as shown in Fig. 1, indicating that charge storage in polyaniline is dominantly undertaken by Faradaic processes. It was also confirmed that "surface confined" and "diffusion controlled" charge storage processes can both take place in polyaniline, largely dependent on the conductivity and thickness of the polymer coating. The implication is that although it is highly challenging, if not impossible [1], to differentiate between double layer capacitance and pseudocapacitance by electrochemical means only, it can be realized using in situ spectroscopic techniques.

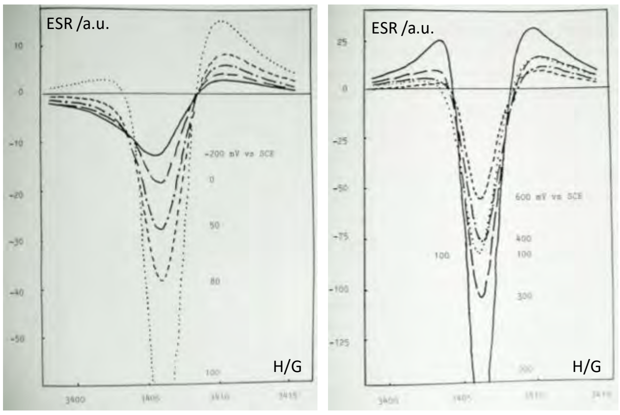

Fig. 1. Electron spin resonance spectra of polyaniline in 1.0 M HCl at the indicated potentials vs. SCE [5].

Bioelectrical Engineering at the Semiconductor-enabled Biointerfaces

Bozhi Tian
Chemistry Department, the James Franck Institute, and the Institute for Biophysical Dynamics
University of Chicago
btian@uchicago.edu

These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated.

Biointerface devices can probe fundamental biological dynamics and improve the lives of human beings. However, direct application of traditional rigid electronics onto soft tissues or cells can cause signal transduction and biocompatibility issues, due to mechanical mismatch at the biointerfaces. One common mitigation strategy is the use of nanostructures or soft-hard composites to form more biocompatible interfaces with target cells or tissues.

My group integrates nanoscience and soft matter physics with biophysics to study several semiconductor-based biointerfaces. In this talk, I will first pinpoint domains where semiconductor properties can be leveraged for biointerface studies, providing a sample of numbers in semiconductor-based biointerfaces. Next, I will present a few recent studies from our lab and highlight key bioelectrical engineering mechanisms underlying the non-genetic optical modulation interfaces. In particular, I will present a biology-guided two-step design principle for establishing tight intra-, inter-, and extracellular silicon-based bioelectrical interfaces in which silicon and the biological targets have matched mechanical properties and efficient signal transduction. The non-genetic methods have the potential to overcome the limitations of current metal electrode-based devices such as bulk and cell membrane disruption, and are not dependent on genetic modifications. Research in my lab has revealed how the physicochemical outputs from the photothermal, photofaradic, and photocapacitive effects of nanostructured semiconductors can be identified, quantified, and utilized at semiconductor-based biointerfaces to modulate electrical activities in neurons, cardiomyocytes and bacterial cells. Finally, I will discuss new materials and biological targets that could catalyze future advances.

Preparation of Carbon Supported 2D Nanocomposites for Electrochemical Analysis, Biosensing, and Electrocatalysis

Shen-Ming Chen
Department of Chemical Engineering and Biotechnology, National Taipei University of Technology,
No.1, 10 Section 3, Chung-Hsiao East Road, Taipei 106, Taiwan
smchen78@ms15.hinet.net

Manufacturing of nanomaterials is an interdisciplinary field covering physics, chemistry, biology, materials science and engineering. The interaction between scientists with different disciplines will undoubtedly lead to the production of novel materials with tailored properties. Binary transition metal oxides (BTMOs) displayed the recognizable benefit in enhancing the sensitivity of analytes detection, these principles preserve all specific properties of both, nanomaterial and biomolecule. Recently, the layered molybdenum selenide with crystal structure has been pointed out as an efficient electrocatalyst for various electrochemical and energy storage applications due to its interesting properties. We have reported transition metals (M = Mn, Ni, Co and Fe) doped $MoSe_2$ and applied as the electrode materials for bio/electrochemical sensors, biofuel cells, and supercapacitors applications. Thus, the utilization of high-quality nanomaterials is now growing and coming to the industrial arena rendering them as the next generation attractive resources with promising applications. Undoubtedly, the existing gap between basic research relating nanomaterials and their application in real life will be overcome in the coming decade. In addition, carbon based materials has been considered as an excellent platform for the preparation of nanocomposite due to its attractive properties including effective surface area, unique structures, mechanical and thermal stability, outstanding charge-transfer characteristics which enhances the electrocatalytic and photocatalytic activity of the supporting material. Moreover, the sulfide functionalities of carbon materials are more responsible for the incorporation of metal molybdates by the electrostatic attraction. Therefore, we are planning to develop an electrochemical sensor based on bimetal sulphides (MxSx, MSx where M =W, Mo, V, Bi, Zn) and sulphides (2D-MS) for the electrochemical detection of various electroactive biomolecules and Supercapactiors applications.

Operando Surface X-ray Diffraction Studies of Structurally-defined Transition Metal Oxide Electrocatalysts during Oxygen Evolution

O.M. Magnussen
Institute of Experimental and Applied Physics, Kiel University, Kiel, Germany
magnussen@physik.uni-kiel.de

Iron-group oxides are among the best precious-metal-free catalyst for the oxygen evolution reaction (OER) in alkaline media [1] and thus of great interest for large-scale electrochemical water splitting into O_2 and H_2. A wide variety of different catalysts, based on oxides of Co, Fe, and Ni, have been synthesized and studied, exhibiting rather diverse nanoscale morphologies and usually an unknown surface structure. This makes it difficult to compare their reactivity and correlate it with *ab initio* theoretical studies, which hinders the development of clear structure-reactivity relationships and unambiguous determination of the OER reaction mechanism.

In this presentation, approaches for studying structurally well-defined transition metal oxides are discussed. It is shown that the combination of methods for the preparation of oxides with controlled surface orientation with synchrotron-based *in situ* and *operando* surface x-ray diffraction (SXRD) methods can provide detailed insights into these electrode materials under reaction conditions. Specifically, the SXRD techniques allow characterization of the surface and bulk oxide structure over a wide potential range, including the OER regime. These can be performed simultaneously with electro-chemical measurements, enabling direct correlations of structure and reactivity.

As an example, SXRD studies of ultrathin epitaxial films of $Co_3O_4(111)$ and β-CoOOH(001) electro-catalysts [2] are discussed. These two materials show very different behavior. While the CoOOH(001) samples are perfectly stable over a wide potential range, fast and fully reversible structural changes are observed for $Co_3O_4(111)$, in good agreement with a previous study of polycrystalline Co_3O_4 catalysts [3]. Specifically, the near surface region of $Co_3O_4(111)$ is converted to a new phase, which is assigned to highly disordered CoOOH. In addition, continuous changes of the Co_3O_4 unit cell volume are found over a wide potential range, which are assigned to changes in the oxide bulk, related to the pseudo-capacitive charging current in the pre-OER potential range. The kinetics of these structural changes is fast and highly reversible. Despite these differences, the catalytic activity of the skin layer covered $Co_3O_4(111)$ and that of the smooth β-CoOOH(001) are almost identical, if the true microscopic surface area is taken into account. This indicates that the number of OER active sites on the two oxides is similar, despite the very different defect density, and is at variance with previous suggestions that di-μ-oxo bridged Co cations are exclusively responsible for the OER activity of Co oxides.

Conducting Polymer Biointerfaces

Jadranka Travas-Sejdic
Polymer Biointerface Centre, School of Chemical Sciences, The University of Auckland, Auckland 1010, New Zealand
The MacDiarmid Institute of Advanced Materials and Nanotechnology, Wellington 6140, New Zealand
j.travas-sejdic@auckland.ac.nz

Conducting polymers (CPs) have been widely used as electroactive biointerfaces in applications such as electrically-stimulated tissue engineering and stretchable organic bioelectronics. In this talk we will present two different approached to electroactive biointerfaces. The first approach overcomes the issue of poor solubility and processability of CP by functionalization of CPs with various moieties, and in particular by grafting of CP backbones with polymeric sidechains. That enables modification of optoelectronic, chemophysical and mechanical properties of the CPs and their use as smart biointerfaces; e.g. responsive to various stimuli, intrinsically stretchable and self-healing. The second approach addresses the issue that electrodes are commonly 2D and as such cannot fully probe the actual 3D cell environment within tissues and organs. Our approach to overcome that is based on a precise fabrication of individually addressable, high aspect ratio, 3D CP-pillar microelectrode arrays by means of 'micro-extrusion printing'. Such 3D microelectrode arrays could be employed in variety of applications, from biological sensing to recording and electrically stimulating cells and tissues, with the design of the arrays being easily adjustable to a particular application.

Electrocatalysis and Bio-electrocatalysis at Nanoscale: The Case for Heterogeneous Catalytic Cascades

Plamen Atanassov
Department of Chemical & Biomolecular Engineering,
University of California, Irvine, CA 92697, USA
plamen.atanassov@uci.edu

Heterogeneous electrocatalysis in many practical applications is being performed on nano-sized or nano-structured metals and metal alloys. Bioelectrochemistry often studies the charge transfer phenomena in immobilized proteins (enzymes) or enzyme aggregates (quaternary structures), which are also at nanoscale. Currently the most popular enzyme or DNA immobilization platforms and catalyst nano-particle support matrixes are either carbon nanotubes or graphene nano-sheets, both with characteristic dimensions in nanometer range. This implies that if we can master the processes of building the individual catalytic moieties in this scale and integrate also molecular catalysts through the so-called approach of "heterogenization", or tethering the redox catalysts at the interface with a spacer/linker molecule, we can have all those building block arranged, integrated and employed in model catalytic systems performing consecutive (cascade) or parallel reactions "as desired" at the interface. This is the notion of "heterogeneous catalytic cascades" developed by us in a consortium with several collaborators from University of Utah, Columbia, Michigan State University and UC Riverside. All the principals in this collaborative project have discussed the philosophy behind this effort and identified "channeling" as underlying principle for effective multi-step catalysis.[1] Our group have focused on research aiming the development of materials solutions for catalytic cascades, which would integrate bio-catalysis with molecular and heterogeneous catalytic steps.[2-4]

In this talk we will review the technical approaches developed by aiming to integrate functional catalysts from these three quite distinct and often considered as "irreconcilable" types: enzymes, molecular catalyst and metallic nanoparticles and create a functional and practical materials platform allowing cascade reactions catalyzed by all these different species/moieties. We will present design and synthesis of a hybrid enzyme/metal nanoparticle/atomically dispersed nano-material functional catalyst cascade. We will exemplify this idea with examples of building bio-electrochemical devices, where enzymatic catalysis will be enhanced by the heterogeneous and molecular one, with all catalytic moieties co-present at a single "designer interface" based on graphene-like carbonaceous material. This heterogeneous catalytic cascade system is designed around 2D carbonaceous nanomaterial (graphene-like nano-flakes), displayed as am aggregate of those at meso-scale as spheroidal colloidal object: 3D-graphene nano-sheet (3D-GNS). This material allows ease of integration by printing into a paper-based microfluidic analytical platform designed for a confocal Raman microscope for *in situ* spectro-electrochemical detection of the reactin intermediates and products.[5,6]

Chiral-Induced Spin Selectivity and its Implications for Spin Chemistry and Asymmetric Electrochemistry

Ron Naaman
Dep. of Chemical and Biological Physics, Weizmann Institute
Rehovot, Israel
Ron.naaman@weizmann.ac.il

Essential aspects of the chiral induced spin selectivity (CISS) effect and their implications for spin-controlled chemistry and asymmetric electrochemical reactions will be described. The generation of oxygen through electrolysis will be discussed as an example in which chirality-based spin-filtering and spin selection rules can be used to improve the reaction's efficiency and selectivity. Next the discussion will be shifted to illustrate how the spin selectivity of chiral molecules (CISS properties) allow one to use the electron spin as a chiral bias for inducing asymmetric reactions and promoting enantiospecific processes. Two enantioselective electrochemical reactions that have used polarized electron spins as a chiral reagent; enantioselective electroreduction to resolve an enantiomer from a racemic mixture and an oxidative electropolymerization to generate a chiral polymer from achiral monomers. A complementary approach that has used spin-polarized, but otherwise achiral, molecular films to enantiospecifically associate with one enantiomer from a racemic mixture will also be discussed. Each of these reaction types use magnetized films to generate the spin polarized electrons and the enantiospecificity can be selected by choice of the magnetization direction, North pole versus South pole. Possible paths for future research in this area and its compatibility with existing methods based on chiral electrodes will be presented.

Electrocatalysis in Nanomaterial Modified Electrodes and Application to Electrochemical Sensors

Christopher M.A. Brett, W. da Silva

The procurement of new materials and design of materials surfaces for control and improvement of electrocatalysis is one of the primary goals of modern electrochemistry, with applications in many areas. This lecture will focus on strategies to promote electrocatalytic effects with the objective of increasing the selectivity and sensitivity of modified electrodes for electrochemical sensing. It is equally, if not more, important as increasing signals by enlargement of the active surface area, that can lead to lower detection limits and better long-term stability. This will be illustrated by recent results from two main approaches. The first is the use of carbon nanomaterials, carbon nanotubes or graphene, or gold nanoparticles as modifiers either singly or together to exploit synergistic effects, e.g. [1], and combine this with voltammetric or impedance detection. The second concerns electroactive redox polymers formed as films by controlled potential electropolymerisation on multiwalled carbon nanotubes or on iron oxide nanoparticles. For this purpose, we have explored the use of aqueous solutions, of room temperature ionic liquids and, more recently, of deep eutectic solvents (DES) [2] as media for polymer formation. It has been found that the surface morphology of the polymers prepared in DES, particularly acid-doped ethaline DES, increases the polymer surface uniformity and leads to more robust sensing capabilities, whilst also promoting electrocatalytic effects – better kinetics – in the polymer itself. Characterisation of the modified electrode platforms by voltammetric, electrochemical impedance and surface analysis techniques will be demonstrated. Electrocatalysis will be illustrated with model compounds and also showing how they can be used as successful mediators with fast kinetics in electrochemical sensors and enzyme biosensors, e.g. [3,4].

The environmental impact of unsustainable growth has led researchers to increasingly address the technologies able to supply clean energy and to minimize wastes. In this new vision, hydrogen is considered a suitable energy vector for renewable energy sources since its utilization is carbon-free and produces only water as a by-product. Particularly, the emerging Power-to-gas concept addresses great expectancy to bio-hydrogen production and also to innovative electromethanogenesis processes which both could exploit culture or coculture of microorganisms in bioelectrochemical systems [1]. The CO2-rich industrial discharged gases and organic wastes could be switched in values, in this way, contributing to solving emission issues and storing otherwise dispersed energy. Methanogenesis usually occurs in thermophile conditions. Nevertheless, thermophile and hyperthermophilic strains, have seldom been explored within the recent attempts to stimulate the bacteria metabolism for novel biotechnological applications.

Thermotogales are among the most hyperthermophilic organotroph (>80 °C) within the bacterial branch of the phylogenetic tree. This bacteria group includes *Thermotoga neapolitana* (DSM 4359, ATCC 49049), a rod-shaped, gram-negative, non-sporulating bacterium, found in the Solfatara craters of Pozzuoli (the volcanic area close to Napoli, Italy), that can release hydrogen and lactic acid from waste organic matter by anaerobic fermentation in marine water [2].

The capability of *Thermotoga neapolitana* to form biofilm and to interact with a polarized carbon surface is presented here, aiming to study new electrochemical biotechnologies of electromethanogenesis in hyperthermophilic conditions. Different types of polarization were tested: i) potentiostatic, ii) potentiodynamic, and iii) no polarization (Open Circuit Potential) in comparison with Control bioreactors without electrodes. Cultures of *T. neapolitana* fed with 30mM of glucose in bioreactors equipped with carbon cloth electrodes, under CO_2 pressure (capnophilic condition) were tested, at 80°C. Chemical analyses of glucose and of the principal glucose metabolites (hydrogen, acetic and lactic acids) were performed after 1-3 days of testing. Biofilm formation on carbon cloth after under different polarizations was documented by SEM observations.

Results from biofilm and electrostimulation tests indicated that a dynamic polarization is able to tune settlement and detachment processes on the electrodes, modifying the bacteria metabolism of glucose fermentation. The presence of electrodes in the bioreactors and polarization caused temporary bacteria starvation on conductive surfaces, followed by high metabolite production. Cyclic potentiodynamic polarizations of ±0.8V between electrodes, with a scan rate of $0.5 mVs^{-1}$, caused an almost totally starvation of bacteria on carbon cloth. An increased polarization of ±1.2V, caused bacteria detachment from electrodes. Some consideration on the type, mode, and intensity of polarization are discussed, from the perspective of a syntropy of this bacteria strain with methanogens in the perspective of an electromethanogenesis process.

E-mails: bwmao@xmu.edu.cn, jwyan@xmu.edu.cn

Lithium metal as one of anode materials of batteries can greatly improve the energy density of the battery because of its highest theoretical specific capacity and lowest electrode potential (vs. SHE) [1,2], and Li electrodeposition and dissolution are most fundamental processes of the batteries during cycling. However, fundamental researches have been rarely reported on the initial stage of Li electrodeposition involving nucleation and growth partially because of the presence of the solid electrolyte interphase (SEI) which impose difficulties for monitoring the underneath deposition process. On the other hand, ionic liquids (ILs) having the characteristics of non-flammability, non-volatility, high ionic conductivity and wide electrochemical window can be used as electrolytes for lithium batteries [3]. Herein, we employ traditional electrochemical techniques to study the formation of SEI and nucleation and growth behavior of lithium on Cu surfaces in pyrrolidinium-based IL electrolytes of mixed $Py_{14}TFSI$ and $Py_{14}FSI$ with different proportion and containing the corresponding lithium salt to understand the roles of the anions.

To reduce the impact of Faradaic currents arising from SEI formation during Li deposition, a stable SEI was formed in advance in the IL mixtures with different anion proportions. Electrochemical impedance measurements, in the same electrolytes for SEI preparation, reveal that the impedances of the SEIs formed are different, and they decrease with increasing FSI^- content. Chronoamperometric measurements were then applied to follow the initial stage of Li electrodeposition. Diffusion controlled nucleation and growth behaviors were observed with reduced overpotential at increasing FSI^- content. Fitting by traditional nucleation model [4], taking into account the residual current from SEI reformation[5], Li nucleation process is found close to 3D progressive, which gradually changes to 3D instantaneous nucleation as overpotential increases. The nucleation density N_0 increases with the increase of the overpotential as well as the FSI^- content, indicating that the SEIs performed in higher content of FSI^- are beneficial to the nucleation and growth of lithium. Our work demonstrates that the Li deposition behavior may be regulated by the FSI^- content to adjust the properties of SEI.

The Nature and Role of Salt Films in Pits

Gerald S. Frankel, Tianshu Li, Sarita Sahu
Fontana Corrosion Center, The Ohio State University
Columbus, OH 43210 USA
frankel.10@osu.edu

A framework for pit stability has been established in a series of recent publications.[1-5] The maximum pit dissolution current density, $i_{\mathrm{diss,max}}$, which depends on temperature and maximum potential at the pit surface in a given pit environment, is proposed and compared with the diffusion current density to determine the conditions for pit stability and salt film formation. For an open pit, the criterion for pit stability is that $i_{\mathrm{diss,max}}$ must be greater than or equal to the critical diffusion current density required for maintaining a critical local environment for active dissolution, $i_{\mathrm{diff,crit}}$. The critical condition of $i_{\mathrm{diss,max}} = i_{\mathrm{diff,crit}}$ is associated with three parameters that must be exceeded for stabilization of an open pit: critical temperature T_{crit}, critical potential E_{crit} and critical pit depth r_{crit}. Analogously, the criterion for salt film formation is that $i_{\mathrm{diss,max}}$ must further exceed the diffusion-limited current density i_{lim}, and three parameters associated with salt film formation are: saturation temperature T_{sat}, saturation potential E_{sat} and saturation pit depth r_{sat}. A salt film is not required for pit stabilization; it is just a consequence of a pit achieving diffusion-controlled growth. The main function of a salt film is to adjust the actual potential at pit surface by regulating its thickness, thus to restrict the anodic dissolution rate of pit surface metal at the value of i_{lim}. The film thickness will respond to any changes in the applied potential, temperature, pit depth, ohmic potential drop in the solution and perforation radius of the pit cover. Downward potential scans from the diffusion-controlled condition were performed on SS316L one-dimensional (1D) artificial pit electrodes in 0.6 M NaCl, and experimental evidence is provided to support the validity of the new framework. Using pits of different depths, the maximum pit dissolution current density, $i_{\mathrm{diss,max}}$, was obtained as a function of maximum pit surface potential, E_{max}, at fixed pit surface metal cation concentration. Charge-transfer-controlled 1D pit growth is a transient state, which will spontaneously transition to diffusion-controlled growth. The salt film formed on a SS304 1D pit surface was preserved by flash freezing and characterized using cryo-based focused ion beam/scanning electron microscopy. The salt film exhibits a porous structure. Ni is co-located with Fe in the salt film, indicating the formation of co-precipitated salt containing Fe^{2+} and Ni^{2+}. A salt film growth model at steady state based on ion transport was proposed in which the salt film grows at the metal/salt film interface, while it dissolves at the salt film/solution interface. The growth rate at metal/salt film interface is determined by pit depth, film porosity and the ion mobility. The metal and chloride ion in the salt film are carried by both migration in channels formed by interconnection of the pores and the outward movement of the salt crystallites from the formation of salt below.

Novel Strategies to Enhance OER Electrocatalysis in Alkaline Media

J.R. Galan-Mascaros, N. López, F. Garcés-Pineda, H. C. Nguyën, M. De Fez-Febré

Institute of Chemical Research of Catalonia (ICIQ)
Av. Països Catalans, 16. 43007 – Tarragona, Spain.
jrgalan@iciq.

The oxygen evolution reaction (OER) is a key process in the general development of sustainable solar fuels, and essential in the progress/growth of an alternative hydrogen economy. This is a very demanding reaction, since a OER catalysts must be fast and efficient, but also stable and robust to high oxidation potentials, water, oxygen, radicals, acids or bases, etc. Several earth abundant metal oxides have appeared as excellent OER electrocatalysts in alkaline conditions, thanks to the robust stability of metal oxides in high pH.[1] The most common agreement suggests that FeNi oxo-hydroxides are arguably the best OER catalyst at pH > 13,[2] although many other binary and ternary candidates appear close in activity.[3] The complexity of this reaction makes difficult to understand and optimize the performance of these catalysts, with the remaining goal to minimize overpotentials, and to maximize current densities. Indeed, after thousands of experiments with multiple phases, the latest progress reports deal with further nanostructuration and smart processing of the materials to increase active surface area.[4]

In this presentation we will introduce some novel strategies to enhance OER activity in alkaline conditions. On one end, we will demonstrate how the use of magnetic fields may boost the performance of classic magnetic metal oxides.[5] On the other end, we will show how a non-redox doping approach opens alternative (and faster) mechanistic pathways.[6] Both strategies were developed from the combination of experiment and theory, as an example of the powerful contribution that computational chemistry can bring to the field, opening new alternatives difficult to disclose or understand exclusively from experimental data analysis.

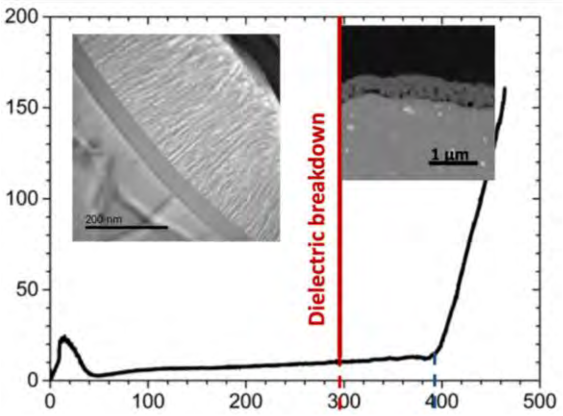
Anodizing of various metallic substrates and alloys over a large potential range

Delphine Veys-Renaux, Emmanuel Rocca
Institut Jean Lamour, Université de Lorraine-CNRS,
Campus Artem, 2 allée André Guinier, Nancy, France
delphine.veys-renaux@univ-lorraine.fr

The electrochemical behavior of various metals, namely magnesium, aluminium, titanium and zinc has been investigated over a large potential range.

Whatever the substrate, three successive anodizing steps may be observed:
i) a first "conventional anodizing" step controlled by the solid-state inward migration of O^{2-} and outward migration of M^{n+} ions under the electric field effect,
ii) beyond the dielectric breakdown potential, a range over which the micro-arc phenomenon may occur, leading to the formation of a ceramic like layer,
iii) a "current wall" induced by the increase of oxide conductivity and characterized by a high release of oxygen due to water oxidation.

Electrochemical behavior recorded on aluminium in alkaline medium and typical morphologies of anodic layers relative to different anodizing stages



The possible formation of a ceramic like coating under the effect of micro-arc discharges depends on the physico-chemical and dielectric properties of the inner layer grown by conventional anodizing and governing the occurrence of the dielectric breakdown. The growth mechanisms and the related properties of this inner layer have been finely characterized by combining in situ electrochemical techniques (voltamperometry, in situ electrochemical impedance spectroscopy) and ex situ characterizations of the anodic layers by scanning electron microscopy, transmission electron microscopy, energy dispersive spectroscopy, X-Ray photoelectron spectroscopy, ellipsometry.

The presence of alloying elements in the substrates may modify the composition and the dielectric properties of the inner layer as well, and consequently the conditions of breakdown occurrence on the one hand and the corrosion resistance of the anodized samples on the other hand.

Through different examples, it has been shown that the chemical composition of the electrolytic solution must be judiciously chosen to ensure an "efficient" growth of the conventional inner anodic layer. Actually, the pH is a key factor to induce an optimal anodic layer growth rate. Moreover, the resistance of the inner layer may be reinforced by the incorporation of additive elements from the electrolyte (silicates, fluorides, etc..). The micro-arc anodizing process may therefore be optimized by lowering the current density necessary to reach the breakdown and the micro-arc regime. The incorporation of additive species in the external porous ceramic layer may furthermore enhance the corrosion performances by acting as sealants during the degradation processes.

In situ studies of the atomic structure/charge distribution at the electrochemical interface

Y. Grunder[1], C.A. Lucas[1], J. W. Beane[1], Y. Joly2, Y. Soldo-Olivier[2]
1 University of Liverpool, Oliver Lodge Laboratory, L69 7ZE Liverpool, UK
*2 CNRS, Grenoble INP, Institut N el, 38042 Grenoble, FranceAddres*s
grunder@liverpool.ac.uk

The presence of specifically adsorbed anions can significantly affect the electrochemical reactivity of a metal electrode which is of major interest for galvanic deposition, etching, corrosion and electrocatalysis. *In-situ* surface x-ray diffraction has enabled an atomic/molecular-level understanding of the interface under reactive conditions, including its potential and time dependence, to be developed. While information about the atomic structure of the electrode surface in electrochemical *in-situ* cells has been widely investigated, insight into the charge distribution and the structure of the electrolyte at the interface is still lacking. Advances in these directions offer possibilities in elucidating atomic scale models of the electrochemical interface and thus will help to establish structure-stability-reactivity relationships.

A fundamental understanding of the nature of the charge transfer, especially the influence of the applied potential and the screening by the electrolyte, is a major goal in electrochemistry to better understand electrochemical processes and charge transfer during adsorption and deposition. [1]

Thus combining x-ray spectroscopy and x-ray diffraction to gain site specific information about the charge distribution at buried interfaces is a promising tool. [2,3]

Examples of how the use of surface x-ray scattering techniques can help to characterise electrochemical interfaces in-situ in order to link, structure, reactivity and stability will be presented. [3,4] Advances in these directions offer possibilities in elucidating atomic scale models of the electrochemical interface and thus will help to establish structure-stability-reactivity relationships.

Mechanism of boosted electron transfer in microbial electrochemical systems with carbon-based materials

Yujie Feng, Peng Zhang, Da Li
State Key Laboratory of Urban Water Resource and Environment, School of Environment, Harbin Institute of Technology
No.73 Huanghe Road, Nangang District, Harbin 150090, P.R.China
yujief@hit.edu.cn

Electrons can be transferred from electrochemically active bacteria to extracellular electron acceptors with the oxidation of organic matters, which plays important roles in areas of energy production, environmental remediation and geochemical cycle systems. Here we reviewed our latest works about the fundamental research involving extracellular electron transfer (EET) process, and the role of carbon-based materials for boosting EET was also discussed.

Electron transfer process from cell to the electrode: Carbon quantum dots (CDs) could increase the extracellular electron transfer and metabolic rate of *S. oneidensis* MR-1, with increased intracellular charge, higher adenosine triphosphate level, quicker substrate consumption and more abundant extracellular secretion like flavin. Meanwhile, the CDs promoted cellular adhesion, electronegativity, and biofilm formation. In bioelectrical systems the CDs-fed cells increased the maximum current value, 7.34 fold, and power output, 6.46 fold. The enhancement efficacy was found to be strongly dependent on the surface charge of the CDs.

Interspecies electron transfer process: The interspecies electron transfer between *Geobacter* coculture could be promoted by adding biochar as the exogenous mediator. This acceleration process showed a highly positive relationship with the oxygen element content rather than conductivity of biochar.
Multiwalled carbon nanotube (MWCNT) also displayed the acceleration of the electron transfer process in the *Geobacter* cocultures system due to its high conductivity which played a role of electron transfer bridge by connecting cells.

Electron transfer process through biofilm: The electron transfer in a biofilm constructed by mixed cultures could be promoted by inserting MWCNT into the hybrid biofilm. Such a designed biofilm can enhance the EET ability of the biofilm. The specific mechanism analysis showed that the MWCNT insertion can reduce the resistance of the electron transfer through the biofilm. Additionally, it showed a superior selectivity towards exoeletrogens in the biofilm which therefore optimized the community structure.

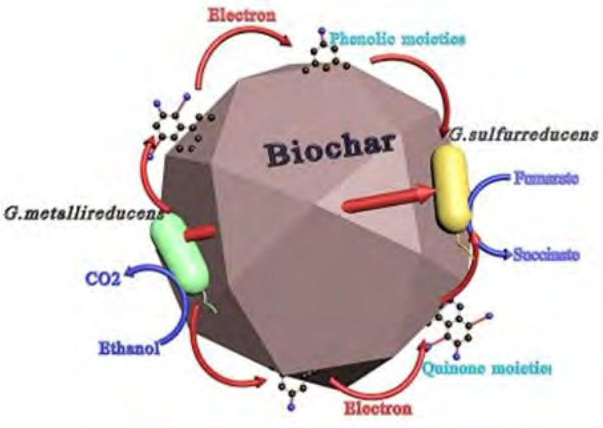

Illustration of the electron transfer process in the microbial electrochemical systems with carbon-based materials

Keywords: mechanism of electron transfer; microbial electrochemical systems; carbon-based materials

Electric Microbes, Metals, and Nanowires

Gemma Reguera
Department of Microbiology and Molecular Genetics
567 Wilson Rd, Rm 6190
Michigan State University
East Lansing, MI 48824
reguera@msu.edu

The Reguera lab investigates electrochemical reactions catalyzed by microbes in natural and anthropogenic systems. Of particular significance is our seminal work investigating how microbes couple their metabolisms via electrical signals and the impact that these activities have in the mineralization of toxic metals and radionuclides. Our interests go beyond the basic research and seek to develop sustainable technologies that harness the electrical activities and conductive cellular components of these organisms in bioremediation and bioenergy applications. In this talk, I will describe novel methodologies we have developed to investigate the physiology of electric microbes and their interactions with biotic and abiotic components of their ecosystem. The basic research provides the fundamental knowledge for applied projects we have developed to harness the power of electric microbes and their components in biotechnology. The translational work also includes collaborations with industrial partners to advance electrochemical technologies for energy and bioremediation applications while providing a training platform for students and postdocs to bridge the great divide between academia and industry.

Pseudocapacitive Effects from Electrolytes and Electrode Materials

Elzbieta Frackowiak
Poznan University of Technology, Institute of Chemistry and Technical Electrochemistry
60-965 Poznan, Berdychowo 4
elzbieta.frackowiak@put.poznan.pl

Electrochemical capacitors EC (named also electrical double-layer capacitors or supercapacitors) are the devices based on the reversible storage of energy by electrostatic (capacitive) attraction of ions. Performance of EC are strongly governed by the type of electrolytes, namely aqueous (acidic, basic, neutral), organic and ionic liquids. As a consequence, practical voltage range of EC in these electrolytes varies from 0.8 V to 3.5 V, respectively. The type of current collector will also affect EC voltage values.

Capacitive charge storage can be increased by faradaic reactions, frequently called pseudocapacitive effects. It must be underlined that only redox reactions which present capacitive behavior should be considered, i.e., capacitance should be proportional to the charge accordingly to formula $C = dQ/dE$. Faradaic contribution can be originated from electrode materials but also from electrolytic solutions. Typical electrode materials with pseudocapacitive character consist of: i) electrically conducting polymers, ii) carbon materials rich in heteroatoms (oxygen, nitrogen, sulphur), iii) oxides, e.g., Mn, Ru, iv) carbon with electrosorbed hydrogen. Dichalcogenides such as sulfides, selenides of transition metals (e.g., Mo, Co, V, W) can be used as electrode components to increase capacitance, in turn, energy of supercapacitor.

Exploring redox active species from electrolytic solution is another possibility for energy increase by pseudocapacitive effects [1,2]. Figure 1 shows a big variety of redox couples which could be eventually used for this target. Practical application of such redox pairs will be determined by reversibility, pH of solution, concentration, price, availability, toxic character, influence on capacitor ageing. Some of them can be used only as an additive to electrolyte. Taking into account their potential values, different redox species could serve for positive and negative electrode.

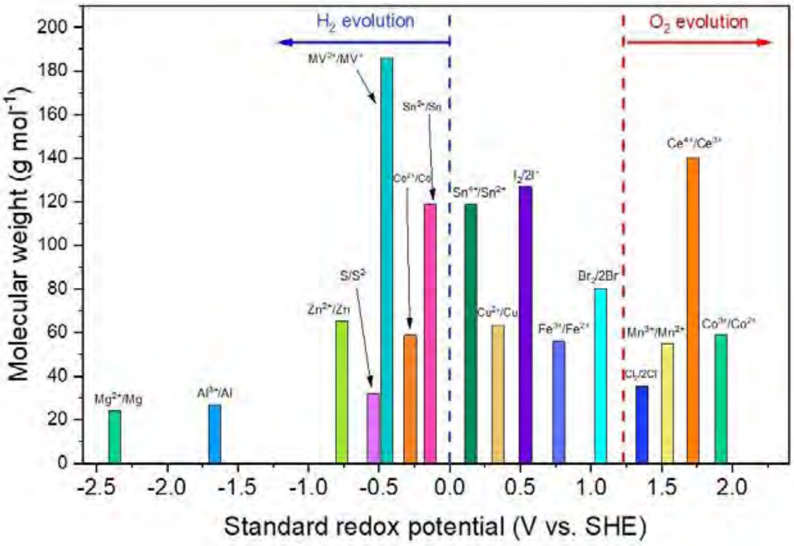

Figure 1: Potential values for various redox couples versus their molecular weight.

From Inhibitor Screening to Advanced Characterization of Active Protective Coatings

Arjan Mol
Delft University of Technology, Department of Materials Science and Engineering
Mekelweg 2, 2628CD, Delft, The Netherlands
J.M.C.Mol@tudelft.nl

A cost-efficient and effective corrosion protection measure for metals exposed to corrosive conditions is the application of active protective coatings. These organic coatings provide barrier protection when intact, but also rely on the release of corrosion inhibitors and/or self-healing to protect coating defects upon damage. For decades corrosion inhibitors were based on hexavalent chromium chemistries, but these are now recognized to be extremely toxic and carcinogenic and subject to strict international health and safety legislation.

Many different compounds have been studied to find a non-toxic and environmentally friendly alternative for hexavalent chromium based corrosion inhibitors in active protective coatings by rapid screening techniques and more in-depth mechanistic studies. As an example, over the recent years, lithium-salts have become of interest as a potential alternative for chromates as leaching corrosion inhibitor in organic coatings and demonstrated active protective properties on aerospace aluminium alloys. Further insights into the active protective mechanism of the lithium-based inhibitor coating technology will be presented: leaching kinetics and in-coating inhibitor mobility, formation of a protective layer in a coating defect, the protective mechanism. The results show the mechanistically different behavior of some high-potential inhibitor doped coating technology compared to other inhibitors and demonstrate the key characteristics that are essential for active protective coatings, providing fast leaching, effective inhibition and formation of an irreversible protective layer in the defect area.

Besides inhibitor-based active protective coating concepts also other novel and smart coating technologies based on self-healing of coating defects show a wide variety of promising concepts. With the implementation of a combined polymer and corrosion inhibitor healing concept, the individual and combined time frames for polymer healing and the active surface healing by corrosion inhibitive pigments is even of more importance. Also the analysis of irreversibility of the active protection as well as the time-evolution and duration of protection performance is shown to be of pivotal importance.

This presentation provides an overview of recent advances in the development and characterization of novel inhibitor systems, inhibitor-based and self-healing active protective coatings. Advanced microscopic, spectroscopic and electrochemical techniques will be presented to unravel local corrosion protection mechanisms, inhibitor mobility and leaching from organic coatings as well as inhibitor-based and self-healing coating performance.

Light- versus voltage-driven electron transfer across multi-heme proteins

**email: j. blumberger@ucl.ac.uk*

Certain bacteria have evolved an astonishing survival mechanisms in response to low oxygen concentrations. When cytoplasmatic oxygen becomes scarce they start to grow µm-long electrically conducting cellular appendages to export electrons from the cytoplasm to extracellular space for reduction of extracellular substrates in place of O_2. Recently it was shown that arrays of Fe-containing multi-heme cytochromes (MHC) confer electric conductivity to those appendages, which garnered much interest for their use in bionanotechnological applications, e.g. bio-compatible field effect transistors. Here I will present recent experimental measurements probing light-driven electron transfer (ET)[1] and voltage-driven electron transport (ETp)[2] through MHCs as well as their interpretation by theory, electronic structure calculations and molecular dynamics simulation[1,2,3]. Specifically, I will discuss recent pump-probe transient absorption spectroscopy results on photo-induced electron injection in Ru-labeled MHCs in solution. We find evidence that the initial ET step along the heme chain occurs via fast, nanosecond heme-to-heme electron hopping[1] in agreement with prior predictions from computations[3]. These results are first experimental evidence for the hypothesis that in biology the micrometer-long electron transport in extracellular respiration occurs via a sequence of many (thousands) of heme-to-heme hopping events. By contrast, we find that voltage-driven ETp in dry MHCs mono-layer junctions is temperature independent and, very surprisingly, best described by coherent tunneling models with tunneling distances of several nanometers spanning the entire protein[2]. The currents across MHCs are orders of magnitude higher (ca 0.1 nA at 0.5 V) than in proteins of similar size (e.g. Azurin) opening up exciting opportunities for the use of MHCs in bioelectronic applications. Taken together, these light and voltage driven studies show that one and the same protein can support different electron flow mechanisms depending on how it is initiated in experiment.

Ionic Liquids as Co-catalysts for CO_2 Electroreduction in Molecular Electrocatalysis

Carlos M. Sánchez-Sánchez
Sorbonne Université, CNRS, Laboratoire Interfaces et Systèmes Electrochimiques, LISE,
75005 Paris, France
carlos.sanchez@upmc.fr

Ionic liquids (ILs) in electrocatalysis have attracted a lot of attention from the seminal work of Rosen et al. [1] where they used a mixture with 18 mol% of 1-Ethyl-3-methylimidazolium tetrafluoroborate ([EMIM][BF_4]) in water as a solvent supporting electrolyte system and achieved a relevant overpotential decrease for CO_2 reduction on a silver electrode by forming adducts between CO_2 and reduced imidazolium cations. In fact, it has been demonstrated more recently that imidazolium cations are reduced on the electrode surface as a first step and then form adducts with CO_2, [2-3] which lowers the energy barrier of the unfavorable first one-electron reduction to CO_2. Nevertheless, most of those studies using ILs have been carried out mainly using heterogeneous electrocatalysts. In contrast, much less work has been done exploring the role of ILs in molecular electrocatalysis for CO_2 electroreduction.

The role of different ILs as simultaneous supporting electrolyte and co-catalyst in acetonitrile for CO_2 electroreduction in the presence of a model molecular catalyst [Re(bpy)$(CO)_3$Cl] is presented here. [4] Thus, the structure-activity relationship of ILs on electrocatalytic CO_2 reduction is evaluated by cyclic voltammetry and controlled potential electrolysis. In particular, the nature of the cation, anion and cation alkyl chain is varied by a choice of 5 different ILs, including imidazolium and pyrrolidinium cations and their results are compared to conventional benchmark supporting electrolyte. Under catalytic conditions an overpotential diminution of 0.33 V for CO_2 to CO conversion is achieved in the presence of ILs. Finally, a mechanistic explanation is provided to justify this behavior and the partial suppression of the IL co-catalytic effect when CO_2 electroreduction takes place in the presence of a proton source.

Beyond Electrochemical ImpedanceSpectroscopy: Advanced Methods forStudying the Dynamics of Electrochemical Processes

Tanja Vidaković-Koch
Electrochemical Energy Conversion, Max Planck Institute for dynamics of Complex Technical Systems
Sandtorstraße 1, Magdeburg, Germany
vidakovic@mpi-magdeburg.mpg.de

Understanding the dynamic regime of electrochemical processes is of great interest for applications such as water electrolysis for intermediate energy storage of fluctuating renewable energies. Furthermore, dynamic methods are widely used for the diagnosis of electrochemical devices such as fuel cells and batteries and for kinetic mechanism discriminations. In my group different dynamic methods based on periodic changes of electrical [1-4] and non-electrical inputs [5-6] for applications in fuel cells, electroenzymatic systems and kinetic determinations are in current focus.

An example is a so-called non-linear frequency response analysis (NFRA). NFRA can be considered as a generalization of the traditional electrochemical impedance spectroscopy (EIS) where instead of small input amplitudes large input amplitudes are used. This drives the system out of a linear range. Therefore, the nonlinear system response contains a linear contribution which corresponds to the electrochemical admittance, as well as nonlinear contributions. These nonlinear parts of the response give a nonlinear fingerprint of an electrochemical system which can be used for sounder kinetic parameter determination or for discrimination of different rivaling model descriptions. However, the NFRA method is not widely understood and accepted, as it requires fundamental physico-chemical modeling for interpretation and advanced measuring tools. Consequently, research groups that use the NFRA method are very scarce, with no consensus on how the NFR data should be analyzed. In this talk applications of NFRA for kinetic mechanism determinations will be show cased using different examples of simple and multi-step electrochemical reactions [1-4].

In addition to periodic changes of electrical inputs (like current or potential), my group uses also non-electrical inputs to study dynamics of electrochemical systems in a so called concentration-alternating frequency response analysis (cFRA) as a new dynamic method to investigate the dynamics of electrochemical systems [5]. We demonstrated an experimental validation and a measurement routine of this new electrochemical method [6]. In cFRA the electrical response of the cell (current or potential) to periodic perturbation of specific reactant feeds is studied by means of linear system analysis. For the example of a polymer electrolyte fuel cell (PEMFC) we show that cFRA, in contrast to classical electrochemical impedance spectroscopy (EIS), detects selectively the effect of the dynamics of mass transport of reactants and products inside the different layers of the PEMFC. cFRA can also diagnose the humidification state of the fuel cell cathode.

2D or not 2D: Graphene and related materials in electrochemistry

Robert A.W. Dryfe
Dept. of Chemistry, University of Manchester,
Oxford Road, Manchester M13 9PL, U.K.
robert.dryfe@manchester.ac.uk

In the 12 or so years since the first papers on graphene in the electrochemical context appeared [1], applications of this material in electrochemistry have grown almost unabated. The use of graphene in most electrochemical applications (batteries, supercapacitors, electroanalysis, corrosion protection) has been widely evaluated and electrochemical methods have also been promoted as a route to prepare 2D materials [2]. Two approaches can be discerned in the literature: a "top-down" one, relying on solution exfoliated dispersions, generally of varying thickness and content of oxygen (and other) atoms [3]; and a "bottom-up" one where single flakes, with well-defined properties, are studied [4].

The second approach tends to be guided by advances in sample preparation, where the physics community is now focusing on the "hetero-structures" formed from layers of 2D materials [5]. "Designer" structures can also be performed by assembly of 2D materials with, for example, organic molecules to form assemblies whose bulk properties differ from those of the re-stacked 2D material [6].

A key question for the electrochemical community - which I believe is still largely unanswered - is how the properties of 2D materials – e.g. graphene – evolve as the material thickness increases toward the bulk value (graphite in this case) [7]. Given that graphene is effectively an interfacial film, its behavior (e.g. capacitance, electroactivity with respect to a redox couple, wetting [8]) is strongly affected by the presence of other interfacial films, whether deliberately or accidentally introduced, and by the substrate on which it is supported. Examples of such effects will be presented, along with current thinking about the comparison with graphene and graphite electrochemistry.

2D materials present interesting possibilities to create "membrane" structures, either via random assembly of their flakes [6], via charge transfer through the material (intrinsic [9], or through a drilled hole [10]) or by assembly of nanochannels from these materials [11]. These structures allow unique studies of ion transport, which have only just begun to be exploited in the electrochemical arena.

This lecture will discuss some of the present and likely future directions for this field.

Electrochemically Gated Charge Transport in Redox Proteins and Photosynthetic Complexes

Pau Gorostiza
Catalan Institution for Research and Advances Studies (ICREA)
Institute for Bioengineering of Catalonia (IBEC)
The Barcelona Institute of Science and Technology
pau@icrea.cat

Interprotein electron transport (ET) is an essential process in cell respiration and photosynthesis. It takes place between redox proteins and complexes, and it displays an outstanding efficiency and environmental adaptability. Although the biochemistry of ET processes is well characterised, nanoscale experimental methods are needed to understand electronic pathways in these redox protein structures, both for fundamental and for technological purposes. Electrochemical Scanning Tunneling Microscopy (ECSTM) is an excellent tool to study electronic materials and redox molecules including proteins. It offers single molecule resolution and allows working in aqueous solution, in nearly physiological conditions in the case of proteins, and under full electrochemical control. ECSTM also allows performing conductance measurements by current-potential and current-distance tunneling spectroscopy. An overview of these methods and current projects in the laboratory will be presented, with special emphasis on cytochromes of the respiratory chain and on photosystem I complexes.

Deposition, Wetting and Ion-exchange of Polyaniline and Polyaniline Composite Films in Deep Eutectic Solvents

Realisation of practical electrochemical devices frequently requires a combination of properties not met by a single component; extension to composite materials is the obvious strategy. Further, electroactive film dynamics - encompassing polymer segmental motion, ion transport and, in certain applications, reactant influx – are dictated by internal electrolyte wetting of the film; the manner in which composite formation influences this is generally unknown. To address these important issues, we explore the relationships between film composition, structure and dynamics as a function of solvent and particulate characteristics for the specific case of polyaniline exposed to a range of protic and aprotic media, from conventional aqueous solutions to deep eutectic solvents.

Commencing from the established baseline of pristine polyaniline deposited from, and redox cycled in, aqueous acid solution, we explore the effect of shifting to the opposite extreme of aprotic ionic liquids (Ethaline and Glyceline) and the intermediate case of a protic ionic liquid (Oxaline). Ion and solvent population changes are determined using acoustic wave measurements (with crystal admittance spectra validating gravimetric responses), as functions of timescale (voltammetric scan rate) and, in selected instances, temperature. Second, we explore the effect of inclusion of physically diverse particulates: multi-walled carbon nanotubes (MWCNT), graphite and molybdenum dioxide; simplistically, these represent geometries of 1D, 2D and 3D inclusions, respectively.

We present the effects of varying solvent characteristics and particulate inclusions on the deposition process and efficiency. For all the combinations (of electrolyte and film components) studied, coulometric and gravimetric assays showed that the films are deposited less than quantitatively, but with acceptable yield. Unsurprisingly, inclusion of particulates influences film morphology. Inclusion of MWCNTs decreases solvation in aqueous medium and in Ethaline shifts maintenance of electroneutrality to cation (choline) transfer, which is reliant upon an adequate internal ionic liquid reservoir, i.e. substantive internal wetting. Multiple redox cycling of Ethaline-deposited films in monomer-free Ethaline drives evolution of film behaviour, but somewhat differently for pristine polymer and MWCNT composite films: pristine polymer is progressively *depleted* of electrolyte, while the composite progressively *accumulates* it. More complex solvation changes accompany medium transfer experiments between aqueous and deep eutectic solvent media, indicative of longer term polymer relaxation processes. These and other effects will be rationalised in terms of the interaction between polymer, the nature of the particulate inclusion and solvent characteristics. The consequences of these outcomes for practical devices will be briefly considered.

Novel highly lipophilic solid contact materials for ion-selective electrodes with reproducible and preadjustable standard potentials

Róbert E. Gyurcsányi, József Kozma, Soma Papp
Department of Inorganic and Analytical Chemistry, BME Lendület Chemical Nanosensor Research Group, Budapest University of Technology and Economic
Szt. Gellert tér 4, H-1111 Budapest, Hungary
robertgy@mail.bme.hu

Ion-selective electrodes are one of the most successful class of chemical sensors that allow separation and sample preparation–free measurements of the activities (concentrations) of a range of essential ions in complex matrices such as whole blood. Even though the potential stability and potential predictability of the conventional liquid contact ion-selective electrodes (ISEs) is hard to surpass, there is a clear trend to replace them with solid contact ISEs. Indeed, the robust miniaturization and mass production of ISEs would largely benefit from a solid contact (SC) configuration. Additionally, ion-selective electrodes emerged most recently as ideal candidates for wearable chemical sensors as they provide a passive transduction mechanism that is not affected by the size of the sensor. However, in case of single use, disposable electrodes it would be desirable if large batches of electrodes with reproducible E^0 and slope could be produced so that the calibration properties of the whole batch could be assessed by calibrating only a limited number of electrodes. Therefore, this aspect gained lately a lot of interest beside ensuring all other criteria for optimal potentiometric behavior of SCISEs.

The two most promising approaches for preparing solid contacts (SCs) for polymeric membrane based ion-selective electrodes (ISEs) are based on the use of large surface areas conducting materials with high capacitance (e. g., various carbon nanotubes) and redox active materials (e. g. conducting polymers). While many of the essential requirements for the potential stability of SCISEs were addressed, the E^0 reproducibility and its predictability, that would enable single use of such electrodes without calibration is still a challenge, i. e., the fabrication of electrodes with sufficiently close E^0 and slope values to enable the characterization of large fabrication batches through the calibration of only a small number of electrodes. The most generic solution seems to be the adjustment of the E^0 potential by polarization prior to the application of the ion-selective membrane. [1]This approach proved to be successful in case of conducting polymer-based solid contacts, and proved to be surprisingly effective also in case of capacitive solid contact based ISEs.[2] Here we are going to report a range of approaches based on chemically modified highly lipophilic carbon nanotubes and similarly lipophilic conducting polymer solid contacts (e.g. perfluorinated alkanoate side chain functionalized poly(3,4-ethylenedioxythiophene)[3] that ultimately led to SCISEs with reproducible potential responses and allowing even for a preadjustment of their E^0 potential.

Acknowledgment:

This work was supported by ERA-Chemistry (OTKA NN117637), and by the BME-Nanotechnology FIKP grant of EMMI (BME FIKP-NAT). We thank Dr. M. Bojtár for the synthesis of the perfluorinated alkanoate side chain functionalized poly(3,4-ethylenedioxythiophene) (PEDOTF).

Anodic TiO_2 Nanotubes: An Overview

Patrik Schmuki
Department of Materials Science WW-4, LKO
University of Erlangen-Nuremberg
Martensstrasse 7
91058 Erlangen, Germany
schmuki@ww.uni-erlangen.de

In the past decade, anodically formed self-organized TiO_2 nanotube layers attracted considerable scientific interest. This is mainly due to the fact that these layers combine the defined nanotubular geometry with a broad range of functional features inherent to TiO_2. Such applications range from solar cells to photocatalysis, over biomedical uses to battery or supercapacitor applications, to support for polymer electrolyte membrane fuel cells.

The presentation will give an overview of the literature available on key features of anodic nanotube layers, as well as critical methods and factors of their formation and most promising properties and applications.

Perspectives on Organic Electrochemistry – One Persons View

R. Daniel Little
Department of Chemistry and Biochemistry
University of California Santa Barbara
little@chem.ucsb.edu

This lecture will describe a few "perspectives on organic electrochemistry" that the author has developed through decades of experience in the area. Attention will be paid to both synthetic applications as well as mechanistic insights from this laboratory as well as those of other researchers.

Facetted Nanochemistry of Compounds for Catalysis & Energy

Aleksandra Vojvodic
Department of Chemical & Biomolecular Engineering
University of Pennsylvania, Philadelphia, 19104, USA
alevoj@seas.upenn.edu

Systematic computational materials modeling strategies using first-principles methods allow one to describe and understand chemistries of already known materials, and, importantly, they can be used to predict new materials through a careful analysis of the surface chemistry at the atomic level. In this talk, I demonstrate how we have been able to computationally predict several new catalyst materials. I begin by discussing catalysts for electrochemical reactions — the hydrogen evolution reaction (HER) on 2D carbide and nitride materials and the oxygen evolution reaction (OER) on transition metal oxides — that have been experimentally synthesized, characterized and tested. I then share recent theoretical insights on the stability-activity conundrum of oxide materials and present a computationally predicted nanostructured OER catalyst-systems that exhibit a new surface activation phenomenon leveraging our theoretical understanding. I conclude with new efforts to understand more complex nanostructured compound materials' chemistries and geometries used in energy applications beyond catalysis, such as fuel cells and batteries.

Improving the design of electrochemical devices with theory and modelling

Clotilde S. Cucinotta[1]

[1] Dept. of Chemistry, Imperial College London

In this talk I will highlight my research on materials and fundamental atomic process that underpin different areas of energy and nanotechnology, such as in electrolysers, batteries and memristors. I will introduce some issues connected with the simulation of electrified interfaces at the nanoscale focusing on modelling the effect of an applied potential to a cell by simulating charged electrodes. I will present some recent progress in our understanding of the interactions of the electrolyte with the metal under applied potential in the technologically relevant Pt-water interface.

Probing the Spatial Heterogeneity of Electrooxidation and the Oxygen Evolution Reaction on Au Operando with Nonlinear Optical Microscopy

[*]*Fritz Haber Institute of the Max Planck Society, 14195 Berlin, Germany;* [#]*Laboratory for Fundamental BioPhotonics, École Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland; *Faculty of Physics, University of Duisburg-Essen, 47057 Duisburg,*
richard.campen@uni-due.de

Perhaps the most promising path to the creation of a global energy economy based on the combustion of hydrogen – with its attendant benefits for climate and environmental quality – employs devices based on electrolytic water splitting. Despite much effort, finding relatively inexpensive catalyst materials with high activity and stability has proven challenging. Decades of empirical studies suggest that optimizing the oxidative half reaction, *i.e.* the oxygen evolution reaction (OER), is particularly difficult. Building the best possible devices this underlying chemistry allows requires experimental insight into the *mechanism* of the OER. Gaining such insight requires overcoming at least two hurdles: (a) materials of practical interest are most often heterogeneous over a wide range of length scales and (b) for the most promising metal (oxides) electrodes oxidation of the metal cation occurs at similar potentials to that of the OER. The first limitation implies that a, preferably wide-field, microscopy is required while the second suggests such a microscope should allow *operando* electrode characterization and be capable of imaging both electrooxidation and the formation of molecular oxygen.

In this talk I will discuss our recent efforts to meet these dual challenges through application of the nonlinear optical technique, second harmonic microscopy (SHM), to the operando characterization of electrooxidation and the OER on two different types of structurally heterogeneous Au working electrodes. Because SHM is a background-free probe of surface dielectric function it, allows more precise focusing on the solid/liquid interface and offers a window into surface polarization not available using more conventional optical characterization techniques (with near video rate acquisition). At potentials below the OER and electrooxidation two distinct types of surface optical responses are apparent[1]. More than 80 % of the surface shows a clear positive quadratic response expected from a simple analytic model of electronic polarization of the metal/electrolyte interface. ~ 20 % of the electrode surface area, often near grain boundaries, shows a negative quadratic response with increasing potential consistent with a roughened surface at which anion adsorption occurs at potentials significantly below that of the electrode as a whole. Moving to still more oxidizing potentials we observe the appearance, growth and detachment of individual bubbles[2]. The ability to quantify the flux of O_2 and its spatial distribution makes it straightforward to conclude that the reactivity of the surface with respect to the OER is dominated by < 1 % of the total surface area. These active areas are of two types: presumably deeply penetrating motifs that are stable under potential cycling and more reactive sites that are unstable during surface reconstruction. The later type of active areas are the active sites of Burke et al.'s incipient hydrous oxide/adatom mediator model of electrocatalysis[3].

Correlative Electrochemical Multi-Microscopy: Towards a Multiscale Understanding of Electrochemical Processes and Interfaces

Patrick R. Unwin,[1] Cameron L. Bentley,[1] Minkyung Kang,[1] Viacheslav Shkirskiy,[1] Enrico Daviddi,[1] Daniel Martín-Yerga,[1] Lewis C. Yule,[1,2] Binglin Tao,[1] Baoping Chen,[1] Oluwasegun J. Wahab,[1] Danqing Liu,[1] Xiangdong Xu,[1] Dimitrios Valavanis,[1] Ian J. McPherson,[1] Geoff West[2] and Alex W. Colburn[1]

Coventry, CV4 7AL, United Kingdom
p.r.unwin@warwick.ac.uk

Electrodes of practical importance are usually complex on a range of length scales, from the nanoscale to the device level. To address this complexity, we have introduced new approaches, whereby nanoscale information on electrode activity is obtained by electrochemical microscopy in the form of **activity maps** and **activity movies**,[1,2] and these rich datasets are mapped onto **co-located** electrode structure and properties from complementary high-resolution microscopy and spectroscopy techniques. This ***correlative electrochemical multi-microscopy*** strategy helps us to resolve the relationship between local electrode structure and activity. With this detailed microscopic information, an interesting question is can we predict the behaviour of electrodes on larger length scales? More generally, what do we learn about electrochemical systems from a multiscale approach?

This contribution will highlight our recent work using nanoscale scanning electrochemical cell microscopy (SECCM), scanning ion conductance microscopy (SICM) and combined scanning electrochemical microscopy (SECM)-SICM as key techniques for the synchronous acquisition of electrochemical activity-electrode topography,[3,4] coupled with a wide range of microscopy techniques, spanning electron microscopy and electron backscatter diffraction, micro-Raman spectroscopy and atomic force microscopy to pinpoint the nature of particular active sites. With this approach, complex electrode surfaces are studied as set of "single entities" (*e.g.*, individual steps, terraces, defects, crystal facets, grain boundaries, single particles).[1,5] The resulting nanoscale understanding of reactivity is used to create models for electrochemical interfaces and determine how they translate across broader lengthscales and timescales. A wide range of illustrative examples of this general approach will include investigations of 2D materials, single particles and ensembles on electrode supports, and structurally and/or compositionally heterogeneous surfaces, such as polycrystalline metals and polymer composite electrodes. Applications include electrocatalysis, battery electrodes and corrosion. Ultimately, the approaches we advocate provide a roadmap that should facilitate the rational design of functional (electro)materials.

We thank our many collaborators, external to Warwick, who have contributed to our work in this area and will be mentioned throughout this lecture.

Electrocatalysis on Well-Defined Metal Oxides: Combining Ultrahigh Vacuum Surface Science and Electrochemistry

Ulrike Diebold
Institute of Applied Physics, TU Wien
Wiedner Hauptstrasse 8-10/134, A-1040 Vienna, Austria
diebold@iap.tuwien.ac.at

Transition metal oxides are promising materials for photoelectrochemical and electrocatalysis. For a molecular-scale understanding of the underlying mechanisms and processes, experiments on well-characterized samples are necessary, i.e., specific facets of single crystals with a known composition, geometry and defect structure. Here the advanced methods of surface science, particularly Scanning Probe Microscopy (SPM) with atomic resolution, Thermally Programmed Desorption (TPD) with accurately-determined coverages, and X-ray Photoelectron Spectroscopy (XPS) with high resolution, together with first-principles computations based on Density Functional Theory (DFT) give unique insights. Bridging the gap to a (photo-) electrochemical environment is challenging, however.

In the talk we will address a first question, namely whether the atomic structure of oxide surfaces – once it is well-established in Ultrahigh Vacuum (UHV) – survives the exposure to liquid water. We use a novel apparatus that allows us to expose UHV-prepared samples to liquid water without exposure to air [1]. We find that the $TiO_2(110)$ surface maintains its (1×1) termination and that a (2×1) superstructure that is typically observed after water exposure in air stems from an ordered layer of carboxylates [2]. In contrast, the $TiO_2(011)$-(2×1) reconstruction is lifted upon exposure to liquid water, and the surface is fully hydroxylated [3]. The $(\sqrt{2}\times\sqrt{2})R45°$ reconstruction [4] of the $Fe_3O_4(001)$ surface is also lifted in water, but the change proceeds slowly together with the growth of an oxy-hydroxide phase with a self-limiting coverage of 0.4 monolayers [5]. By adding CO_2, the pH of the water drop can be adjusted; etching was found to commence below pH~4. Fe_3O_4 was also tested for OER in alkaline conditions, and found to be stable at the nanoscopic scale, with a facet-dependent reactivity [6].

Interfacing Biocatalysts with Porous Metal Oxide Electrodes for Semi-artificial Photosynthesis

Erwin Reisner

Department of Chemistry, University of Cambridge
Lensfield Road, Cambridge CB2 1EW, UK
E-mail: reisner@ch.cam.ac.uk

Semi-artificial photosynthesis interfaces biological catalysts with synthetic materials to overcome limitations in natural and artificial photosynthesis.[1-2] This presentation will summarise my research group's progress in integrating biocatalysts in bespoke hierarchical 3D electrode scaffolds and photoelectrochemical circuits, including the characterisation of the biocatalyst-material interface.[3,4] I will first discuss the fundamental insights gained by integrating isolated enzymes such as the water oxidation enzyme Photosystem II and the CO_2-reducing formate dehydrogenase,[5-11] followed by the more recent exploration of live cells from *Synechocystis* sp. PCC 6803 and *Geobacter sulfurreducens.*[12-14]

The resulting biohybrid electrodes can be explored in the development of novel approaches to solar-to-fuel (and chemical) conversion. For example, the wiring of Photosystem II to a formate dehydrogenase has enabled the *in vitro* re-engineering of natural photosynthetic pathways using semi-artificial Z-scheme architectures.[8,9] In contrast to natural photosynthesis, these hybrid systems allow panchromic light absorption by using complementary biotic and abiotic light absorbers. The underlying photoelectrochemical circuit provides effective electronic communication without losses to competing side-reactions.

Nanopore Electrochemistry for Single-Molecule Analysis

Yi-Tao Long
State Key Laboratory of Analytical Chemistry for Life Science, School of Chemistry and Chemical Engineering, Nanjing University, Nanjing 210023, P. R. China
E-mail: yitaolong@nju.edu.cn

Nanopore electrochemistry refers to the promising measurement science based on elaborate pore structures, which offers a well-defined geometric confined space to adopt and characterize single entities including single cells, single particles, and even single molecules by electrochemical technology.[1-3] The electrochemical confined effect within the nanopore displays the incredible ability to achieve single entity discrimination by focusing energy (e.g. electrochemical, light energies and et al.) into small areas, converting the intrinsic properties of single entities into visible electrochemical read-outs with ultra-high temporal-spatial resolution. Furthermore, the excellent resolution of confined nanopore technology also permits the possibility to resolve the transient signals for further revealing the information of single biomolecules dynamics. The chemical controlled confinement inside nanopore provides the advanced electrochemically confined effects to convert the transient single molecule difference into the enhancing signal with high temporal-spatial resolution. In our group, the nanopore electrochemistry has been further applied into disease diagnostics by identifying rare sub-populations, DNA/protein sensing by reading the sequential differences and uncovering the fundamental chemical reactions pathways by revealing the hidden intermediates. With the advents of advanced measurement mechanism, instrumentation and data algorithm, electrochemically confined nanopore is certainly an exciting and promising field. We expect the next avenue for the wide applications of nanopore electrochemistry in a variety of disciplines, leading us explore the new chemistry at a much smaller scale.

Insights into the stability and reactivity of solid/liquid interfaces from ab initio calculations

Mira Todorova, Suhyun Yoo, Sudarsan Surendralal and Jörg Neugebauer
Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany

Processes at solid-liquid interfaces are at the heart of many present day technological challenges related to the improvement of battery materials, electro-catalysis, fuel cells, corrosion and others. Obtaining the microscopic information needed to describe and quantify the underlying fundamental mechanisms is equally challenging to experiment and theory. Density functional theory (DFT) calculations are able to resolve processes at the microscopic scale. However, modelling electrochemical systems is particularly challenging, due to the presence of different classes of materials and phenomena such as metal electrodes, liquid water, huge electric fields within the same system.

Adapting concepts originally developed in the field of semiconductor physics [Phys. Rev. Applied **1**, 014001 (2014)] has enabled us to successfully address questions related to electrochemical processes. This will be demonstrated by two prototypical applications: the selective stabilisation of polar ZnO(0001) surfaces by an aqueous environment [Phys. Rev. Lett. **120**, 066101 (2018)] and the corrosion of Mg surfaces [Phys. Rev. Lett. **120**, 246801 (2018)]. Our development of a novel potentiostat design, which can be easily implemented in all existing periodic DFT codes, allowed us to identify the atomistic mechanism behind the anomalous H_2 evolution reaction on anodically polarized Mg surfaces, which has puzzled electrochemists for more than 150 years.

From Lithium-Rich Cathodes to Solid Electrolyte Interfaces: Atomic-Scale Insights into Battery Materials

Saiful Islam

Department of Chemistry, University of Bath, UK

m.s.islam@bath.ac.uk

Further breakthroughs in lithium- and sodium-ion batteries require advances in new compositions and underpinning materials science. Indeed, a greater fundamental understanding and insights into these energy-related materials require atomic-scale characterization of their redox, transport and interface behaviour. In this context, combined modelling-experimental work is now a powerful approach for investigating these properties at the atomistic level. This presentation will describe such studies [1-4] in two principal areas: (i) transition metal and oxygen redox chemistry in Li-rich disordered rocksalt cathodes; (ii) ion conduction mechanisms and grain boundary effects in solid electrolytes.

Iontronics and Reverse Electrodialysis towards Aqueous Circuits

Seok Hee Han, Song Yi Yeon, Seung-Ryong Kwon, Seol Baek, Taek Dong Chung
Department of Chemistry, Seoul National University
Seoul National University, Seoul 08826 503-206, Republic of Korea

tdchung@snu.ac.kr

Ions are charge carriers, which are also main players along with electrons in electrochemistry. Non-faradaic electrochemical systems driven by ion transfer are found in human brains in which neurological circuits exploit difference in electrochemical potential to generate and propagate signals for information processing. Since the new term, *iontronics*, was defined in 2009, ionic circuit for information processing has been increasingly discussed. Starting with ionic diodes, a series of logic gates and even transistors appeared so that aqueous information processor should be on the horizon in terms of the device function as well as material. While the majority of current iontronic systems have relied on electronic power sources like batteries, reverse electrodialysis (RED), an ionic system that produces electricity from salinity gradients, suggests an intriguing settlement of this issue. Recently, RED has evolved not only to increase the maximum power density but also to be miniaturized for applications to various small devices. Highlighting recent advances of iontronics and RED, this talk will discuss the future of combining those two themes.

Coupling Electrochemical Detection with DNA Amplification: an Attractive Approach to the Point-of-Care Diagnosis of Virus

Benoît Limoges

Laboratoire d'Electrochimie Moléculaire, Université de Paris/CNRS, 15, rue Jean-Antoine de Baïf, 75205 Paris Cedex 13, France

The health threats posed by viral infections such as COVID-19, HIV, hepatitis, influenza, Zika, chikungunya or Ebola, have highlighted the need for rapid, sensitive and selective diagnostic tools to manage the spread of these diseases. In particular, controlling the severe acute respiratory syndrome-related coronavirus-2 pandemic depends critically on the use of genomic diagnostic tests over a large scale. While conventional technologies such as quantitative real-time polymerase chain reaction (real-time PCR) have been broadly used to detect virus (detected through the presence of the viral RNA sequence in a biological fluid), they are expensive, time-consuming, labor-intensive and unavailable in remote settings. Consequently, the development of low-cost and user-friendly point-of-care (POC) viral RNA/DNA testing devices, allowing detection of early infections at limited resource settings or on-field in close proximity to the patient, represent a powerful approach to systematic and decentralized virus detection. To be suitable for limited resource settings, genetic POC devices should ideally be affordable, highly sensitive (the concentration of virus in biological samples can be very low, especially early in the disease cycle, requiring sometime to detect as low as 10^4 RNA copies of viral genome per mL), specific, portable, robust, user-friendly and capable of screening a large number of unprocessed samples in a short time. Toward this end, a major effort has gone into the integration of the gold standard method of nucleic acid analysis, *i.e.* the fluorescence-based real-time PCR, in portable lab-on-chip miniaturized devices. However, to date, real-time PCR has only seen slow transition to POC, in part because of the need for precise thermal cycling, but also because of the requirement for a rather complex, fragile and costly miniaturized fluorescence-based optical detection system. In order to circumvent these limitations, the substitution of PCR by an isothermal DNA amplification, and the replacement of the optical fluorescent read-out by a simpler electrochemical detector, is an attractive solution.[1, 2] Isothermal alternative to PCR have indeed the merit to reduce or eliminate the need for accurate temperature control and cycling, thus affording the development of simpler and smaller battery-operated portable devices. Also important are the numerous advantages offered by an electrochemical detection, namely a lower-cost, a facile integration in a miniaturized format that requires little energy, a good sensitivity, a high robustness without need for periodic recalibration, and the ability to operate in non-transparent reaction mixtures and reaction vessels with complex biological samples. The presentation will be focused on the different approaches we have pioneered and developed,[1-5] including thus the development of a small house-built automatized electrochemical read-out device, optimized for parallel monitoring of up to 48 samples. Some of the recent advances proposed by other groups including chip-based and paper-based POC devices will be also discussed.

Evolution of Tools in Undergraduate Electrochemistry Education

Johna Leddy and Daniel L. Parr IV

Department of Chemistry, University of Iowa, Iowa City, IA 52242
johna-leddy@uiowa.edu

The skills and tools of the modern undergraduate differ dramatically from those of generations past. Undergraduates have near instantaneous access to sources of information through electronic devices tied to the Internet. The amount of available information approaches overwhelming. Generations past assimilated scientific content by reliance on more limited information and more sophisticated arithmetic manipulations. Today's undergraduates are facile at retrieving information but perhaps less well schooled algebraically. To help train effective chemical and electrochemical researchers in future generations, educational opportunities must capitalize on the inherent skills of undergraduates and provide tools to organize and manipulate the near unbounded amount of information. Where skills and tools combined effectively, well-educated scientists will be enabled to tackle important problems in electrochemistry.

A new approach to undergraduate education in electrochemistry has recently been undertaken at the University of Iowa. The basic approach is to design modules that couple undergraduates' skills for facile information retrieval with ubiquitously available spreadsheets to build tools that can be used in the course and applied to research problems after completing their degrees. This approach tracks the rapid evolution of information technologies and capitalizes on the undergraduates' inherent skills.

The current course, Analytical Chemistry I, is taken by upper-level juniors and seniors who are largely majoring in chemistry and engineering. The two main topics for Analytical Chemistry I are equilibria and electrochemistry. Modules for equilibrium are based on the systematic treatment of equilibria. Modules for electrochemistry cover equilibrium measurements, spontaneous redox reactions and titrations, nonspontaneous processes such as electrolysis, and the dynamics of voltammetry. In each component, appreciation of the fundamental processes underlying electrochemical behavior is emphasized. The spreadsheets are a tool but also a vehicle for electrochemical education.

Several spreadsheet modules will be demonstrated.

Potential Axis Tool: A spreadsheet-based tool plots a potential axis. From the potential axis, students interpret spontaneous reactions as well as identify the order in which species are electrolyzed. Potential axis is an equilibrium tool with reference to the Nernst equation.

Redox Titration Tool: Students develop a spreadsheet based on fractional concentrations to model redox titrations. This is also based on an equilibrium model.

Voltammetry Tools: Several spreadsheets are developed to appreciate dynamics in electrochemistry. A spreadsheet that emphasizes the critical ideas of flux, current, gradients, and diffusion is developed in a finite difference format for steady state voltammetry. The spreadsheet is modified to transient measurements for chronoamperometry and linear sweep and cyclic voltammetry. The simulations are not precise but suffice to demonstrate the concepts important in electroanalysis. Spreadsheets map the transition from reversible to quasireversible to irreversible electron transfers. Some simple following reactions are also demonstrated.

In preliminary development of spreadsheets to demonstrate ideas of equilibrium and electrochemistry, student learning was enhanced by these tools. In the current Analytical Chemistry I course, students are allowed access to the tools they have built for exams and homework. They also have a final project to use their newly developed tools to either model a system of interest, create a murder mystery problem, or write next year's final.

Acknowledgments

Development of these modules for undergraduate education is supported by the Carver Curriculum Development Grant from the Roy J. Carver Charitable Trust.

Monitoring plant physiology with organic electrochemical transistors

Eleni Stavrinidou
Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, 601 74, Norrköping, Sweden

Plants are the basis of food, providers of oxygen and regulators of the ecosystem. Plants convert solar energy into chemical energy with the process of photosynthesis where carbon dioxide is converted to sugar molecules. Sugars are not only the energy source in plants but also important signalling molecules, involved in regulation of physiology including stress responses. Currently there are no methods that allow real time monitoring of sugar transport in plants. Sugar detection is based on enzymatic assays, chromatography and/or mass spectrometry; all of these methods require sample collection and preparation. Organic electrochemical transistors (OECTs) are ideal tools for interfacing with organisms, since they can translate complex biological input to an electronic readout signal. OECT sensors can operate in complex media and they can directly detect products from the biological unit. In my group we are developing sugars sensors based on the organic electrochemical transistor for monitoring plant processes in-vitro and in-vivo. In a first example we measure the export of glucose in real time, from isolated chloroplasts, with a temporal resolution of 1min. The OECT based platform is able to distinguish the metabolic phase of the chloroplast prior isolation from the plant. In another example we developed implantable OECT-based sugar sensors for in-vivo, real time monitoring of sugar transport in trees. The OECTs sensors show high device to device reproducibility, stability during the operation in the in-vivo environment and most importantly they do not cause a significant wound response from the plant. The sensors reveal kinetics of sugars transport that were not observed before. Our work establishes the OECT-based sensors as powerful tools for monitoring processes in plants, in real time in in-vivo and in-vitro systems.

Electrodeposition of Platinum Metal Films and Alloys Using Surface Limited Redox Replacement Method

Dr Natasa Vasiljevic
School of Physics, University of Bristol
H.H. Wills Physics Laboratory, Tyndall Avenue, Bristol BS8 1TL, UK
n.vasiljevic@bristol.ac.uk

Electrodeposition methods to create epitaxial Pt films and alloys are attractive routes for the design of nanostructures of various shapes and sizes ideal for many fundamental and practical applications. Surface Limited Redox Replacement (SLRR) method has been one of the most successful approaches developed to date that can produce ultra-thin monolayers of Pt with high control of atomic structure [1]. This method is based on the galvanic replacement of a sacrificial underpotentially deposited (UPD) layer of a less noble metal with a more noble Pt through an irreversible surface-controlled limited redox reaction.

Different experimental configurations for the SLRR deposition developed so far include: 1) electrode immersion and transfer between the two solutions containing the sacrificial UPD metal and the replacement metal; 2) the flow-cell set up where the two solutions are exchanged and 3) the deposition in a one-cell configuration, where the UPD sacrificial layer formation and the galvanic replacement reaction with Pt are conducted in the same cell by optimizing solution composition and the potential control.

In this talk, the SLRR method in 'one cell' configuration used for the growth of Pt epitaxial films, and alloys will be described. Electrochemical and surface characterization studies were used to demonstrate the fabrication of high-quality 2D Pt bimetallic systems with controlled film thickness and surface composition. The nature of UPD sacrificial metal and ions present in the solution affect the quality of epitaxial Pt films structure which was exploited in fundamental studies of structure-electrocatalytic activity correlations [2-4]. Besides Cu UPD and Pb UPD based SLRR growth, we demonstrated that hydrogen UPD could be successfully used for Pt thin films growth [2] as well as Pd. The incorporation of UPD sacrificial layer was exploited in the SLRR approach to control the formation of random alloys. By interrupting the UPD galvanic replacement reaction, we showed that it is possible to have controlled 2D $Pt_x Pb_{1-x}$ alloys formation.[5] The SLRR deposition allowed us to examine changes of the adsorption (H and CO) and catalytic behaviour of Pt-Pb alloys as a function of their composition [5].

arh7@le.ac.uk

A key feature of criminal investigations is establishing identities of suspects, victims and witnesses. The most common physical evidence that accomplishes this is a fingermark, since it is unique to an individual and is time-invariant. Its presence can establish contact between an individual and an object (a weapon or an item of value), or place the individual at a fixed location (a crime scene). Most such marks are *latent* (non-visible) fingermarks, which must be rendered visible by a suitable chemical or physical treatment.

A number of latent fingermark techniques rely on electrochemical deposition processes. Interestingly, both students and practitioners commonly find redox chemistry and electrochemical control of surface processes confusing at a fundamental level and difficult to deliver in a practical context. There is a challenge in motivating practitioners to use these methods and students to engage with the underlying science. However, the visual nature of the outcome and its real-world significance can be a potent educational motivator. This presentation conveys recent activities in these areas involving the deposition of conducting polymers and metals using electrochemical control and redox chemistry; in the latter case, we consider circumstances in which the redox chemistry may take place at a metal surface or in solution

We have recently developed a new approach to the visualisation of latent fingermarks on metal surfaces, relevant to both violent crime (bullet casings, knives) and volume crime (tools, handles at points of entry). Simplistically, the fingerprint residue acts as an insulating mask, such that electrochemical processes can only occur on areas of bare metal surface [1-3], to generate a negative image of the fingerprint. When the deposited reagent is a conducting polymer, its electrochromic properties permit electrochemical optimization of image contrast. Solution redox chemistry can also be used to electro-generate elemental silver or gold particles that deposit selectively on the fingermark residue, to generate a positive image of the fingerprint. We have been studying the underlying fundamentals in the application of this concept to the physical developer (PD) method used on paper (documents, currency) and the multi-metal deposition (MMD) method used on polymer surfaces (drug and explosive wrappings).

This presentation will describe translation of these research topics to the educational arena. The primary focus is development of an undergraduate teaching laboratory experiment for students undertaking a *Chemistry with Forensic Science* degree programme. Inclusion of material science, spectroscopic and imaging techniques has the educational benefit of demonstrating the inter-disciplinarity of contemporary scientific research. Educationally, the experiment offers an opportunity to discuss fundamental electrochemical concepts, including electron transfer, coupled chemical (EC-type) processes (proton transfers [1]), electrodeposition, nucleation and growth, redox-driven ion-exchange, and the development of a band structure (in a growing polymer) from the molecular orbital structure (in the monomer). Distinction between thermodynamic and kinetic electrochemical aspects can also be addressed.

The experimental activity can be adjusted to suit students studying at different levels or with diverse backgrounds. It can be delivered in a closed manner based on proscriptive instructions, or it can be extended in various technical directions, incorporating spectroscopic/imaging techniques. Students can also contribute to the experimental design, by selection of appropriate materials or by exploring more applied aspects such as exposure of the "exhibits" to different environments that mimic a crime scene.

Teaching Translational Research in Electrochemistry: From Fundamental to Product

Woonsup Shin

Department of Chemistry, BioMedical Engineering, Sogang University, shinws@sogang.ac.kr
CareMedi Co., shinws@caremedi.co.kr

Electrochemistry is a discipline of science and technology connecting electron transfer reactions with electrical input and output through electrodes. Therefore, electrochemistry has a fundamentally multidisciplinary nature, which relates chemistry, chemical engineering, material science, process engineering, electronics, and electrical engineering. The key element in electrochemistry is the electrode where electrochemical reaction, reduction, or oxidation, occurs. The charge separation, followed by the electrochemical reactions at the interface, is a fundamental phenomenon in material/energy conversion and mass/ion transport. The understanding of electrode materials and electrochemical processes is the most important in developing the devices and the processes in the fields of energy conversion, power sources, environmental processes, medical devices, and sensors. Therefore, electrochemistry is inherently translational research, which connects the fundamentals of electrochemical phenomena and the applications in developing devices and processes. In this education lecture, I'll use two examples of translationals research, which are currently under development in my lab. 1) CO_2-to-formate or formic acid process is one of the actively pursuing CCU (carbon dioxide utilization) technologies. We succeeded in producing formate to 1.2 M concentration in 30 hrs with the current efficiency of 80~90% at 100 mA/cm^2. The continuous electrolysis could be operated for more than a month. The developed process was applied to build a pilot system of 500 kg/day conversion unit in Hadong power plant, Korea, in 2019. 2) Electroosmosis is a phenomenon in which the fluid moves upon applying an electric field through a capillary or a porous ceramic membrane. This is a rare example where electrochemistry is utilized for a mechanical transducer. Electroosmotic pumps are the simplest one, consisting of two electrodes separated by a porous membrane. We developed a non-gassing electroosmotic pump, in which the traditional platinum electrode is not in use, and made the pump system stable and efficient. It also enabled the pump battery-operable. The pump is currently being used to develop drug pumps such as an insulin patch pump and an implantable morphine pump.

Activity of electrocatalysts. From common wording to common pitfalls

Wolfgang Schuhmann

Analytical Chemistry – Center for Electrochemical Sciences (CES), Faculty of Chemistry and Biochemistry, Ruhr University Bochum, D-44780 Bochum, Germany.

wolfgang.schuhmann@rub.de

Activity of an electrocatalyst is an intrinsic property which essentially is related to the turnover frequency of an active site exposed at the surface of a catalyst modified electrode to the electrolyte and can be expressed as the current per active site at a given overpotential with respect to the thermodynamic value. Evidently, common laboratory praxis is to integrate powder-based electrocatalysts into an ink together with a binder material (often Nafion) and/or conducting additives (typically carbon materials), to drop-coat a rotating disk electrode or the disk of a rotating ring/disk electrode and to investigate linear sweep voltammograms at a typically not too fast scan rate. Normalization is then often performed by dividing through the footprint of the electrode surface. This leads to a current density value at a chosen overpotential which is then used to compare different catalyst activities.

As a matter of fact, this is by far too simple to describe and even more to compare catalyst materials and later use the words “better” or “best” for the candidate with the highest value for a given reaction.

In this presentation the aim is to alert for the use of words like “onset potential”, consideration of how to calculate the potential against the reversible hydrogen electrode, the complex impact of catalyst film thickness, inter-particle conductivity, local pH values, ion movement, the role of the double layer, the presence of porous materials on the response in a simple linear sweep voltammograms.

Furthermore, it will be described why using single entity electrochemistry by application of nanoelectrochemical tools are contributing to an improved understanding of the processes ultimately govern the complex current response during electrocatalysis.

Teaching electrochemistry with youtube.
Something new under the sun?

Neso Sojic

University of Bordeaux, Bordeaux INP, ISM, UMR CNRS 5255, 16 avenue Pey-Berland.
33607 Pessac, France.

sojic@u-bordeaux.fr

Electrochemistry is an experimental science with beautiful visual phenomema. There are many ways to teach electrochemistry, its methods, concepts, theories, models, laws, reactions, mechanisms, etc. The teaching may be based on historical or phenomenological approaches. It can also start from the concepts and then move to the applications. Whatever the selected approach is, it depends on the teacher, its pedagogical goals and of course the audience, in other words, the students.

Most of our present and future students belongs to the generation Z (the next one is the generation Alpha). This generation has never known a world without computers and cell phones. In fact, most of them integrated completely the multimedia technology, internet and the social networking sites (Facebook, MySpace, Twitter, LinkedIn, etc.). The way they learned by sitting at a desk with a book, notebook and pencil is changing. Textbooks and notebooks are being replaced with tablets and the pencil by the stylus. Touchscreen technology and cloud computing are transforming how, where, and even when students learn. They are much more stimulated by the visual impact of images and videos. Therefore, the teachers have to adapt to these new students.

In this talk, we will present a few examples based on videos mainly from youtube to teach electrochemistry.

Education, a vehicle of transformation.

Priscilla G. L. Baker

Chemistry department, University of the Western Cape, PB X1, Bellville, South Africa

Email: *pbaker@uwc.ac.za*

Historically education was based on knowledge as a transformation tool from poverty to wealth as humanity dealt with inequalities brought about by colonialism, racism, geographic disparity and many other obstacles. Education was the key, the wealth and the new bartering currency as society transformed itself. The first industrial revolution brought industrialization and urbanisation to agriculture. This was closely followed by a second transformation wave, with advances in steel production, electricity and petroleum, leading to a series of innovations that changed society. The third industrial revolution saw a rise of electronics, telecommunications and of course computers, opening the doors to space expeditions, research, and biotechnology.

For society to benefit fully from its investment in science education, knowledge must be accessible and familiar to a global community of users who have the skills, knowledge and understanding to unpack and apply learning to societal challenges (1). Scientists need to draw on multiple data and information sources, data analysis skills, statistics and models to create knowledge that is communicated effectively to decision-makers in government, industry, and civil society.

The World Economic Forum (WEF) estimates that 65% of children entering primary schools today will end up working in entirely new occupations or jobs that do not exist now. Therefore the fourth industrial revolution appears threatening to many. It is perceived to be a threat to job security as well as the ordinary way of doing things (2). The various technologies that power the 4IR concept include, artificial intelligence and robotics; ubiquitous linked sensors; virtual and augmented realities; additive and distributed ledger technology; advanced materials and nanomaterials; energy capture, storage, and transmission; and new computing technologies, biotechnologies, geoengineering technologies, neurotechnology, and space technologies. In this paper we will provide some perspectives on technology as a threat or opportunity, as we move from old into the new, examining relevant weaknesses and strengths of education as a vehicle of transformation.

The Importance of Practical Elements in Electrochemistry Education

Andrea E. Russell
School of Chemistry, University of Southampton
Highfield, Southampton, UK SO17 1BJ
a.e.russell@soton.ac.uk

Drawing on experience from outreach activities, such as the Southampton Electrochemistry Circus, and continuous professional development activities, such as the Southampton Electrochemistry Summer School, I will show how hands-on practical elements help to both inspire the next generation of electrochemists and deepen understanding of the theoretical aspects, respectively.

Electrochemical Biosensors: A good example for teaching at the boarder of disciplines

Sabine SZUNERITS
Institut d'Electronique, de Microélectronique et de Nanotechnologie (IEMN), UMR CNRS 8520, University of Lille,
Avenue Poincaré-BP 60069, 59652 Villeneuve d'Ascq, France,
e-mail address: sabine.szunerits@univ-lille.fr

Quantification of biological or biochemical processes are of utmost importance for medical, biological and biotechnological applications. However, converting the biological information to an easily processed electronic signal is challenging due to the complexity of connecting an electronic device directly to a biological environment. Electrochemical biosensors provide an attractive means to analyze the content of a biological sample due to the direct conversion of a biological event to an electronic signal.

The signal transduction and the general performance of electrochemical sensors are strongly determined by the surface architecture that connect the sensing element to the biological ligand. Furthermore, the choice of the surface linked receptor as well as of the electrode material used influence the ultimate sensitivity of the biosensor. New nanotechnology-based approaches have become crucial in the development of advanced electrochemical biosensors. Some of these aspects will be presented here to make these aspects more understandable to the young generation of electrochemists interested in this field.

Effective online teaching in electrochemistry and beyond: teacher and student perspectives

David Read
University of Southampton
Highfield, Southampton, SO17 1BJ, UK.
d.read@soton.ac.uk

Chemistry is recognized as one of the most difficult subjects at all levels of education, and electrochemistry is seen as one of the most challenging components of chemistry programmes for teachers and students alike. The worldwide shift to online education in spring 2020 further compounded the difficulties faced by educators in making chemistry accessible to learners and, with the likelihood that campus teaching will be disrupted for some time to come, it is imperative that we enhance our provision of remote learning going forwards.

This presentation considers the findings of research carried out to investigate students' experiences of online learning on a chemistry course at the University of Southampton towards the end of the 2019/20 academic year. The mode of delivery implemented was informed by previous work in the area of flipped teaching[1] and self-assessment activities for students[2]. The findings of the research provide clear guidance regarding effective approaches that others might wish to adopt to ensure student engagement in online learning and maximize student achievement in electrochemistry and other areas of the subject.

Electrochemistry and Electrochemical Engineering: University of California Irvine comprehensive graduate program at PhD, MS and ME levels

Plamen Atanassov
Department of Chemical & Biomolecular Engineering,
University of California, Irvine, CA 92697, USA
plamen.atanassov@uci.edu

UCI Electrochemistry & Electrochemical Engineering graduate program initiative was born in a series of ad-hock meetings of groups of UCI faculty members early in the Fall of 2018 with realization of reaching a critical mass in this intrinsically interdisciplinary area of research, two decades of offering a "classic" electrochemistry class in Chemistry (part of School of Physical Sciences), the existence of multiple electrochemistry modules and a set of Fuel Cell Technology classes at the Advaced Power and Energy Program, Samueli School of Engineering. Artur M. Sackler Colloquium of the National Academy of Sciences on *Status and Challenges in Science for Decarbonizing our Energy Landscape* (October 10-12, Beckman Center, Irvine, CA) saw the presence of some 17 UCI professors with a self-declared adherence to electrochemical science and engineering ranging from photo-electrochemistry, bio-electrochemistry, sensors & actuators, high-temperature electro-chemistry and solid-state ionics, electrochemical energy technology and power systems and corrosion. It was this very fact of self-identification that is the most powerful impetus for this initiative to create a graduate program at both PhD and MS/ME levels.[1] It came with the spark realization that at present, in the US, (and could be also in Europe or in Japan), there is no other university campus with such high concentration of achievement and talent in the general area of electrochemistry. It came also with the call from the key constituencies: the high-technology wave of renewable energy integration into the grid, highest demand for electricity storage, new mobility and propulsion and with the need to transform critical chemical processes, like Haber-Bosch ammonia synthesis, or Fischer-Tropsch processing of CO and hydrogen to liquid fuels. Electrochemical sciences will play fundamental role in freeing humanity from dependence on fossil fuels and associated high temperature / high pressure processes. Electrochemical engineering is one of the ways to introduce environmentally friendly, low-temperature, solution-based technologies and is the base of hydrogen economy, as a path to ultimate decarbonization.

With this in mind, an initiative group had set-off to create a proposal for a graduate program first as interdisciplinary engineering PhD degree program within Samueli School of Engineering, with Chemical & Biomolecular Engineering, Materials Science & Engineering and Mechanical & Aerospace Engineering initial participation, with an extension to professional Masters in Engineering (ME) and then as a cross-disciplinary (campus-wide) program to include School of Physical Sciences, with Chemistry, Physics & Astronomy and Earth Systems Sciences participation. The initial thrust is to build on fundamental electrochemistry towards materials and energy applications. Extending the program to include sensors and sensor systems as well as water quality and treatment will naturally lead to inclusion of Electric Engineering & Computer Engineering, Biomedical Engineering and Civil & Environmental Engineering faculty. By this all departments in both schools would become contributive partners in the program. The class schedule for the first accomplish year of teaching is presented in Fig. 1. This flow chart incudes also some planned classes (not realized yet). All though classes are indicted with course number and instructor's name and departmental affiliation. This first 3 teaching quarters have not been formally organized as a program but rather were "self-harmonized" between the faculty as a pedagogical experiment. This presentation will discuss curriculum links and program building challenges.[2]

---

[1] In the United States PhD students must take formal scheduled classes for credit and grade, both core disciplinary classes and technical electives, determining specialization.

[2] The University of California Irvine (as well as most of the UC System campuses) is teaching on a Quarter System: three 10-week long teaching periods: Fall, Winter and Spring.

Electrochemical Education for a Broad Range of Students in China

Bin Ren

State Key Laboratory of Physical Chemistry of Solid Surfaces, MOE Key Laboratory of Spectrochemical
Analysis and Instrumentation, Collaborative Innovation Center of Chemistry of Energy Materials,
College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, China
bren@xmu.edu.cn

The electrochemical education is encountering great change in the past 30 years in China. The different background of the students and the request from the Ministry of Education to reduce the course hours urgently call for the reform of electrochemical education.

In the 1990's, the electrochemical education in Xiamen University was divided into two parts. One was in the third year physical chemistry, teaching the basis of solution properties, potential and basic electrochemical reaction. The second part was in the four year of undergraduate study, which included kinetics of electrode process, the research methods in electrochemistry, the electrochemical experiments, and applied electrochemistry (including corrosion, electrodeposition, batteries). These courses were also called the specialized courses, which allow the students to have a solid basis of electrochemistry. However, after 2000, the electrochemistry courses in the undergraduate level except that in physical chemistry are removed, which severely discounts the students' understanding of electrochemistry. Furthermore, the students graduated from other universities, who did not have the chance to attend the graduate electrochemistry courses, have very weak electrochemistry background. Therefore, from 2004, the electrochemistry division in Xiamen University started to reform the electrochemistry courses. The specialized courses were integrated into the graduate course, except for the applied electrochemistry as optional courses for both undergraduate and graduate students. The kinetics of electrochemistry was moved to graduate course. The research methods in electrochemistry was integrated with experimental electrochemistry to include the basis of electrochemical interfacial structure, the basis of electrochemical experiments, electrochemical instruments, the transient methods, the steady state methods, the electrochemical impedance spectroscopy, and advanced in situ methods for electrochemistry (including spectroelectrochemistry, infrared, Raman, X-ray and synchrotron based methods, scanning probe microscopies). The students allow to choose at least four experiments from totally 9 experiments, including construction of potentiostat, rotating disk electrodes and fuel cell, cyclic voltammetry and the factors influencing the electrochemical responses, research methods for lithium ion batteries, photoelectrochemsitry, electrochemical in situ methods (infrared, Raman, XRD, SPM). The experiments were arranged in parallel to the theoretical courses. This reform indeed helps improve the electrochemistry basis of the students in Xiamen University.

However, with the increased use of electrochemistry for characterizing the performance of materials for lithium ion batteries, fuel cells, electrocatalysts from materials sciences and inorganic chemistry, we found urgent needs of electrochemsitry from these types of researchers all over China. However, their home universities do not have the resources to teach them the most up-to-date electrochemistry. On considering this situation, we integrated our research methods' course with the materials of the electrochemistry summer school originally run by Southampton group, to run the electrochemical summer school for Chinese students biannually, and recently annually. We invited professors from Xiamen University, Wuhan University, Fudan University, Changchun Institute of Applied Chemistry of CAS, as well as professors from Southampton University to have a tutorial level lectures to selected audiences from all over China, including young faculty members, Postdocs, and PhD and Master students. This greatly help dissemination of electrochemistry for Chinese researchers and this year also to oversea China scientists. We hope in the future such a strategy can be adopted globally.

Living biofilms for sense and respond with electrical current

Some bacteria establish lines of communication among themselves and electrodes by forming a network of conductive proteins and molecules that carry electrical current, a process known as extracellular electron transfer. Through genetic engineering, such natural electroactive biofilms are being redesigned to create new living microbial electronics for sense and respond applications. We have engineered the biofilm-forming marine bacterium, *Marinobacter atlanticus*, to sense chemicals in seawater and report using electrical current. Biofilm formation and protein expression were first assessed in an electrochemical flow cell in real-time while also measuring current. An isopropyl β-D-1-thiogalactopyranoside (IPTG) inducible system driving yellow fluorescent protein was used to characterize the spatiotemporal activation of protein expression within the biofilm at different stages of growth and induction dynamics. The response time ranged from 30 minutes to 5 hours, depending on the early or late stages of biofilm formation. Fluorescence was detected closer to exposure time and was brighter when biofilms were exposed earlier. More mature biofilms had a slower response time and decreased fluorescence intensity, particularly during transient exposure where most biofilm cells did not express YFP. Chemically induced expression of the *Shewanella* MtrCAB, CctA, and CymA protein electron transfer conduit in *M. atlanticus* resulted in 5 times higher electrical current than the non-engineered strain. A second copy of the native *M. atlanticus* cytochrome *c* maturation system was required for detectable and reproducible expression of these *c*-type cytochromes. To confer bi-directional electronic communication, we are designing inward electron transfer conduits based on the EET pathway of "*Candidatus* Tenderia electrophaga", a marine electroautotroph that grows by carbon fixation using an electrode as an electron donor. Critical EET pathways for "*Ca.* Tenderia electrophaga" were determined by comparison of key proteins across 17 putative members of the family *Tenderiaceae.* Cloning and expression of those identified as membrane-associated, charge-carrying *c*-type cytochromes is currently underway. Combining the *Marinobacter* electrical reporter strain with the inward electron transfer conduit will result in a living electrical material for sense and respond applications.

The Graphite/electrolyte Interface

Robert A.W. Dryfe
Dept. of Chemistry, University of Manchester,
Oxford Road, Manchester M13 9PL, U.K.
robert.dryfe@manchester.ac.uk

Carbon-based electrodes are ubiquitous in electroanalysis and in electrochemical energy conversion/storage, however many of their fundamental properties are quite poorly understood. The heterogeneity of carbon materials is one reason for this. Graphite, particularly the basal plane of pyrolytic graphite, can serve as a useful model material. There has been debate in recent years about the electroactivity of the basal plane relative to the edge plane [1,2]. A related factor, which has also provoked debate in the literature, is the wetting properties of graphite and the susceptibility of contact angle measurements to ambient contamination [3,4].

In this context, the capacitance of graphite electrodes is worthy of re-evaluation. The reference points in this field are the seminal works of Yeager and Gerischer, who studied the capacitance of graphite in aqueous and non-aqueous electrolytes, respectively [5,6]. We have shown recently that capacitance is a sensitive probe of the contamination seen in contact angle measurement [7]. We have also observed specific ion effects within capacitance measurements, which may shed some light on the structure of the graphite/electrolyte interface [8]. As has been noted for single crystal studies of metal electrodes, a key component to understand the metal/electrolyte interface is the structure of interfacial water [9]. Such effects are at least as important at graphite/electrolyte interfaces, where unusual phenomena related to aqueous transport have been reported, including reversible electrowetting effects [10-12].

The future direction of this field will require a “surface science” approach, which has transformed our understanding of the metal/electrolyte interface, to be applied to the graphite/electrolyte interface.

Strategies for Sustainable Electrochemical Engineering Education: Online Integration

Gerardine G. Botte

Chemical Engineering Department
Whitacre College of Engineering, Texas Tech University
Box 43121, Lubbock, TX 79409, USA
gerri.botte@ttu.edu

One of the recent trends in education has to do with Education for Sustainability (EfS). EfS is defined as "a transformative learning process that equips students, teachers, and school systems with the new knowledge and ways of thinking we need to achieve economic prosperity and responsible citizenship while restoring the health of the living systems upon which our lives depend. [1]" Education for Sustainability presents a great opportunity for Electrochemical Engineering, but it raises the question how could programs in Electrochemical Engineering Education (EEE) become sustainable? In addition to this singular challenge, the recent worldwide COVID-19 events have introduced the complexity of limited face to face education to the complete transition to online and in an optimistic aspect, hybrid models. This brings the additional concern to identify how can we effectively transition to incorporate online education in electrochemical engineering while maintaining the classical effectives and interaction with students that face to face education brings into a classroom. Interestingly, effective e-learning can be a platform for EfS [2].

This talk will discuss experiences in developing sustainable electrochemical engineering education programs that involve course curricula, independent design projects, outreach programs [3-4], curricula development for educating science teachers, and the integration of "Online Mode."

Corrosion of emerging materials

Nick Birbilis
Australian National University

As technologies rapidly advance, key factors that are critical to materials durability include, (i) materials being utilised in previously unconsidered environments and unique scenarios, and (ii) the durability of emerging materials (and new alloys) is not well understood. The emergence of new materials, and the ability to produce them, has markedly increased in the past decade - owing to a widespread emergence of computational materials design and additive manufacturing. Such aspects will be discussed quite generally, along with specific examples of the durability of emerging materials. A contemporary perspective on what alloy ‘passivity’ may mean in a practical sense is explored; along with new insights into what factors constitute corrosion resistance.

Multi-scale Advanced Characterizations for Solid-State Lithium Batteries

Xiqian Yu, Junyang Wang, Rusong Chen, Hongyi Pan, Quan Li, Lufeng Yang, Jie-Nan Zhang, Hong Li, Liquan Chen, Xuejie Huang
Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China
E-mail address: xyu@iphy.ac.cn

In the critical area of next-generation batteries, solid-state batteries (SSBs) have drawn increasing attention because of their potential safety, energy-density, and cycle-life benefits.[1] Though promising, they still face challenges that impede their practical application, such as limited ionic conductivity and chemical stability, interfacial stability, electrochemical incompatibility between various components of the SSBs, and thus unsatisfied performance.[2,3] Recognizing this, multi-scale characterization techniques, such as synchrotron and neutron based techniques, are necessary to be employed to study the complex and elusive chemical/physical process in SSBs. Thus, it can offer a deep perspective on various bulk, interface and nanoscale phenomena of the SSBs within the scientific community.

To be specifically, SSBs and the corresponding key cathodes and anodes materials all include complex hierarchical structure and multi-scale interface within the material or devices, those buried structures and interface play critical roles in determining the essential property of the SSBs, such as lithium diffusion, charge transfer, the reactivity and reversibility of the interfacial reaction, structural stability. In this talk, I'm going to introduce the application of synchrotron X-ray spectroscopic, imaging, and neutron scattering techniques, particularly by operando method, on the probing of the fundamental working mechanisms of the key battery materials, components and in SSBs. With gaining a deep understanding of the correlation between the interfacial reaction within the composite electrode materials in multi-scale and the overall electrochemical performance of the SSBs, it inspired us to provide the optimizing strategies for the SSBs.

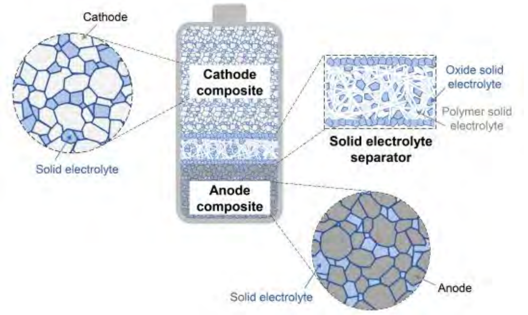

Figure 1. The illustration of the multi-level structure and complex interface between the electrode materials and solid electrolyte within SSBs.

A “simple” model system to understand the OER in alkaline media: the Ni-doped $Fe_3O_4(001)$ surface

Francesca Mirabella
Institute of Applied Physics, TU Wien
Wiedner Hauptstrasse 8-10/134, A-1040 Vienna, Austria
mirabella@iap.tuwien.ac.at

Electrochemical water splitting is an environmentally friendly technology to store renewable energy in the form of chemical fuels. Among the Earth-abundant, first-row transition metal-based catalysts, mixed Ni-Fe oxides have shown promising performance for effective and low-cost catalysis of the oxygen evolution reaction (OER) in alkaline media. However, the synergistic roles of Fe and Ni cations in the OER mechanism are unclear[1].

In this talk I will discuss using the well-defined $Fe_3O_4(001)$ surface as a model system for understanding the OER and establishing the structure-reactivity relation on mixed Fe/Ni oxides. Reconstructed $Fe_3O_4(001)$ provides well-defined sites for the adsorption or incorporation of various metal atoms including Ni[2,3]. In an experimental approach going from UHV via neat liquid water all the way to electrolyte and operation conditions, we report how the Ni-modification changes the reactivity. We use surface science techniques in ultra-high-vacuum (LEED, XPS, ISS, STM) as well as in air (AFM), in combination with electrochemical methods (CV and EIS) in alkaline media.

To first test the stability of the Ni-modified $Fe_3O_4(001)$ surface in liquid water, we used a novel experimental setup[4] that allows bringing a UHV-prepared surface in contact with liquid water without exposure to air. Finally, we performed cyclic voltammetry as well as impedance spectroscopy on the Ni-modified surface, and we observed a significant improvement in the OER activity compared to the clean Fe_3O_4 (001). An optimum Fe:Ni ratio in the range 20-40% is found, which is in good agreement with what is observed in powder catalysts[1,5]. This observation makes our model system well suited to study the OER in alkaline media due to its high level of control of the surface and near-surface region, robustness and simplicity.

Electrochemical Biosensing based on Nanomaterial Labels

Anastasios Economou
Department of Chemistry, National and Kapodistrian University of Athens
Panepistimiopolis, Athens 157 71, Greece
aeconomo@chem.uoa.gr

This work reports some examples of electrochemical bioassays based on the use of quantum dots (metal salt nanocrystals) as labels. The principle of the bioassays is that the target biomolecules are selectively labeled with quantum dots of appropriate composition; subsequently, the labels are dissolved releasing the respective metal cations which are quantified by electrochemical stripping analysis [1]. This bioassay format: i) ensures high sensitivity which is due to the synergistic effect of the high loading of each target biomolecule with labelling moieties and the inherent electrochemical signal amplification afforded by stripping analysis ii) enables simultaneous multiplexed detection of more than one biomolecules based on the use of quantum dot labels of different composition.

In this presentation, electrochemical transducers and integrated platforms for nanomaterial-based biosensing are described, fabricated via different microfabrication technologies (such as thin-film micro-engineering approaches, screen-printing, injection-molding and 3D-printing) and representative applications of paper-based, flexible, foldable, fluidic and multiplexed devices are provided [2-7]. Initial results of on-going research in this field will be presented and discussed.

Solid State Sodium Batteries: from Solid Electrolytes to Functional Device

Dina Fattakhova-Rohlfing[a,b], Qianli Ma[a], Frank Tietz[a]

Li-ion batteries (LIBs) dominate the electrochemical energy storage technology because of their extraordinary performance, high energy density, and long cycle life. Still, the enormously growing demand of Li due to the expanding market raises concerns about the costs and the availability of lithium in the future, necessitating the development of beyond-lithium electrochemical energy storage concepts. Sodium is among the most investigated alternatives for lithium due to its abundance, widespread availability and much lower costs. The simple replacement of lithium with sodium in liquid electrolyte cells while keeping otherwise similar cell design results however in lower energy densities as compared to LIBs due to a higher molar mass, more positive redox potential and higher reactivity of sodium with liquid electrolytes as compared to lithium. In combination with solid electrolytes, however, much higher energy densities can be expected due to a possible use of metallic sodium as an anode instead of currently used hard carbons, opening new perspectives for the development of Na-based electrochemical energy storage systems [1].

Fundamental prerequisite for the development of high-performance solid state sodium batteries is a sufficiently high total conductivity of all its components at room temperature. The latter includes the ionic conductivity of the electrolyte (simultaneously acting as a separator in solid state batteries), the combined electronic/ionic conductivity of the cathode and the anode half-cells, as well as a high conductivity of key interfaces between the electrolyte and the electrode materials. The total conductivity critically relies on the bulk properties of individual materials, but also on their nanomorphology in the component assemblies as well as on the processing- and operation-dependent interface between the materials [2]. The materials challenge therefore goes far beyond the bulk structure level, including the other fundamental aspects of materials chemistry (such as integration of materials into components, optimization of component microstructure, interface properties), electrochemistry (individual contributions to the total impedance, degradation mechanisms upon cell operation), and engineering (development of processing technology enabling fabrication of optimized components).

We will give an overview of the sodium solid state battery development that spans from the development of solid state sodium conductors to their processing to functional battery components and finally to the fabrication and testing of the complete cells. We will discuss bottlenecks in the battery performance and will show the concepts for the mitigation of critical steps.

Gas is evolved in many important electrocatalytic reactions, including those involved in energy conversion and storage, e.g., H_2 and O_2 production from water electrolysis, N_2 and CO_2 generation in fuel cells, and in industrially important reactions, such as the chloralkali process. Gas bubbles formed on electrode surfaces, block the transport of reactants to the electrode surface, creating an additional overpotential and lowering efficiency. Understanding the physical processes that lead to the formation of bubbles on electrode surfaces is therefore of significant interest.

Nucleation is the first-step in the generation of gas bubbles. It requires surmounting the energy barrier represented by the formation of a critical nucleus of 10s to 100s of gas molecules, after which bubble growth is thermodynamically favorable. Overcoming the barrier is a stochastic process, and so characterizing it requires repeated measurements in reproducible conditions.

Driving a gas-evolving reaction at a nanoelectrode generates a controllable supersaturation of gas at the electrode surface, which can induce the formation of a single stable nanobubble.[1] In contrast to work with larger electrodes, in which multiple bubbles can simultaneously nucleate, grow, coalesce, and possibly detach, at a nanoelectrode only one bubble nucleates and can rapidly be detected (temporal resolution <1 ms). As the nanobubble rapidly dissolves on cessation of the current (<50 ms),[2] nanoelectrodes can repeatedly measure the time to nucleate a single bubble; thus characterizing the distribution of times taken to overcome the nucleation barrier.

From these measured distribution of nucleation times, as a function of applied current (supersaturation), we gain physical insight into bubble nucleation, including the shape and number of molecules in the critical bubble nucleus, rates, energetic barrier heights.[3] Measurement of the nucleation of H_2, O_2, N_2, and CO_2 bubbles will be reported.[4,5,6]

Nanoelectrochemistry for Studying Neurotransmission in Real-Time

Prof. Mei Shen

Department of Chemistry, University of Illinois at Urbana-Champaign, 600 S Mathews Ave, Urbana, Illinois, USA, 61801
mshen233@illinois.edu

Nanoelectrodes have the advantage of low background charging current, when coupled with scanning electrochemical microscope,[1] it can provide nanometer spatial resolution imaging with high temporal resolution.[2] My group developed the Nano-Interface between Two Immiscible Electrolyte Solutions (ITIES) as a unique analytical platform for the study of ionic species of biological interest such as neurotransmitters on living bio-structures, i.e. single cells and single syanpses.[3, 4, 5, 6, 7, 8] A typical nanoITIES electrode consists of a laser pulled pipet with an orifice in the few nm range that can be filled with an immiscible organic solution for its immersion into biologically-relevant fluids, thus forming a liquid/liquid interface. We studied acetylcholine neurotransmission activity at single neuron structures from the model organism *Aplysia californica*. We employed scanning electrochemical microscopy (SECM) for accurate positioning of our nanoprobes on selected regions of cells and their synapses. By using nanoITIES electrodes, we circumvent challenges in the evaluation of redox inactive neurotransmitters using electrochemical methods.

Our results show that our Nanoelectrochemistry platform, consisting of nanoITIES electrodes and SECM, is powerful for elucidating the mechanisms of cellular signaling.[8] A multitude of information including concentration of transmitters, number of transmitter molecules, dynamics of transmission have been measured in real time.[7, 8] Additionally, we have demonstrated the power of nanoelectrochemistry in determining the number of vesicles per unit area while providing real time transmission information,[8] a big advantage compared to conventional methods using electron microscopy.

Smart scaffolds for electrochemical monitoring of cell cultures

Claudia Caviglia, Suhith Hemanth, Yasmin M. Hassan, Jesper Y. Pan, Babak Rezaei Stephan S. Keller
National Centre of Nano Fabrication and Characterization – DTU Nanolab, Technical University of Denmark, Ørsteds Plads, Building 347, 2800 Kongens Lyngby, Denmark
suke@dtu.dk

In bioelectrochemical applications, cells are typically incubated on 2D electrodes. The major limitation of this approach is that planar electrode geometry poorly mimics the natural environment of the cells. 3D polymer scaffolds have been developed to provide a more realistic environment for the cells but these structures usually lack integrated sensor functionality to perform *in situ* measurement in the 3D cell culture. Here, we address these limitations and demonstrate the *in situ* electrochemical analysis of the alkaline phosphatase (ALP) activity in a 3D bone tissue model with integrated electrochemical sensing using 3D pyrolytic carbon microelectrodes. Previously, pyrolytic 3D carbon electrodes have been introduced for electrochemical monitoring of human neural stem cells [1,2].

In this study, a novel approach for fabrication of multi-layered 3D electrodes was developed [3] based on photolithography followed by pyrolysis. 3D culturing of Saos-2 osteosarcoma cells in gelatin hydrogels deposited on 2D and 3D carbon microelectrodes was established (Figure A-B). Saos-2 cells cultured on the electrode express ALP on the surface of their cellular membrane. P-aminophenyl phosphate (PAPP) is added as substrate and hydrolysed by ALP to release p-aminophenol (PAP). The oxidation of PAP to quinoneimide (QI) is carried out during a potential scan in square wave voltammetry (SWV) that generates an oxidation peak current used as signal (Figure C) [4].

In the 3D environment provided by the gelatine hydrogels slower increase of ALP activity was observed compared to 2D cell cultures probably due to reduced proliferation of the Saos-2 cells. Integration of 3D carbon microelectrodes allowed the recording of higher peak currents due to larger surface area of the electrodes (Figure D). For 3D cell culturing for more than one week, a decrease in ALP activity was recorded. This was attributed to the formation of spheroids in the hydrogels, which was confirmed using imaging of the 3D cell cultures with confocal microscopy.

In conclusion, the combination of 3D cell cultures with 3D carbon microelectrodes as smart cell scaffolds is a promising approach for development of *in vitro* cell models.

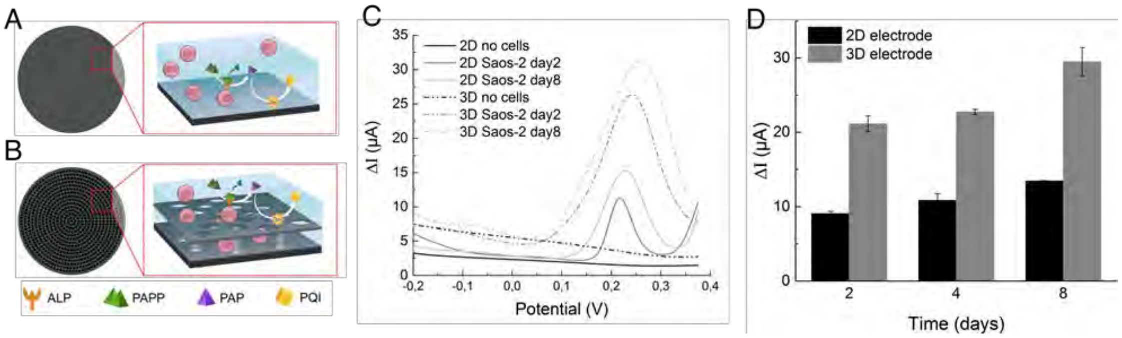

Figure: Schematic illustration of the electrochemical assays: Saos-2 cells are encapsulated in gelatin/TG hydrogel deposited on (A) 2D electrodes and (B) 3D electrodes. (C) Representative SW voltammograms recorded at Day 2 and Day 8 for Saos-2 cells cultured on 2D and 3D electrodes after 1 hr incubation with PAPP. D) Time course of the oxidation peak current due to PAP formation.

Direct Borohydride Fuel Cells (DBFCs) are considered as promising power sources for portable and mobile applications. Their advantages are high theoretical energy density, and high theoretical cell voltage. However, currently available platinum group metal-based (Pt, Pd) electrocatalysts do not allow one to take full advantage of the low standard potential of the BH_4^-/BO_2^- couple (-0.41 V *vs*. RHE) due to the competing faradaic hydrogen evolution reaction and non-faradaic heterogeneous hydrolysis of BH_4^- [1].

We have recently demonstrated that electrodeposited Ni largely outperforms Pt in the borohydride oxidation reaction in the low overpotential interval, both in half-cell and in unit fuel cell configurations [2, 3].

Here we combine electrochemical, *operando* Fourier-Transform infrared spectroscopy (FTIRS), and differential electrochemical mass spectrometry (DEMS) measurements with DFT calculations to propose a tentative mechanism of the borohydride oxidation reaction on Ni.

Hollow Carbon Spheres Codoped with Nitrogen and Iron as Effective Electrocatalysts for Oxygen Reduction Reaction

Qiaoxia Li, Yumeng Ma, Shasha Luo,Qunjie Xu*

Shanghai Key Laboratory of Materials Protection and Advanced Materials in Electric Power,
Shanghai University of Electric Power, Shanghai 200090, China

e-mail: xuqunjie@shiep.edu.cn

Design and engineering of low-cost, effective catalysts for oxygen reduction reaction (ORR) plays a critical role in the development of fuel cell and metal-air battery. Herein, we report a facile template-assisted strategy for the fabrication of hollow porous carbon spheres codoped with nitrogen and iron species (FeNC) for ORR electrocatalysis. The samples were synthesized via one-step pyrolysis of a core-shell precursor, which was prepared by in-situ growth of a Fe-doped zeolite imidazolate framework (ZIF) shell onto the surface of polystyrene nanoparticles. The obtained FeNC composites exhibited a unique hollow structure with a large surface area, hierarchircal porosity, and abundant FeNx sites. Notably, the sample prepared at 950 ℃ (FeNC-950) exhibited the best ORR activity among the series in alkaline media (with an onset and half-wave potential at +0.94 and +0.84 V vs. RHE, respectively), a performance on par with that of Pt/C and markedly better than those of relevant catalysts reported in recent literature, where ORR proceeded mostly via the efficient four-electron reduction pathway. The FeNC-950 catalyst also displayed superior stability and tolerance to methanol, as compared to commercial Pt/C. The results suggest that high-performance ORR catalysts can be derived by deliberate structural engineering of the metal-organic framework precursors.

This work discusses the protective role of cerium tri(bis(2-ethylhexyl)phosphate) - Ce(DEHP)3, a pH-sensitive corrosion inhibitor additive in coatings for enhanced corrosion protection. The effect of the inhibitor on the coating barrier properties and corrosion protection performance was studied by electrochemical impedance spectroscopy.

Localized electrochemical techniques was used to probe the self-healing effect at microscopic level. For that purpose, a defect was created in the coating exposing the substrate. The corrosion inhibition effect was studied using localized impedance spectroscopy (LEIS), the scanning vibrating electrode technique (SVET) and localized potentiometry (SIET). Complementary experiments were performed using SEM-EDS.

EIS results carried out for 2 years clearly demonstrated the enhancement of the coating barrier properties in the presence of the additive and its protective role. Localized electrochemical techniques illustrated the self-healing effect and evidenced the corrosion inhibition effectiveness of the pH sensitive additive.

The corrosion inhibition mechanism seems to involve i) a cathodic inhibition effect due to the formation of a protective layer containing Ce-species; ii) inhibition of the anodic reaction due to formation of a stable film of DEHPA and iii) reduction of electrolyte uptake in the coating due to hydrophobization of the coating pores.

Overall, the work demonstrates the improved corrosion protection of epoxy coatings modified with a novel corrosion inhibitor that is activated by local pH changes.

Over the past decades, great progress has been made on the electrochemical technologies for the treatment of effluents containing organic pollutants. The electrochemical oxidation (EO) of organics for wastewater treatment, the most popular technology, can be attained in different ways: (i) Direct EO, where electron transfer occurs at the electrode surface without participation of other substances [1]; (ii) Indirect EO where organic pollutants are oxidized through the mediation of some electroactive species generated at the anode surface, which act as intermediaries for electrons shuttling between the electrode and the organic compounds [1]. The efficiency of the process is affected by operating conditions and above all by the nature of the electrode material. In particular anodes with low oxygen evolution overpotential, such as IrO_2, RuO_2 or Pt have "active" behavior and favor the partial and selective oxidation of pollutants (i.e. electrochemical conversion), while anodes with high oxygen evolution overpotential, such as SnO_2, PbO_2 or boron-doped diamond (BDD) have "non-active" behavior and so are ideal electrodes for the complete electrochemical oxidation of organics to CO_2 in wastewater treatment. According to the literature, carboxylic acids are common intermediates in the electrochemical oxidation of several organic substrates or real wastewaters [1]; and these substances are usually neglected. In the past decades, great advances have been made in synthesis of different carboxylic acids [2]. However, expensive or air/water sensitive substrates were usually used in stoichiometric reactions, silanes and/or metallic reducing agents were often required; clean and cheap reductants were necessary to obtain higher yields and multi-steps procedures were also proposed. For this reason, the plan to obtain these chemicals from biomass [3] by electrosynthetic way is of practical importance because the development of green processes to produce compounds with technological application is still a real necessity [4]. In this context, this work aims to combine the distinctive characteristics of a non-active anode to obtain high-added value products (mainly, carboxylic acids) from cashew-nut shell liquid (CNSL) waste, an abundant and renewable raw material in the Northeast Brazilian region. During the environmental-electrosynthetic approach (treatment of effluent to synthetize selectively high added-value products); the concentration of the carboxylic acids was monitored as well as the chemical oxygen demand and energy requirements were determined. The evolution of five carboxylic acids was followed over time for the experiments of the three different current densities using 0.1% of t-CNSL in 1.00 mol L^{-1} NaOH at $Ti/TiO_2RuO_2IrO_2$ anode. At 40 mA cm^{-2}, the most notorious increase in the organic acids concentrations took place during the two last hours achieving selective electrochemical conversion of CNSL for producing acetic acid.

Transport and Reactivity of Ionic Phases of the Lithium SEI

Betar M. Gallant, Rui Guo
Department of Mechanical Engineering
77 Massachusetts Avenue, Cambridge, 02139
bgallant@mit.edu

The origins of major challenges faced by Li anodes – high reactivity, insufficiently high Coulombic Efficiency, parasitic electrolyte consumption and loss of active Li - can be traced back to the chemical, ionic, and mechanical properties of the native solid electrolyte interphase (SEI). The SEI consists of nominally ionically-conductive, physically-blocking inorganic and organic phases derived from the reaction of Li with the electrolyte such as inorganic LiF, Li_2O, Li_2CO_3, organic semi-carbonates, and polyolefins. After decades of study, the native SEI formed on Li (< 100 nm) remains challenging to experimentally probe, and the individual and collective function of SEI phases is not well-understood. To identify strategies for improvement, understanding of the chemistry, structure, and function of sub-components within the SEI will be beneficial. One challenge has been a lack of empirical data on the properties of individual SEI phases, and specifically when present at a metallic Li interface, where the chemical potential imposed by Li will yield different properties than bulk analogues typically invoked to understand behavior.

In this talk, I present our recent studies of single-component interfaces on Li, which we have conducted to gain deeper insights into the possible roles of common interfacial constituents found in nearly all Li SEI. We have developed synthetic approaches based on gas-phase reactions of Li with oxide- and fluoride-donating reactants that permit introduction of single phases with high spatial uniformity. We show results of controllable growth (10 – 100 nm thickness) of ionic Li_2O and LiF directly onto Li foils. The formed layers are conformal, compact, polycrystalline, and thus serve as model interphases further qualitative and quantitative study. First, electrochemical impedance spectroscopy, combined with interface modeling, is used to extract transport properties (ionic conductivity, diffusivity, charge carrier concentration and activation energy barriers) of $Li|Li_2O$ in symmetric cells with EC/DEC electrolyte. EIS analysis indicated that the ionic conductivity ($\sim10^{-9}$ S/cm) and diffusivity of Li_2O on Li were several orders of magnitude higher than reported values obtained using bulk pellet measurements of Li_2O, which is attributable to the dramatically different chemical, ionic, and microstructural environments. The Li_2O SEI is further studied as a function of synthesis condition, revealing microstructural sensitivities that can be tuned to modulate transport behaviors. Results are compared with single-phase LiF interfaces, and with the native SEI, to isolate chemistry- and structure-specific differences. Finally, I will present our emerging understanding of the chemical stability of these individual phases, Li_2O and LiF, in contact with carbonate electrolytes. Using X-ray absorption near-edge spectroscopy, we have probed the reactivity of ionic SEI phases upon exposure to electrolyte, and find evidence of varying interfacial stability as a function of SEI and electrolyte composition due to reactions at the SEI-electrolyte interface. These results help illuminate the origins of commonly-observed changes in symmetric-cell impedance over hours or days in certain electrolytes, which have lacked chemical specificity to date. The integration of this knowledge to guide design of improved SEI chemistries for transport and stability will be discussed.

In this contribution, synthesis and electrochemical characterization of recently synthesized copper complexes (artificial enzymes) mimicking tyrosinase activity are presented. Tyrosinase is a biologically important oxidase, which acts as the rate-limiting enzyme for controlling the production of melanin. It belongs to the group of proteins with a bicopper active center [1]. Unfortunately, tyrosinase has limited lifetime and therefore development of artificial enzymes offers new approach towards the higher stability e.g. in electrochemical sensors [2–4].

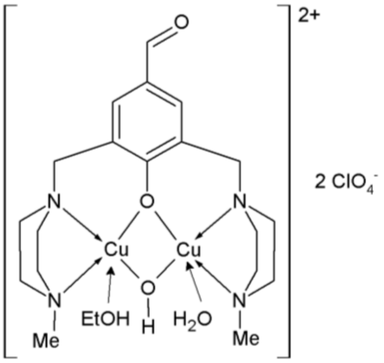

Figure 1: Example of studied $[Cu_2L(OH)(H_2O)(EtOH)](ClO_4)_2$ complex.

Factors controlling biomimetic (catalytic) activity of selected complexes (e.g. on Fig. 1) towards different substrates (3,5-Di-tert-butylcatechol, 2,5-Di-tert-butylhydroquinone, dopamine, serotonin, etc.) are summarized and explained. For this study, electrochemical as well as spectroscopic experiments in aqueous as well as in non-aqueous media were performed. Moreover, another important role plays deposition of artificial enzyme complex on an electrode surface. The obtained results of kinetics of catalytic substrate conversion were compared with those obtained by using enzyme (tyrosinase).

In the presented paper, fabrication, and tests of an electrochemical chemosensor for selective determination and quantification of cilostazol is described. Cilostazol, 6-[4-(1-cyclohexyl-1H-tetrazol-5-yl)butoxy]-3,4-dihydro-2(1H)-quinolinone, is an antiplatelet agent and a phosphodiesterase III inhibitor. It is used for the treatment of intermittent claudication (IC), a preliminary symptom of peripheral arterial disease (PAD). PAD is most commonly caused by atherosclerosis. It affects millions of patients worldwide and is associated with significant morbidity and mortality.[1] Fast, simple and reliable method of this drug determination along with its principal active metabolites is important from the point of view of personalized drug dosage. In order to devise selective chemosensor for determination of cilostazol in biological matrices, molecularly imprinted polymer nanoparticles (nanoMIPs) were prepared by precipitation polymerization of the selected acrylate derivatives and were characterized.[2] Furthermore, density functional theory (DFT) calculations were performed for better understanding of interactions between the acylate monomers and the target analyte, and also with its principal metabolites. The result indicated pre-polymerization complex formation mainly through H-bonding.

In the next step the nanoMIPs were immobilized on the gold electrode. Then, the obtained electrodes were characterized electrochemically and spectrally. Moreover, morphology of the obtained electrodes was studied by AFM microscopy. Finally, the analytical tests of the devised chemosensor were performed.

Highly Energy-efficient Electrochemical Advanced Oxidation Processes Based on Natural Air Diffusion Electrode

Minghua Zhou*, Qizhan Zhang, Yanchun Li, Yawei Li
College of Environmental Science and Engineering, Nankai University, Tianjin 300350, China.
No.38 Tongyan Road, Jinnan District, Tianjin , P.R. China 300350
zhoumh@nankai.edu.cn

Electrochemical advanced oxidation processes (EAOPs) based on in-situ H_2O_2 electro-generation have acquired an extraordinary significance for the removal of persistent organic pollutants from wastewater [1, 2]. High mineralization efficiency and low energy consumption are the core requirements for the application of EAOPs. The cathode plays an important role in EAOPs, which determines the production of H_2O_2 in the system[3]. However, low oxygen utilization efficiency (<1%) and high energy consumption ((3-20 times electric energy consumption of treatment) are still obstacles to in-situ synthesis of H_2O_2 on the cathode [4].

Herein we propose a superhydrophobic natural air diffusion electrode (NADE) to greatly improve the oxygen diffusion coefficient at the cathode about 5.7 times as compared to the normal gas diffusion electrode (GDE) system and apply it to the treatment of wastewater in EAOPs. NADE allows the oxygen to be naturally diffused to the reaction interface, eliminating the need to pump oxygen/air to overcome the resistance of the gas diffusion layer, resulting in fast H_2O_2 production (101.67 mg h^{-1} cm^{-2}) with a high oxygen utilization efficiency (44.5%–64.9%). Long-term operation stability of NADE and its high current efficiency under high current density indicate great potential for environmental remediation on an industrial scale [5].

In order to promote application of EAOPs for organic pollutants degradation, we studied innovative EAOPs using NADE to improve H_2O_2 production without aeration and enhanced H_2O_2 utilization efficiency in electro-Fenton (EF), photoelectro-Fenton (PEF) and peroxi-coagulation (PC) processes. In the EF process, sulfamethazine (SMT) was removed effectively, but the mineralization degree was not high due to the generation of organic acids which were difficult to be further degraded. While in the PEF process, organic contaminant can be destroyed by the combined action of Fe^{2+}/H_2O_2, UV/H_2O_2 and UV radiation, and more higher mineralization (>83.5%) at low current (50 mA) was attained, which might be attributed to the high H_2O_2 utilization (70-90%), rapid regeneration of Fe^{2+} and photolysis of intermediates. In addition, it was verified that the PEF system had a good adaptability to pH and pollutant concentration. Compared with aeration system, the use of this active gas diffusion cathode in EAOPs significantly reduced energy consumption [6]. 2,4-dichlorophenoxiacetic acid (2,4-D) was efficiently removed by peroxi-coagulation (PC) using NADE as the cathode. In PC using NADE, the 2,4-D removal was 24.6% higher than that of PC using aerated air electrode (AAE), which resulted from higher generation of H_2O_2. Besides, the energy consumption (12.01 kWh kg^{-1} TOC) in PC using NADE was lower than PC using AAE (20.51 kWh kg^{-1} TOC). PC also overcame the narrow pH limitation and showed relatively stable performance upon initial pH of 3-9 when compared with EF system.

The superior performance of NADE and high utilization efficiency of H_2O_2 make it a good application prospect as cathode in EAOPs for environmental remediation.

Robust immobilization of biomolecules is one of the crucial steps when constructing biosensors, since biological activity may be compromised in solid interfaces. Biocompatible polymers, with reactive sites for biocompounds covalent attachment, allow an effective immobilization of the biorecognition element and signal transduction. Polydopamine-based surface modifications have been widely studied [1] and employed in biomedical, energy and industrial applications, including biosensing. However, spontaneous oxidative polymerization does not allow control over structural homogeneity, oxidation state and conductivity of thin films. Recently, electrosynthesis of polydopamine [2,3] has shown to yield better transducing interfaces in enzymatic biosensors than the standard chemical synthesis, highlighting the great potential of electrochemical methods to better tune the chemical and physical properties of polycatechols. Although the catechol group is well known for providing the adhesive characteristics of these films, the role of other chemical functionalities is far less studied and its effects on the final materials properties poorly understood [4].

In this work, we carried out a detailed investigation of the potentiodynamic and potentiostatic polymerization of catechol and distinct bioinspired catecholamines (dopamine, norepinephrine and L-DOPA), disclosing novel insights of their electropolymerization mechanisms. The electrochemical data is supported by electrogravimetry, spectroscopy (FTIR, UV-vis, XPS), atomic force microscopy, ellipsometry and wettability assays. Poly(norepinephrine) displayed the most regular growth and the highest electroactivity. The effect of the different surface chemical groups is accessed towards the electrochemical behaviour of several ionic and molecular species. Furthermore, real-time surface plasmon resonance assays are conducted to assess the adsorption of different proteins to the biomimetic films. Also, the relative ability for polymers *in situ* functionalization is demonstrated with model electroactive compounds and biomolecules (e.g. enzymes, antibodies). Finally, the analytic performance of the different films as amperometric biosensors towards phenolic compounds is also discussed.

fabiana.arduini@uniroma2.it

As reported by World Economic Forum, by 2030, the very nature of disease will be further disrupted by technology. The fourth industrial revolution will ensure that humans live longer and healthier lives, so that the hospitals of the future will become more like NASCAR pit-stops than inescapable black holes. You will go to hospital to be patched up and put back on track, revolutionizing the healthcare from hospital to home-spital. Currently commercially available wearable sensors are aimed at physical sensing to monitor physiological parameters including heart rate, electrical activity of the brain from the scalp and oxygen saturation in arterial blood, but they do not provide any information at molecular levels (chemical sensing). In the research field at academia level, several groups have recently demonstrated that miniaturised devices can potentially monitor electrolytes, metabolites, and heavy metals, directly on the body in various biofluids, such as sweat and wound exudate, however the chemical sensors need to further improved for delivering smart wearable sensors for effective and fast measurement in sweat samples.

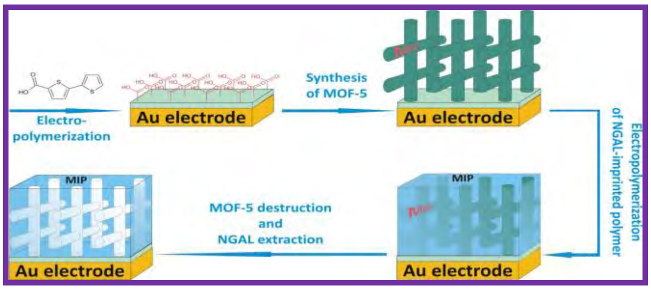
In this overall scenario, we developed a miniaturized all-solid state ion-selective electrode for Na^+ detection in sweat sample based on a low-cost fabricated screen-printed electrode modified with Carbon Black to effectively convert the ionic signal through the ion-selective membrane into an electronic signal. Two different membranes were used to modify CB-modified graphite working electrode surface for the selective sodium ion detection and the Ag/AgCl reference electrode for stabilising the potential of reference electrode.

Several parameters were investigated including the volume of carbon black to modify the working electrode, the volume of liquid membrane to modify working and reference electrodes, and the conditioning time. A calibration curve was obtained by potentiometric measurements with a linear response in the range between 10^{-3} M and 1 M described by the following equation $y = 0.068\ x + 0.262$, $R^2= 0.973$. The interference and recovery studies demonstrated the selectivity and accuracy of the sensor developed. Finally, sodium ions were detected in sweat samples collected after physical activity of three volunteers obtaining values equals to (44 ± 4) mM, (55 ± 6) mM, (47 ± 3) mM. in agreement with the physiological range values (e.g. 46.8 mM).

Molecular imprinting of drugs and biomolecules in the conductive polymer matrices – a controlled way of sensor recognition layer fabrication

Krzysztof R. Noworyta
[a]*Institute of Physical Chemistry, Polish Academy of Sciences*
Kasprzaka 44/52, 01-224 Warsaw, Poland
knoworyta@ichf.edu.pl

In this contribution application of thiophene and carbazole-based conductive polymers, molecularly imprinted with range of analytes, as the selective recognition layers in chemosensors is described. Combination of electrochemical deposition of molecularly imprinted polymer (MIP) films with selected electrochemical transduction techniques allowed for development of sensors with good selectivity and appreciable limit of detection.



Scheme 1. Formation of NGAL-imprinted porous polymer films with help of sacrificial metal-organic frameworks.

Selective chemosensor fabrication typically requires formation of a recognition layer coupled with suitable transduction element [1]. The recognition layer is not only allowing selective analyte binding but its properties are quite often important in overall sensor performance. Electrochemical deposition of the recognition layer allows for facile control of the process via applied potential, current, as well as solution composition [2]. That way, it is feasible to control deposited film thickness, morphology, porosity or electrical properties, therefore tuning the sensor parameters and response. Furthermore, this method can be easily used to deposit such films on the transduction elements with variety of shapes. Molecular imprinting is an elegant and relatively facile method for devising a sensor selective recognition layer for variety of analytes ranging from small molecules to bacteria and viruses [3]. This approach is based on formation of a pre-polymerization complex between analyte template and functional monomers in solution, followed by its polymerization in presence of cross-linking monomer. Thus, MIP film with molecular cavities with shape, functional groups set-up and properties allowing for selective binding of the imprinted analyte is formed. Application of monomers capable of electrochemical polymerization allows for coupling of this approach with electrochemical deposition of conductive polymers [4]. Such conductive MIPs offer advantages of controlled film deposition, as well as possibility of changing their electrical properties with applied potential, which could allow for development of stimuli-responsive "smart" materials.

Over few years, we have devised and fabricated variety of chemosensors with recognition layers based on conductive polymers molecularly imprinted with variety of analytes. The analytes imprinted in such polymers range from small molecule biomarkers, to drugs, to proteins. In our studies thiophene and carbazole derivatives were used as functional and cross-linking monomers. Deposited conductive MIP films morphology and properties were studied and analytical parameters of the final chemosensors were tested. Possibility of controlled formation of highly porous polymeric structures is also presented. Finally, advantages and disadvantages of this approach are discussed.

.

Sewage sludge is the main waste generated in the wastewater treatment. Solid waste mismanagement is posing the risk of environmental pollutions due to releasing the harmful pathogens (e.g Escherichia coli, etc.). Anaerobic digestion is the typical technology for sewage sludge treatment. However, sludge hydrolysis is the limiting step for sludge degradation in the anaerobic digesters. Therefore, it results in long residence time in the digester reactors (approximately 20-30 days) and considerable energy consumption. Moreover, it has been reported that waste disposal is a cost and energy intensive process and accounts for approximately 50- 60 % of the operational cost in the wastewater treatment facilities. Hence, new treatment methods need to be developed to decrease energy consumption and capital cost.

It has been shown that alkaline treatment is efficient for the sludge biodegradation. Besides, electrochemical oxidation of the biomass is the clean alternative technology for sludge disintegration and pathogen destruction. To overcome the conventional treatment method limitations, our research group has developed a novel, energy-efficient pathway for wastewater treatment by integrating alkaline and electrochemical oxidation techniques at room temperature. The results showed a considerable solid reduction and energy consumption when compared to similar research studies. The biosolid characterization after treatment represented the potential of generating value-added chemicals in the liquid phase and the successful removal of pathogens for safe disposal or agriculture application.

Innovative Structuration of Carbon-Ink Electrodes for Electrochemical Detection

Michael Spann(a)*, Maxime Gougis(a), Pascal Mailley(a)
(a)Univ. Grenoble Alpes, CEA, LETi,
F-38000 Grenoble, France
*michael.spann@cea.fr

Electrochemical sensors are powerful and versatile analytical tools in different fields, for example medical analysis and healthcare application. Today's requirements on them correlate with the advances in electrode design: The fabrication of miniaturized electrodes allows for the design of small-scale sensors or arrays, respectively, corresponding to the demand of portable and even implantable "point-of-care" devices for monitoring application, as well as the analysis of small sample volumes [1].

Electrode miniaturization, however, imposes a physical limitation linked to the reduction of the electrochemically active electrode area. For amperometric sensors (biosensors), this implies a loss in faradaic current, resulting in a lower signal. In case of solid-state Ion-Selective-Electrodes (ISE), the charge storage capacity and the quality of the charge exchange on the selective membrane/collector interface are reduced, leading to a degradation of sensitivity, stability, dynamic range and limit of detection. While the impact of electrode structure has been profoundly studied [2] and numerous interesting approaches exist on the laboratory scale, the majority involves complex, multi-step processes of time-consuming nature, which thus seem unsuited for the production on a larger scale. Printing techniques on the other hand, which are well established in the industrial production of low-cost solid-state sensors, are not designed to generate structured electrochemical interfaces.

In this work, commercial carbon ink, suited for screen-printing, was deposited on polymer substrates and subjected to a process-oriented, environmentally friendly treatment (patent pending) with the aim to structure the surface and increase the electrochemically active area. Scanning Electron Microscopy studies (SEM) confirm the surface structuration (Fig. 1a), as well as the generation of a porous network in the bulk. Electrochemical characterization consisted of Cyclic Voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS). Results were compared to a cured, unstructured electrode, for which fast, reversible electron transfer and semi-infinite linear diffusion were observed. Upon treatment, the reversible nature of the charge transfer was conserved (Fig. 1b); however the voltammetric response indicates a temporal characteristic and a combination of semi-infinite and thin-layer finite diffusion [3]. Faradaic and capacitive currents increased by more than one order of magnitude. Impedance studies confirmed the pronounced capacitive nature of treated electrodes (Fig. c). ISE and amperometric sensors containing as-structured electrodes are currently under study and the potentiometric measurements already presented promising results.

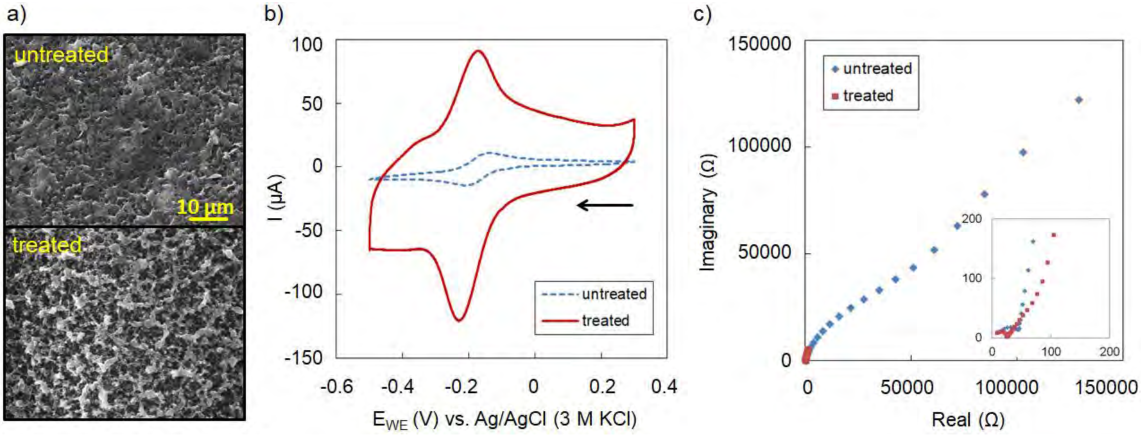

Fig. 1: Untreated and treated electrode deposit characterization, a) SEM: V_{acc}=30 kV, V_{extr}=5.6 kV, b) CV: 1 M KCl, 1 mM $Ru(NH_3)_6^{3+/2+}$, 50 mV/s, c) EIS: 1 M KCl, 0.1 Hz to 1 MHz.

Structure-Dependency on the Photoelectrochemical Performance of Two-dimensional Transition Metal Dichalcogenides

Péter S. Tóth,[a,b] Gábor Szabó,[b] Csaba Janáky[b]
[a]*MTA Premium Post Doctorate Research Program,*
[b]*Department of Physical Chemistry and Materials Science, University of Szeged,*
Rerrich Sq. 1., Szeged, 6720, Hungary
toth.peter.sandor@chem.u-szeged.hu

The two-dimensional (2D) semiconductors, the transition metal dichalcogenides (TMDCs), have received great interest during the last decade because of their high chemical stability and good electrocatalytic properties [1]. The photoelectrochemical (PEC) properties of 2D nanoflakes depends on the structural properties (the number of layers, the basal-planes or edges) [2-4]. We need to understand their fundamental PEC properties in the function of their structural properties, using a microscopy-based approach with spatial resolution.

Firstly, I will show our recently developed custom-designed PEC-microscope setup. The deposited 10–50 μm sized microdroplet acts as an electrochemical cell on the chosen sample area of the 2D flake, which will be illuminated by a spot at 25–50 μm in diameter. The TMDC nanosheets (MoS_2, $MoSe_2$, WSe_2) were mechanically exfoliated to get bulk, few-layered, and monolayer specimens. Additionally, liquid phase exfoliation was used to prepare bulk and few-layer TMDC dispersions. The number of layers, and defect types in the separated nanosheets were characterised by Raman spectroscopy and atomic force microscopy. I present the use of model reversible redox species to mimic photoelectrocatalytic processes, proving the differences between basal-planes and edge sites. Then, I show the effects of varying the number of layers and role of the edge-sites on the light harvesting, charge transport, and recombination properties with photoelectrochemical measurements unfolding reasons behind the poor PEC activity of exfoliated 2D samples.

Finally, I demonstrate the effect of structural domains for PEC performance of 2D materials in three points. i) The photocurrent losses with growing the fraction of the heterogeneous surface (edge sites), with the parallel rise of dark currents. ii) The higher defect density changes the PEC activity for water oxidation as well, the activity is found to be larger for both basal-plane of bulk and few-layer $MoSe_2$ in the presence of hole scavenger, so the higher photocurrent cannot be harvested for oxidation. iii) The LPE produced $MoSe_2$ and WSe_2 bulk and few-layer flakes in kinetic control free water reduction and oxidation, achieving only μA cm^{-2} current densities. This decrease in the PEC performance can be explained by the growing of defect densities, because of the number of edge sites is increased and the lateral size (area) is decreased of LPE flakes.

dbond@umn.edu

Geobacter sulfurreducens can grow as a conductive biofilm when utilizing a poised electrode as an electron acceptor. These biofilms show redox hydrogel-like behavior in scan rate analysis, confocal Raman spectroscopy, and interdigitated array electrode redox-gating experiments. Recent NanoSIMS imaging revealed a gradient of anabolic activity within these biofilms, with the highest activity closest to the electrode[1]. Based on the diffusional limitations of electron transport within redox hydrogels and this evidence of a metabolic gradient, we hypothesized that a redox potential gradient exists within these biofilms, becoming lower with distance from the electrode until it restricts respiration. We previously reported that there are two routes out of the inner membrane quinone pool in *G. sulfurreducens*, one that predominantly functions above redox potentials of 0 V vs. SHE[2], and another that only operates between redox potentials of 0 and -0.2[3]. With the discovery of a third pathway that only is expressed at redox potentials below -0.2 V vs. SHE, we can construct double and triple mutants which will only grow in specific redox potential windows. We also screened a series of GFP-based reporters driven by constitutive or redox-dependent promoters, to produce mutants expressing green, red, or cyan fluorescent proteins at levels detectable by standard fluorescent or confocal microscopy after ~1 min of oxygen exposure. When two strains of *G. sulfurreducens* able to grow at different redox potentials are mixed together, cells favoring high redox potential only colonize the electrode surface, while cells favoring lower redox potential are only found at the top of the biofilm, away from the electrode surface. Similar results are obtained when a low redox-potential dependent promoter is used to drive GFP expression: expression is only detected far from the electrode. These results support a model of differential metabolic states within biofilms, with cells closest to the electrode being most metabolically active due to high redox potential. By cultivating these mutants on arrays of interdigitated electrodes, alternating bands of cells only able to respire at low- or high-potential can self-assemble within 48 hours, and produce living conductive materials that rectify electron flow to only one of two drain electrodes.

irena.hoskovcova@vscht.cz

Carbene complexes are characterized by presence of a formally double bond M=CR$_2$. In electrophilic carbenes of Fischer type, the M$^{\delta-}$ = C$^{\delta+}$ polarity of this bond is typical. An extended study of mononuclear complexes (CO)$_n$M = C(NR')R showed that there are two rather independent redox-active centers present: oxidation is aimed at and influenced by, the metal atom, while reduction proceeds on the carbene moiety. Analogous behaviour was found at compounds bearing condensed benzene-heterocycle substituent.

Studied compounds, M = Cr, W		
		Cr-bpyr; W-bpyr	Cr-bfur; W-bfur	Cr-bthi, W-bthi

The molecules were studied using cyclic voltammetry on GC, Pt, and HMDE electrode, by IR and UV-Vis spectro-electrochemistry. Preparative electrolysis was performed using Hg pool working electrode, the products were identified by MS and IR spectra.

The oxidation process is quasi-reversible, it proceeds in two steps and oxidation potentials of the compounds with the same central atom lay within 50 mV range, depending on the substituent; it increases in sequence M-bfur < M-bpyr < M-bthi. For W compounds, oxidation potentials are by 250 mV more positive. The inductive influence of the heterocycle itself (heteroatom) is evident.

The reduction of the presented compounds is impacted by substituents of the carbene carbon. It proceeds at similar potential values for both Cr and W compounds, potential range is about 200 mV. The most negative E_{red} value belongs to M-bpyr, the reduction of M-bfur and M-bthi proceeds at very similar potential values.

The most pronounced difference between chromium and tungsten compounds was observed in their reductive electrolysis products. While chromium complexes reduction leads to a dimeric product, the electrolysis product of tungsten complexes consists only of monomeric products. Similar behaviour has been described [1] for chromium complexes substituted by simple heterocycles.

Reductive electrolysis product of Cr complexes	Reductive electrolysis product of W complexes

Chemomechanical Models for Locally Non-neutral Solid Electrolytes

Charles Monroe
University of Oxford, Department of Engineering Science; The Faraday Institution
Parks Road, Oxford OX1 3PJ UK; Harwell Campus, Didcot OX11 0RA UK
charles.monroe@eng.ox.ac.uk

Recently our group has focused on developing, parameterizing, and accurately solving models that describe chemomechanical phenomena in electrolytes, *i.e.*, situations in which stress in a material may be coupled with its electrochemical state. Our approach, based in irreversible thermodynamics [1], has followed the general transport modelling programme initiated by Newman [2], but extends that theory to account for a phase's compressibility or elasticity, as well as local deviations from electroneutrality.

Although we have produced informative preliminary results by applying the chemomechanical theory in idealized cases [3,4], a number of foundational problems remain unresolved. The development of thermodynamically consistent flux laws applicable to non-ideal, non-neutral, elastic electrolytes poses several problems at the most elementary level. One desires a straightforward parameterization of electrochemical potentials in terms of familiar thermodynamic properties, such as partial molar volumes and Darken factors for dissolved salts and solvents, and a transport model that includes familiar transport properties, such as Fickian salt diffusivity, ionic conductivity, and cation transference number. When electroneutrality is relaxed, the standard definitions for the transport properties becomes substantially more complicated [5], and the thermodynamic property set becomes ambiguous [6]. Further, it is unclear how classical properties involved in electrostatic equilibria, such as permittivity, or elastic properties, such as the bulk modulus, should be brought into models in a self-consistent way.

This talk will address the general problem of multicomponent mass-transport modelling for non-isobaric, non-neutral elastic electrolytes. We will discuss a new constitutive framework that can be deployed to formulate the electrochemical potentials, which brings colligative properties measured in an electroneutral state naturally into the non-neutral transport model. These new 'core chemical potentials' relate to the Guggenheim electrochemical potentials through a straightforward sequence of linear transformations, which can be expressed in terms of matrix multiplications and depend only on the species charges. The core potentials can be mapped into the popular electrochemical-potential frameworks developed by Guggenheim [6], Smyrl and Newman [2], and Kokotov [7]. The new theory allows thermodynamically consistent modelling of, for example, voltage-dependent interfacial capacitance in concentrated double layers, transient diffusion driven by the Gibbs–Donnan effect, or stress diffusion in solid ion conductors.

niki-vita@yandex.ru

It is well known that conducting polymers can serve as solid-contacts of ion-selective electrodes. To improve the performance of solid-contact ion-selective electrodes (SC-ISEs) alternative to classical potentiometry readout principles have been proposed [1].

The constant potential techniques seem to be the most promising and solving the main problem of background drift and potential instability of potentiometric SC-ISEs. However the constant potential amperometric flow-injection analysis (FIA) for conducting (electroactive) polymer-based sensors has not been reported yet. The proposed earlier amperometric FIA uses potential step methods. Thus the sensor readout principal is voltammetric rather than amperometric.

We report on the flow-injection amperometry at constant potential with polymer-based sensors for detection of electroinactive inorganic ions and organic molecules. Polyaniline, poly(3,4-ethylenedioxythiophene), Prussian Blue films and nanoparticles were used as solid contacts of K^+ and Na^+-selective electrodes. Sensors based on self-doped polyaniline, substituted with boronic acid, without ion-selective membranes were applied for amperometric detection of electroinactive organic compounds (lactate, fructose), due to selective interaction of diol- moieties with boronic acid group.

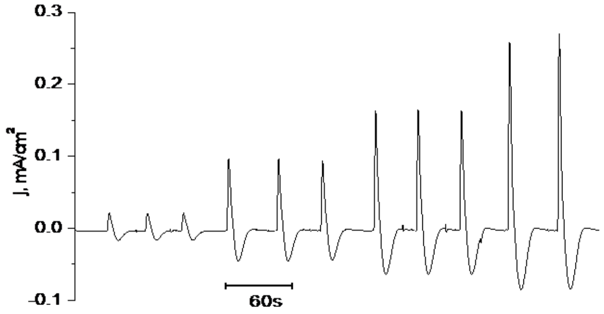

Fig.1. Amperometric response of PEDOT-modified sensor towards injections of KCl (1, 5, 10, 15 mM).

Regardless of the polymer support the amperometric response of the electrode towards analyte injection is a couple of oppositely directed peaks (Fig.1). The peak current is dependent on the concentration of analyte. We've shown that in a constant analyte solution flow mode only one current peak is observed. Thus the emerging current is a result of polymer oxidation/reduction reaction in order to maintain the constant electrode potential. Notably that current direction (cathodic or anodic) depends on the ability of ion to interact with the polymer functional groups. The influence of applied potential also has been investigated. Two cases were considered: 1) polarization of the electrode / polymer interface due to ion transfer through the polymer / solution interface; 2) specific interaction of ions or molecules with polymer at the polymer / solution interface. The suggested technique was applied for flow-injection analysis of human sweat. The successful amperometric detection of lactate with boronate-substituted polyaniline-based sensor has been performed.

The constant potential amperometry provides the advantageous analytical characteristics: the signal-to-noise ratio in amperometric mode is 20–25 times higher in comparison to potentiometric one [2]. Thus it is a promising method for detection of ions and molecules with polymer-based sensors and SC-ISEs.

The financial support of the Russian Science Foundation (Grant No. 19-13-00131) is greatly acknowledged.

The need for highly efficient catalysts for sustainable energy has led to remarkable improvements and insights in the design rules for (electro-)catalyst materials. Many successful examples employ perovskite-type oxides (ABO_3) because of the large tunability of chemical and electrical properties. Because of inherent differences in surface and bulk properties, further advances in catalyst stability and activity engineering necessitate the derivation of surface-composition-activity relationships in addition to descriptors based on the bulk properties.

Single crystalline surfaces offer the ideal platform to derive such relationships. They enable direct comparison to surfaces investigated in density functional theory (DFT), which are typically limited to a single facet that may or may not be present in catalysts fabricated using traditional routes. Epitaxial thin films allow investigation of perovskite catalysts fabricated with unit-cell precision.[1–3]

Here, we will demonstrate surface-composition-activity relationships in epitaxial $LaNiO_3$ thin films, which are atomically flat both before and after application as electrocatalysts for the oxygen evolution reaction (OER) during water electrolysis, and which possess a controllable surface cationic composition. For the $LaNiO_3$ surface, the Ni-termination is electrocatalytically active and undergoes a surface transformation that preserves the surface cation stoichiometry of the as-prepared state, while La-termination leads to high overpotentials and eventual failure. Our work thus suggests that the (meta)stable surface layers evolving at the solid/liquid interface, and therefore the electrocatalytic activity, can be selectively adjusted through the choice of as-synthesized surface composition.

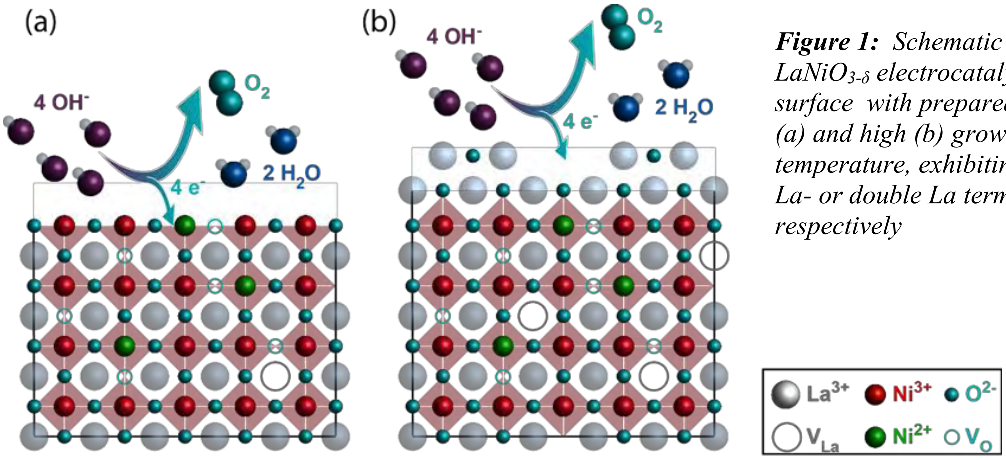

Figure 1: *Schematic of a $LaNiO_{3-\delta}$ electrocatalyst surface with prepared at low (a) and high (b) growth temperature, exhibiting Ni- and La- or double La termination, respectively*

Teaching Impedance using a Python-Based Regression Program

Mark E. Orazem*
Department of Chemical Engineering, University of Florida, Gainesville, FL 32611 USA
*meo@che.ufl.edu

Interpretation of impedance spectra requires in principle an evaluation of the error structure and a process model that accounts for the proposed reactions and physics. The measurement model was developed in our group in the 19990s as a tool to extract the stochastic part of the impedance measurement from repeated measurements and to assess the consistency of the measured impedance with the Kramers-Kronig relations.[1-3] Our measurement model approach has been difficult to explain, in no small part because our original measurement model program, written in a combination of FORTAN and Matlab® programming languages, was not generally available. We were reluctant to share the code because each new version of Matlab® broke the Matlab® part of the program, and a part of the FORTRAN code was not ours to share.

A new version of the measurement model has been written in the Python language and will be made available under the open-source license GNU GPL Version 3, which allows free use for scientific purposes but limits commercial use. The new code was written from the ground up in Python, although some portions of the backend libraries, such as numpy, use C. Unlike many Python-based impedance regression programs, the measurement model program provides a graphical-user-interface that facilitates navigation through the different stages of the measurement model analysis. This program also allows regression of arbitrary functions to impedance data. Rather than employ electrical circuit components such as resistors and capacitors, this part of the program is equation-based. The formula is input as Python code and may make use of imported Python packages. The equation-based approach enables regression of a broad range of models.

We have found that, by using this Python-based measurement model program, students develop a better appreciation for the power of impedance spectroscopy and for the importance of error structure in impedance measurements. The objective of this presentation is to demonstrate the program and suggest ways in which it can be employed in teaching impedance spectroscopy. Our goal is that, by providing the tools needed for a more sophisticated analysis of impedance data, we will allow students to take full advantage of the information that can be extracted from electrochemical impedance spectroscopy measurements.

Reactive oxygen species (ROS) are produced in living cells in several physiological and pathological processes [1,2]. Reactive oxygen species production by organic polymer upon photostimulation is gaining more and more interest for its high throughput capability, selectivity and resolution. Organic copolymers are generally good photo-transducers, with tunable optical properties, good photocatalytic efficiency and characterized by excellent biocompatibility. Nanoparticles of poly-3-hexyl-thiophene (P3HT) have been showed to be internalized within the cell cytosol and generate ROS upon photo-stimulation [3].
We employed electrochemical approaches, such as Scanning ElectroChemical Microscopy (SECM), to measure ROS production by P3HT thin films and explored the impact on H_2O_2 production in the presence of a model cellular redox protein, Cytochrome C [4]. Spatially-controlled illumination of substrates and simultaneous detection of hydrogen peroxide production at the micrometric scale were achieved by coupling SECM with a fluorescence inverted microscope. Hydrogen peroxide was measured with high sensitivity employing platinized-microelectrodes. ROS were recorded in dark and upon illumination in close proximity of the P3HT thin film substrate and compared to bare ITO substrates. We resolved the profile of H_2O_2 production by P3HT thin films upon photostimulation at the micrometric scale.
The interaction between P3HT thin films and Cytochrome C (in the dark or upon photostimulation) was investigated exploiting our SECM/fluorescence microscope apparatus: our results indicate that upon photostimulation Cytochrome C is reduced at the organic semiconductor/liquid interface.

**renatogil19@gmail.com*

Biogenic amines are organic bases of low molecular weight with a high impact in food quality control. The most common analytical methods used for their assessment are based on liquid chromatography coupled with spectrophotometric detection, such as UV-vis and fluorometry [1]. However, the high polarity of biogenic amines difficult their retention on conventional reversed-phase chromatographic columns while their low detectability by spectrophotometric techniques hinders the detection limits and sensitivity, which requires additional derivatization steps to circumvent these drawbacks.

Alternatively, electroanalytical detection offers high sensitivity with simple and inexpensive instrumentation, without the need for derivatization steps. Amperometric and conductimetric detectors have been proposed for the determination of biogenic amines after separation by HPLC but those based on potentiometry seem overlooked [2].

In this work, a novel RP-HPLC method for the determination of ten underivatized biogenic amines is proposed based on ion-pair chromatography combined with a miniaturized potentiometric electrode inserted in a low-dead volume wall-jet flow-cell. Aliphatic amines – methylamine, ethylamine, cadaverine, putrescine, spermidine, and spermine as well as the aromatic heterocyclic amines - histamine, tyramine, phenethylamine, and tryptamine were selected. It was used an amine-selective electrode based on cucurbit[6]uril as an ionophore, enhanced with MWCNT's for a better improvement of the ion-to electron transduction. A gradient elution method with butane 1-sulfonic acid as ion-pair agent, and acetonitrile as an organic modifier, flows through a Luna® Omega 5µm Polar C18 150x4.6mm column with a flow-rate of 1.2 mL min^{-1}. The optimized method allowed the separation of all studied amines with a good resolution. The total analysis time was 25 min.

The proposed method was validated according to the requirements of ICH (International Conference on Harmonisation). The analytical signal was transformed by using the equation $tR = 10^{E/S} - 1$, where E is the potential (mV) and S the slope of the typical Nikolsky-Eisenman equation [3]. When tR was plotted against the analyte concentration a linear regression model was obtained with R^2 varying from 0.983 to 0.996. Repeatability was evaluated at three different concentration levels of standard solutions. The relative standard deviation (RSD) values were lower than 10.9%. Detection limits ranged from 9.3 to 60.7 µg L^{-1} and quantification limits from 31.1 to 202.3 µg L^{-1}.

Biogenic amines in the different food samples are yet to be determined.

The current water crisis, caused by climate change (and lack of rainfall), has prompted researchers to find alternative and efficient ways for converting sea water into fresh drinkable water. Ionic diodes have been found recently to offer one such approach [1,2]. In the current work, carbon nanofibers (CNFs) are converted from cationic current rectifiers to anionic current rectifiers by surface modification with boron and amine functional groups using hydrothermal means (forming BNCNFs, with boric acid, generation-3 poly(propylene imine) dendrimer, and urea. To confirm surface charge, morphological changes and carbon nanomat thickness, zeta potential analysis, transmission electron microscopy (TEM) and scanning electron microscopy (SEM), were used. When a dispersion of surface modified carbon nanofibers in DMF is drop-cast asymmetrically to form nanomats onto laser drilled microholes (5, 10, or 20 µm diameter) of poly (ethylene terephthalate) substrates and immersed into aqueous electrolyte solutions, anionic diode behaviour is observed (in contrast to pristine carbon nanofibers, which exhibit cationic diode behaviour). The effects of electrolyte type, ionic strength, and microhole diameter on ionic diode performance were investigated using cyclic voltammetry, chronoamperometry, and impedance spectroscopy. Future applications in desalination are proposed.

Phenolic compounds have been enlisted by the United States Environmental Protection Agency (USEPA) and the European Union (EU) as pollutants of priority concern. This enlistment is due to the fact that these chemicals are noted to be toxic and have severe short- and long-term effects on humans and animals. The occurrence of phenolic compounds in the aquatic environment is therefore not only objectionable and undesirable but also poses a danger as far as human health and wildlife are concerned.
South Africa is known to have used and abused most chemicals listed by developed and developing countries as endocrine-disrupting chemicals. Endocrine disrupting chemicals have been reported in water. The winemaking industry produces large volumes inorganic wastewater that pose an environmental threat if not treated correctly. The increasing numbers of wineries and the demand for wine around the world are adding to the growing problem. This increase has further aggravated the pressure which the industry exerts on natural resources such as water, soil and vegetation. [1].
No two effluent produced by Wine estates are the same. This variation is as a result to the differences that exists processing techniques, regions of farming and cultivar of grapes used. Thus electrochemistry is seen as a clean, versatile and powerful tool for the detection of pollutants in water and making these sensors a good tool for testing pollutants in winery water waste.
Wastewater is regarded as the most significant environmental risk at wineries and because water is a limited natural resource in South Africa, water monitoring and saving should be encouraged [2].

The aim of this study was to design, construct and develop a tyrosinase biosensor modified on a Boron-doped Diamond (BDD) platform in order to determine the levels of polyphenols in real aqueous winery wastewater samples. Specifically Gallic Acid and Caffeic Acid was chosen as the polyphenols of study. The BDD surface was electrochemically coated with polythiophene (Pth) film, containing in-situ deposited tyrosinase (Tyr). Electropolymerization of Pth was done via cyclic voltammetry (CV) at 50mV.s^{-1} versus Ag/AgCl). The morphologies of the composite films where studied by scanning electron microscopy (SEM). Detection of polyphenol substances was done and square wave (SQW). Further Uv-Vis was used to verify the conservation of polyphenols during these electrochemical; and enzyme oxidation steps.

Capacitive deionization (CDI) is an emerging technology for the removal of charged ionic species from water and is often applied to brackish water desalination and water softening [1]. CDI typically uses inexpensive nanoporous carbon electrodes to desalinate, and carbon surface functionalization can increase the adsorption capacity, rate, and selectivity [2]. Sulfonation, the attaching of strongly acidic sulfonic groups to the carbon material, creates a surface that is strongly negatively charged in an aqueous environment at all electrolyte pH values. This property is highly desirable for CDI, yet such electrodes are largely unexplored.

In our study, the sulfonated activated carbon fibers (SACFs) are prepared using the following protocol. Two grams of activated carbon fibers (ACFs) are sulfonated with 100 ml of 20% fuming sulfuric acid for 24 hours. The product is then washed with hexane and ice water, and dry in the oven at 50°C. The final product is referred to as SACFs. Fourier-transform infrared spectroscopy (FTIR) tests were performed for both ACF and SACF samples. An acid-base titration was used to quantify the nanopore chemical charge concentration of the sulfonated material. The result are shown as in Figure 1 (a), which are obtained from the fitting titration data to a micropore EDL model described in [3]. Results show sulfonation imparted a significant strong acid group micropore concentration, $c_{A1,0}$, of 2.75 M.

CDI tests were conducted in a flow-through electrode CDI cell with either two ACF electrodes or one ACFs anode and one SACFs cathode. We used a 20 mM NaCl feed solution, 4 hours for each charge-discharge cycle, a charge voltage of 1 V, and discharge voltage of 0 V. In Figure 1 (b), we show measured salt absorption, demonstrating that the SACFs show enhanced performance in CDI specific salt capacity comparing to pristine ACFs.

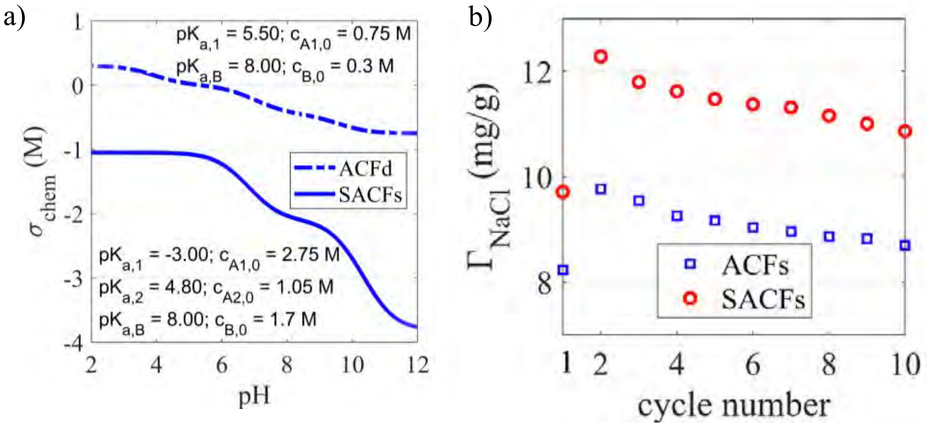

Figure 1: a) Nanopore chemical charge concentration versus pH, obtained from titration model to data fitting, pK_a and $pK_{a,B}$ are equilibrium constants for acid and a weak basic groups, c is the concentration of each group in the unit M, i.e., mole per micropore volume. b) Measured salt electrosorption in a CDI cell versus cycle number, using either two ACF or one ACF and one SACF electrodes.

Enhancement of Electrooxidation of Simple Organic Fuels at Noble Metal Nanoparticles Supported onto Mixed-Metal-Oxides

Pawel J. Kulesza, Iwona A. Rutkowska
Faculty of Chemistry, University of Warsaw,
Pasteura 1, 02-093 Warsaw, Poland.
pkulesza@chem.uw.edu.pl

There has been growing interest in utilizing small (simple) organic molecules, as alternative fuels to hydrogen, in electrochemical energy conversion systems. In addition to ethanol (biofuel), that can be ideally oxidized to carbon dioxide thus delivering twelve electrons, recent important systems include dimethyl ether as well. But realistically the respective reaction is rather slow at ambient conditions. Obviously, there is a need to develop novel electrocatalytic materials.

Platinum has been recognized as the most active catalytic metal towards oxidation of ethanol at low and moderate temperatures. But Pt anodes are readily poisoned by the strongly adsorbed intermediates, namely by CO-type species, requiring fairly high overpotentials for their removal. To enhance activity of Pt catalysts towards methanol and ethanol oxidation, additional metals including ruthenium, tin, molybdenum, tungsten or rhodium are usually introduced as the alloying component. More recently it has been demonstrated that catalytic activity of platinum-based nanoparticles towards electrooxidation of ethanol has been significantly enhanced through interfacial modification with ultra-thin monolayer-type films of metal oxo species of tungsten, titanium or zirconium.

We pursue a concept of utilization of mixed metal (e.g. zirconium/tungsten or titanium/tungsten) oxide matrices for supporting and activating noble metal nanoparticles (e.g. PtRu) during electrooxidation of methanol and ethanol. Among important issues is incorporation of Rh nanostructures capable of weakening, or even breaking, the C-C bond in the ethanol molecules. On the other hand, rhodium itself is not directly electrocatalytic toward oxidation of ethanol. The oxides and noble metal nanoparticles have been deposited in a controlled manner using the layer-by-layer method. Remarkable increases of electrocatalytic currents measured under voltammetric and chronoamperometric conditions have been observed. The most likely explanation takes into account possibility of specific interactions of noble metals with transition metal oxide species as well as existence of active hydroxyl groups in the vicinity of catalytic noble metal sites. In addition, formation of “nanoreactors” where ethanol is partitioned (at Rh) to methanolic residues further oxidized at PtRu cannot be excluded.

We also demonstrated here that deposition of Pt and bimetallic PtRu nanoparticles onto nanostructured zirconia (pristine or admixed with tungsten oxide) support leads to the enhancement of their catalytic activities toward electrooxidation of dimethyl ether (DME). It is reasonable to expect that the ability of oxides to induce acid catalysis (weakening of C-O bond in the ether), increase proton mobility, and to donate active hydroxyl groups at the electrocatalytic interface are responsible for the observed catalytic enhancement effects. Mutual activating interactions between ZrO_2 and platinum or ruthenium components resulting in the formation of sub-stoichiometric oxide and changes in the electronic properties of Pt and Ru are also feasible. The fact, that the onset potential for the oxidation of DME is somewhat shifted toward less positive potentials in the presence of zirconia, is of practical importance.

Microbial Fuel Cell Stack for Treatment and Off-grid Power from Human Urine: Multi-parameter Analysis

An estimated 4 billion people do not have access to safe-sanitation systems, which is one of the most critical global challenges. Numerous innovations are being pursued for cost-effective and resource-conserving treatment of human waste [1]. The main aim of this study is to demonstrate the production of electricity from human urine in the field, using Microbial Fuel Cells (MFC) and at the same time, analyse the treatment performance in laboratory conditions. The MFC technology is driven by a microbial "engine" in the anode (negative half-cell) that transforms chemical energy of the 'fuel' (urine) directly into electrical current. As long as urine is supplied to the MFCs, the bacteria continuously metabolise urine producing electricity.

This study focuses on the laboratory-based part of the work, carried out at UKZN, Durban, South Africa. Two laboratory-based prototypes were tested, whose performance informed the monitoring and evaluation of the large field demonstration in an informal settlement in Durban. The urine was supplied directly from one of the urinals in the community to the MFC field prototype to power LED lighting in the toilet block (reported in a separate publication). The two laboratory-based prototypes were constructed using two types of unglazed ceramic cylinders (membranes) as follows i) small-cylinder cascade was constructed from 50 mm height cylinders and 66 MFCs (22 units/module), ii) large-cylinder (80 mm height) cascade consisted of a total of 18 MFCs (6 MFCs/module). Anode electrodes were made of carbon veil fibre and cathode electrodes were constructed using activated carbon fitted inside the ceramic cylinders. All MFCs were electrically connected in parallel. Both cascades were fed with human urine collected from the urinal and monitored over a 6-month period for power performance, COD treatment, macro (N,P,K) and micronutrient content, pH and ionic strength.

Power output from the small-cylinder cascade was 13-39 mW, while the large-cylinder cascade was 5-26 mW (Fig 1) which might be due to the increased surface to volume ratio in the small cylinder cascade. The COD removal was up to 45 % (avg. 23%) in the small-cylinder cascade and up to 34 % (avg. 11%) in the large-cylinder cascade. Up to 73 % and 63 % COD removal was recorded in the catholyte extracted from the small and large cascades, respectively. An important feature of *in situ* electrochemical oxidation is the process of electro-filtration of the urine into a purified catholyte [2]. This finding is in agreement with previous studies. The electrochemical activity showed pH and ion separation between the anolyte and the newly formed catholyte in all tested systems as a function of MFC performance.

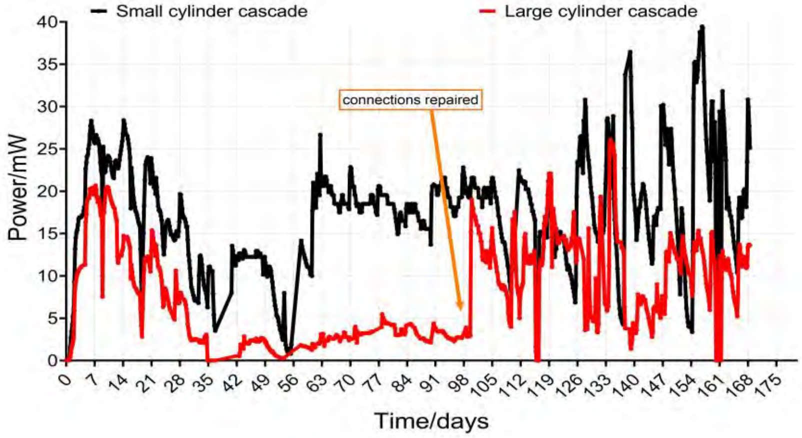

Fig.1 Power performance of small-cylinder and large-cylinder MFC cascades over 6 months.

Opportunities and challenges were identified during the long-term operation of MFC cascades to advance the technology further into self-sustainable sanitation systems and to emphasise the importance of stacked MFC prototypes for the production of off-grid power from human urine with simultaneous treatment.

The interest of the scientific community for nanotechnologies and nanomaterials has increased in the last years due to their peculiar characteristics: increased surface / volume ratio, new optical and physical properties, high active surface, increased or modified material transport, increased selectivity. All these features make nanomaterials extremely suitable for a wide range of applications, from energy to catalysis and, last but not least, sensors [1].

Recently, apart from the application of nanomaterials characterized by a single component, the use of "hybrid" nanomaterials, composed of two or more components in "intimate" contact, is also rapidly growing [2]. This is connected to the fact that, since in a hybrid material the establishment of synergistic properties is confined to the contact region between the different components, in nanomaterials, given the small size, these effects can become a dominant factor of the entire structure. The result is precisely the establishment of new and unexpected properties (often desired and interesting) which are not the simple sum of individual contributions. Therefore, hybrid materials are excellent candidates for applications in the most varied fields, including electroanalysis, which can greatly benefit from these systems.

In this context, this work aims to present the construction of devices based on hybrid metal-semiconductor nanomaterials (based on silver or gold nanoparticles and titanium dioxide) [3-5]. In these systems, the presence of metal nanoparticles is exploited for the electroanalytical determination of analytes of medical / diagnostic or environmental interest, while the presence of TiO_2 is essential for overcoming the problems of fouling and passivation of the electrode surface following the determination of the molecule under examination. The possibility of renewing the electrode surface simply by irradiating the device with ultraviolet light, allows to use the devices remotely for a long time, without their continuous recovery [5]. In the case of the Ag-TiO_2 system, an "intimate contact" interphase between the silver nanoparticles and titanium dioxide was also found [6], which makes the hybrid a real new material, with different characteristics and with interesting applications compared to its precursors.

Manufacturing ion-conducting membranes with high ionic conductivity and durability is a crucial challenge in the development and large-scale distribution of electrochemical energy conversion devices. Perfluorosulfonic acid polymers are the state-of-the-art solid electrolytes used in low temperature proton exchange membrane (PEM) fuel cells and electrolyzers [1]. Desirable PEMs must be highly proton conductive under hot and dry conditions, thermally and dimensionally stable, impervious to fuels, as well as to electrons.

In the present work, composite membranes based on a Nafion polymer matrix, incorporating a non-stoichiometric calcium titanium oxide ($CaTiO_{3-\delta}$) additive, were synthesized and characterized [2,3].

Fundamental characterizations, by means of thermal and dynamic mechanical analyses, as well as of broadband dielectric spectroscopy, were carried out. Composite electrolytes, containing 5 and 10 wt.% of the $CaTiO_{3-\delta}$ additive, with respect to the dry Nafion content (respectively, M5 and M10), were compared to a plain, additive-free Nafion membrane.

The membrane with the lower amount of additive displayed the highest water affinity and the highest conductivity, indicating that a too-high dose of additive can be detrimental for these particular properties. The mechanical behavior of the composite membranes is similar to that of plain Nafion, slightly improved by the filler addition. These findings indicate that perovskite oxides can be useful as a water-retention and reinforcing additive in proton-exchange membranes for fuel cell applications.

Indeed, the composite membranes developed in this study were evaluated in a DMFC single cell at 30 °C, 60 °C, 90 °C and 110 °C. Interestingly, when the operation temperature is raised to 110°C, the cell adopting M5 composite membrane shows the best electrochemical performance, as a result of the enhanced M5 thermal stability.

Ensuring access to safe water and sanitation is essential to human health, and water quality is an integral part of several United Nations Sustainable Development Goals. One of the utmost concerns is associated to Nitrogen cycle imbalance associated in part to anthropogenic NO_3^- water pollution. Among the nitrate challenges, drinking water with elevated NO_3^- levels is harmful to human health and is associated to respiratory and reproductive system illness, some cancers and thyroid problems. Nitrate pollution is one of the top ten water quality violations reported worldwide [1]. Point-of-use (POU) treatment systems are small treatment units that can remove hazardous pollutants at household level or under your water tap. These types of units should be user-friendly, chemical-free, and avoid waste generation (i.e. brines, biosolids). In this frame, electrocatalytic reduction of nitrate (ERN) is an emerging technology that can selectively reduce NO_3^- to innocuous dinitrogen (N_2). Actually, the current science challenge is how to step at a mid-point oxyanions state, like N_2 rather than NO_2^- or NH_4^+ [2].

Fundamental research on ERN studied the electrocatalytic properties of noble metals and platinoid materials as cathodes. However, these electrocatalytic materials would be the cost driver of POU units and would hinder application and commercialization. Moreover, considering life cycle analysis of the operational life of such endangered elements suggests that their use would be non-sustainable [3]. Therefore, the aim of this paper is to provide a framework for selection of promising earth-abundant elements (carbon-based, cobalt, copper, iron, nickel, titanium, tin, or zinc) that could be used to electrocatalytically degrade nitrate in drinking water to innocuous byproducts using identical conditions. Discussion is sustained in terms of the performed balance considering electroreduction kinetics, selectivity towards nitrogen evolution, electrical energy per order, and material cost/availability. Electrokinetic reduction rates of nitrate using earth-abundant elements were ~1.5-fold faster than Pt (k_1 = 3.7×10-5 s^{-1}). BDD and Sn revealed the highest average selectivity over time towards nitrogen gases evolution (55% and 64%, respectively) and outperformed the Pt electrode which only had 1%. The earth-abundant electrode materials allowed the highest Faradaic efficiencies (10-22%) with electric consumption per order of about 39-49 kWh m^{-3} $order^{-1}$.

These encouraging results highlight the opportunity to apply low-cost materials, which global availability is still not endangered, to nitrate removal. Finally, the use of nanotechnology is a further strategy plan to enhance the competitiveness of these materials.

The microbial electrochemical snorkel (MES) is a short-circuited microbial fuel cell, which does not produce power but ensures the highest possible electrochemical reaction rates that the system can support. Since proof-of-the principle [1], various possible applications of MES have been reported [2], but not for metal recovery till now. In this study, we provide for the first time evidence for copper recovery performed by MES. A plain copper sheet, immersed in 1 g/L Cu^{2+} solution, was directly connected to an anode of long-term operating sediment microbial fuel cell. In another identical set up a copper cathode and an SMFC anode were connected through a 510 Ω load resistor. The potential of copper electrodes and the current was monitored over time (Fig. 1a), and the concentration of dissolved Cu^{2+} in the catholyte was analyzed by spectrophotometric measurements (Fig. 1b). In the frame of 7 days, 53.1% and 56.3 % copper recovery were achieved for the MES and MFC, respectively. The high extent of copper recovery obtained paves the way for the scale-up of the MES technology for practical application.

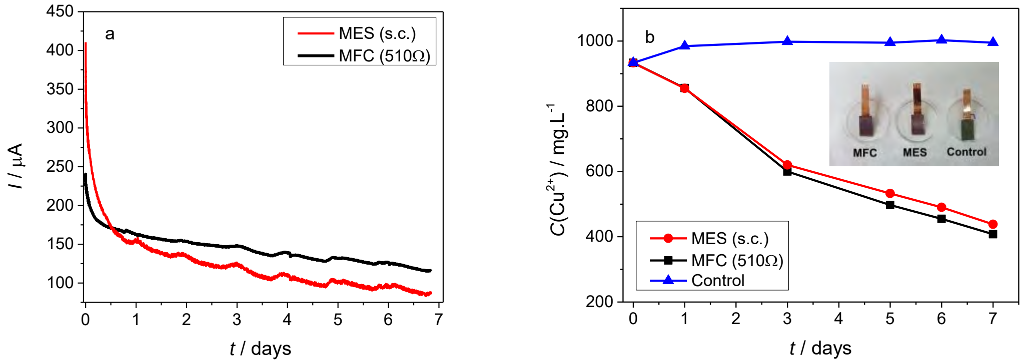

Fig. 1. Changes in: a) current during copper recovery by MES and MFC; b) copper concentration in solution over time.

The environment of a CO_2 electroreduction (CO_2ER) catalyst is intimately coupled with the surface reaction energetics and is therefore a critical aspect of the overall system performance. The immediate reaction environment of the electrocatalyst constitutes the electrical double layer (EDL) which extends a few nanometers into the electrolyte and screens the surface charge density. In this talk, we resolve the species concentrations and potential profiles in the EDL of a CO_2ER system by self-consistently solving the migration, diffusion and reaction phenomena using the generalized modified Poisson-Nernst-Planck (GMPNP) equations which include the effect of volume exclusion due to the solvated size of solution species. We demonstrate that the concentration of solvated cations builds at the outer Helmholtz plane (OHP) with increasing applied potential until the steric limit is reached. The formation of the EDL is expected to have important consequences for the transport of the CO_2 molecule to the catalyst surface. The electric field in the EDL diminishes the pH in the first 5 nm from the OHP, with an accumulation of protons and a concomitant depletion of hydroxide ions. This is a considerable departure from the results obtained using reaction-diffusion models where migration is ignored. Finally, we use the GMPNP model to compare the nature of the EDL for different alkali metal cations to show the effect of solvated size and polarization of water on the resultant electric field. Our results establish the significance of the EDL and electrostatic forces in defining the local reaction environment of CO_2 electrocatalysts.

Furthermore, gas diffusion electrode (GDE) based setups have shown promising performance for CO_2 electrocatalysis and further development of these systems will be important on the path to industrial feasibility. To better understand this system, here we model an effective catalyst pore within a flow-cell to study the influence of the catalyst structure and operating conditions on the reaction environment for CO_2 electrocatalysis at practically relevant current densities. We show that the length of the catalyst pore as well as the boundary conditions at the gas-electrolyte and electrolyte-electrolyte interfaces across this length are highly influential parameters for determining the conditions within the catalyst pore. Properties such as electrolyte pH and buffer breakdown, ionic strength and CO_2 concentration are sensitive to the catalyst layer thickness, gas pressure, electrolyte flow rate and the flow-channel geometry. The applied potential impacts the concentration of ionic species in the pore, which in turn determines the solubility of CO_2 available for the reaction. Our results underline the need to understand and manage transport within GDE-based electrocatalysis systems as an essential means to control catalyst performance. Benchmarking of GDE-based electrocatalytic systems against their structural and operational parameters will be important for achieving improvements in performance that can be ultimately translated to large-scale operation.

Semiconducting Transition Metal Dichalcogenide 2D Nanoflakes for Photoelectrochemical Applications

Kevin Sivula
Laboratory for Molecular Engineering of Optoelectronic Nanomaterials (LIMNO), Institute of Chemical Sciences and Engineering, Ecole Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland.
e-mail: kevin.sivula@epfl.ch

Given their established robustness and favorable optoelectronic properties, the layered semiconducting transition metal dichalcogenides (TMDs, e.g. MoS_2 and WSe_2) are attractive for optoelectronic applications including photoelectrochemical solar fuel production.[1] Recent advances in the liquid-phase exfoliation (LPE) of semiconducting TMDs into mono- or few-layered 2D nanoflake dispersions and their processing by inexpensive roll-to-roll techniques suggests that large-area TMD-based devices can be fabricated scalably and at low cost.[2] However, the high concentration of defects in these materials act as recombination sites for photogenerated carriers and limit their performance. In this presentation the challenges with charge transport, separation, recombination, and interfacial transfer in LPE TMD nanoflake thin film devices will be discussed with respect to the 2D flake size and defect passivation/charge extraction treatments.[3] Our results give insight into the roles of both edge and internal defects and suggest routes for improvement. Overall it is shown that LPE semiconducting TMDs with suitable defect mitigation can achieve internal quantum efficiency for photon harvesting similar to bulk single crystal samples. Specifically, we show that WSe_2 nanoflake thin films achieve absorbed-photon-to-current efficiency over 50% and photocurrent densities for solar water reduction at 4 mA cm^{-2} under standard testing conditions.[4] These results suggest that roll-to-roll processed 2D WSe2 may be a suitable photocathode for economical solar-to-hydrogen conversion with a photoelectrochemical tandem cell. The role of the exfoliation methodology on the formation of defects and a path towards further performance enhancement (including increasing the photopotential of the TMD photocathodes), are also discussed.

Optically transparent and UV-light photoactive hybrids based on TiO_2 nanocrystals (NCs) surface modified graphene, were synthesized by a direct and facile solution-based procedure. Graphene was grown by Chemical Vapor Deposition (CVD) and transfered on ITO coated glass substrate as single- or multilayer (up to file layers) films., TiO_2 NCs synthesized by a chemistry colloidal route and surface functionalized by 1-pyrene butyric acid (PBA) by a capping exchange procedure [1], were anchored onto the graphene films thanks to π-π interactions.

SEM, EDS, AFM and Raman spectroscopy were conducted to physico-chemically characterize the materials. It was verified the successful immobilization of the colloidal NCs onto the graphene films, which preserves and concomitantly enhances the graphene intrinsic structural properties. In particular, we observed an electrical conductivity higher than that measured for the bare graphene films, which has been accounted for by a p-doping effect, due to a hole transfers from the nano-objects to graphene, mediated by the short aromatic ligand acting as charge channel.

Cyclic Voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS) measurements were then employed to complete and enrich the characterization of the hybrids. It was observed that the hybrids-properties are strongly dependent on the number of layers of the CVD graphene. The use of two redox mediator probes, namely the inner-sphere, surface sensitive ($K_4Fe(CN)_6$) and the outer-sphere, surface insensitive ($Ru(NH_3)_6Cl_3$), allowed understanding these features from a morphological point of view. The results showed a strong difference between the mono-, the bi- and the other multi-layers, in terms of different diffusional mechanism and redox active sites [2-4].

Moreover, the stacked layers of the pyrene-coated TiO_2 NCs are found to increase the electroactivity, the capacitive behavior, as well as the photo-electrical response of graphene, concomitantly maintaining its high charge mobility.

For all the above reasons, the described hybrids have a great potential as optically transparent components for manufacturing photoanodes to be integrated in (photo)electrochemical sensors, as well as solar cells or photodetectors and in FETs.

One consequence of intensive agriculture is pollution of natural waters by nitrate. At high concentration nitrate coupled with phosphate pollution triggers eutrophication and green algae bloom in the environment. One possible application of microbial electrochemical technology is the stimulation of denitrification in natural waters. In 2007, the first denitrifying bio-electrochemical system (BES) was reported.[1]

In this study, denitrifying bio-cathodes with specific design were developed under constant polarization during incubation in natural sediments and water supplemented in nitrate at different time. The electrodes were built using stainless-steel with three different separated compartments for each electrode in which graphite granules were added and also polarized (cf. figure 1). The goal of this design is to see a possible difference in bacterial communities depending on the compartment the graphite granules were collected, the first compartment being buried in sediments, the second being half in water and half in sediments and the third being totally in water. To compare the efficiency of the bio-cathodes and to increase the reliability of the global experiment, six pilots were launched, three with the same polarized electrodes and three without as negative controls.

Results collected during the incubation show both an electrochemical response to nitrate addition on chronoamperometry for two of the pilots with electrodes and a noteworthy increase of nitrate removal for all the three pilots with electrodes although the increase, in the case of the third pilot showing no electrochemical response to nitrate, remains lower compared to the two others.

This third electrode showing no electrochemical response to nitrate addition became an interesting tool of comparison for the 16S rRNA study, making possible to compare the bacterial communities between the two electrodes sensitive to nitrate on chronoamperometry and this last one in order to have a more precise idea of the strains involved in bio-electro-chemical denitrification.

After 27 days of incubation under polarization, the three electrodes were dismantled and the graphite granules from the three compartments of each electrodes were submitted to DNA extraction protocol and sent to 16S rRNA sequencing. The first noticeable result was a higher abundance of the Proteobacteria group in the middle compartment (half in sediments, half in water), this group being known in literature to contain a large proportion of the identified electroactive denitrifying species[2]. After a closer look at microbial communities on the middle compartment of each electrodes, it is possible discern noticeable differences between the two electrochemical nitrate responding electrodes and the last one showing no reaction to nitrate addition on chronoamperometry.

The most interesting difference is the presence of a specific bacterial species named Azoarcus spp. in the middle compartment of the two first electrodes responding to nitrate (20 and 15% of relative abundance) and its near absence in the middle compartment of the third, indicating that this specie could be involved in the electroactive denitrification, *Azoarcus spp.* being already identified in many MFC but not yet characterized as electroactive[3].

Anions play an important role in biological systems. At the same time, many of them are the major environmental pollutants and substances endangering living organisms. Anion recognition, elimination and sensing would find application in many areas including medicinal or environmental chemistry. Suitable examples of anionic pollutants are phosphates, which could cause eutrophication of water and they are also known for their limited removal from body fluids, which could lead to serious health problems. Therefore, the aim of our research group is the design and preparation of new anionic receptors with suitable binding sites to bind these anions.

In the first step of our synthesis we prepared a series of substituted nosylamides (fig. 1a, b). These substances are suitable intermediates in the synthesis of novel receptors bearing ureido functions. The sulfonamide motif is known from the literature as a neutral hydrogen bond donor. Therefore the main question in this study was the role of the sulphonamidic hydrogen, its acidity in correlation with the structure and substitution of the whole molecule. For better understanding and for "tuning" of the behavior of the final urea receptors, the properties of these intermediates were studied electrochemically using polarography and cyclic voltammetry with mercury drop electrodes in dimethylformamide with $Bu_4N\ PF_6$ as electrolyte, and by various spectroscopic methods.

The nitro groups in our intermediate molecules are not only important substituents enabling continuation in synthesis, but also electrochemical "probes" reflecting the electron properties of the parent molecule. Their reduction in aprotic media is generally known: after the first one-electron reversible reduction step where a stable radical anion is formed, a three-electron irreversible process follows resulting in the corresponding hydroxylamine.

Whereas the electroreduction of the series 1a (as models) occurs according to the expected pattern and the observed potential shifts follow the influence of the *p*-substituted R according to the linear free-energy relationship (LFER) of the Hammett type [1-2], the reduction pattern of the series 1b is entirely different: After the first irreversible step (theoretically involving 4/5 of electron) a one-electron reversible reduction takes place followed by a multielectron process. This behavior corresponds to the autoprotonation mechanism [3] where the acidic hydrogen of the amidic group is involved. In this way, the influence of substitution on acidity is followed.

Technical advances in materials chemistry enable many new possibilities in electrochemistry. This is especially helpful in biohybrid systems. A very broad range of tunable surface characteristics is essential to adapt the electrode to the specifics of the biomolecules. These developments are relevant to all sorts of semi artificial systems, e. g. in the field of bioenergy.

Photobioelectrodes, which use photoactive protein complexes to convert light into current and valuable chemicals, are a comparatively recent field of research.[1] The goal of this work is the buildup of a photobioelectrode based on 3D graphene and photosystem I (PSI). Here a facile, scalable approach was targeted. The construction was realized by using reduced graphene oxide, which is relative cheap and accessible on a larger scale.[2] A 3D structure is generated by a template procedure based on latex beads and spin coating. The general template approach already proved to be successful for photobioelectrodes made of other materials.[3] Different reduction methods were tested and a hydrazine treatment was optimized for the constructed material.

The obtained electrode has been evaluated regarding the interaction with PSI. An assembly as well as the direct electron transfer from electrode to the reaction center is ensured resulting in a cathodic photocurrent. As this communication is not effective, the redox protein cytochrome c is added to connect more PSI complexes. To improve the interaction of the electrode and the proteins different surface modifications have been tested. These experiments indicate that the photocurrent can be further enhanced. The photobioelectrode is characterized with different electrochemical methods such as cyclic voltammetry, chopped light voltammetry and photoaction spectroscopy. Additionally, analytical methods such as UV/VIS spectroscopy and scanning electron microscopy (SEM) have been applied. It is noteworthy that the thickness of the electrode material is adjustable in the manufacturing process. Even by preparing multiple layers the final electrode remains transparent, which is advantageous as it is therefore still suitable as photobioelectrode.

The characterization of nanomaterials is a key aspect of determining if the behavior and/or properties of a 'new' material differs from that of its bulk counterpart. However, determining structure at the nanoscale remains a challenging problem. This issue is compounded for platinum group based materials due to the tendency for them to form larger irregular structures. For platinum nanomaterials, aggregation-based crystal growth is an important synthetic pathway. In this case seed particle coalescence leads to the production of larger semi-disordered mesoporous structures. In order to study the possible catalytic activity an electroanalytical utility of these materials we need to fully characterize their atomic structure and surface areas. This presentation starts by showcasing some advanced transmission electron microscopy techniques, such as tomography (Fig. 1) and quantitative 2D image analysis, and demonstrating to what extent these tools can give us insight in the internal structure of the nanomaterial. Building on work focused on the measurement of single nanoparticle surface areas[1,2], two example catalytic reactions are studied[3,4] and the rate shown to directly reflect the measured surface area of the material, validating and demonstrating the use of this single nanoparticle electrochemical technique.

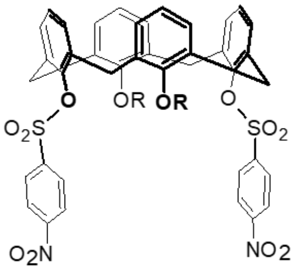
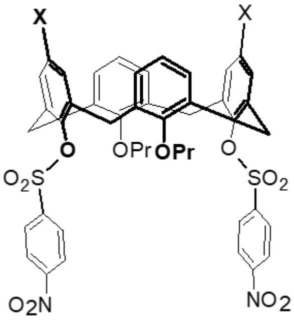
jiri.klima@jh-inst.cas.cz

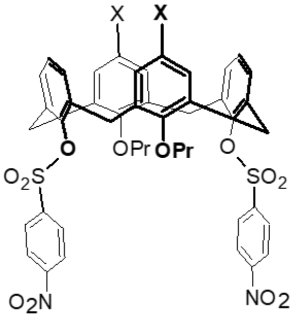
Calix[4]arene nosylates are important intermediates during preparation of ureidocalix[4]arene-based anion receptors, double calix[4]arene derivatives for fluorescent applications, self-assembled calixarene nanotubes or calixarene based molecular capsules.



1: R = CH_3
2: R = $CH_3CH_2CH_2$



3: X = CHO
4: X = CH_2OH
5: X = CH=NOH



6: X = CHO
7: X = $CH(SCH_2CH_3)_2$

Series of seven cone-calix[4]arene sulphonates substituted by various groups (nitro, carbonyl, oxime and other) was investigated in terms of their electrochemical reduction mechanisms. The experimental study includes both DC-polarography and cyclic voltammetry results combined with in situ EPR-spectroelectrochemistry in aprotic DMF.

All the investigated aryl nosylates are reduced in three steps. First electron(s) reduce(s) the molecule reversibly under formation of nitro anion radicals. In case of calixarenes, both nitro groups are reduced simultaneously, which refers to their independency. No or only negligible mutual electronic interaction of both nitro radical centres is confirmed by well resolved hyperfine EPR spectra structure. In the following step, two electrons per one nitro group are accepted, which leads to splitting of the S−O bond, and therefore to formation of phenols and nitro substituted arylsulphinates. The interpretation is based on (i) EPR-spectroelectrochemical measurements (comparison of the EPR-spectra with standards), (ii) DC-polarography and cyclic voltammetry (comparison of the reduction potentials with standards), and finally supported by quantum chemical calculations (identification of the thermodynamically most favourable reaction pathway). At more negative potentials, all nitro anion radicals are reduced (with assistance of protons present in the solution from moisture) by next three electrons to corresponding hydroxylamines.

Since the development of potentiometric ion-selective electrodes, remarkable steps have been taken towards progressive simplification and improved robustness of pH sensing probes. In particular, the design of compact sensing architectures using solid-state components holds great potential for portable and wearable applications. In this scenario, the use of organic electrochemical transistors (OECTs) to fabricate referenceless sensors with potentiometric transduction has been recently reported by our group [1]. Moreover, an innovative gateless (i.e. two-terminal only) configuration has been proposed for Chloride sensing based spontaneous electrochemical gating [2].

In this contribution we report the development of an electrochemically gated device for pH sensing, combining the robustness of potentiometric-like transduction with an extremely simple and integrated geometry requiring no reference electrode [3]. The sensor is a two-point probe device comprising two thin polymeric films, i.e. a charge transport layer based on poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) and a pH-sensitive layer. The latter is based on the Nernstian transducer PEDOT:Bromothymol Blue (PEDOT:BTB) [4]. The transduction mechanism originating the sensitivity to pH variations is thoroughly discussed to introduce the concept of spontaneous electrochemical gating.

The two-terminal pH sensor reported here shows remarkable potential for sensor miniaturisation and the development of portable and wearable electrochemical probes. Indeed, the chemiresistor-like geometry based on flexible, all-polymeric materials is compatible with photolithography-free, high throughput and low-cost fabrication techniques, such as screen-printing, and adapts to conformable substrates with potential integration into clothes or other real-life objects. To prove the versatility of our architecture, we fabricated a two-terminal sensor on a bioceramic fabric for real-time pH monitoring (Figure 1).

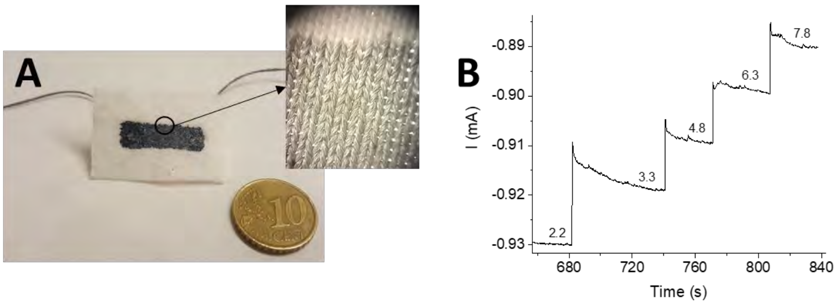

Figure 1. (**A**) Photo of the two-terminal wearable sensor. (**B**) Current vs time response to pH variations in Universal Buffer following 1M KOH additions obtained with the textile sensor. V_{app} = -200 mV.

Combating self-corrosion of Mg anodes via synergistic inhibition

Mikhail Zheludkevich, Linqian Wang, Min Deng, Bahram Vaghefinazari, Sviatlana Lamaka, Daniel Höche, Darya Snihirova
MagIC—Magnesium Innovation Centre, Helmholtz-Zentrum Geesthacht,
Max-Planck Str. 1, 21502 Geesthacht, Germany,
e-mail: mikhail.zheludkevich@hzg.de

Mg-air primary battery recently become more and more attractive for special applications thanks to their environmental benignity, economic viability, and high theoretical specific power density. However, the high tendency to self-corrosion of Mg-based anodes and their fouling during discharge lead to relatively low specific energy efficiency.
This work reports the strategy on decreasing the self-corrosion of Mg anodes via microalloying with Ca and design of the electrolyte additives in order to improve the energy efficiency of Mg-air batteries.

It was shown previously [1], addition of Fe^{3+} complexing agents into electrolyte significantly inhibits parasitic self-corrosion and improves the Mg behaviour under anodic polarization [2]. However, in many cases, hydrogen evolution reaction is not completely suppressed. The relevant method to thoroughly control hydrogen evolution reaction is to use combination of different inhibitors. Herein we combined Fe^{3+}-complexing agents, that prevent detrimental iron re-deposition, with efficient magnesium inhibitors (sodium nitrate and nitrite) that reduce parasitic hydrogen evolution reaction. The combination of inhibitors was chosen based on knowledge of magnesium corrosion mechanism and experience with corrosion inhibitors of Mg. In this work the effect of single additives and their combination was studied. Additionally, localised measurements of pH and dissolved oxygen above magnesium surface during polarisation were done in order to give insights on the inhibition mechanism. The results show that use of combination of inhibitors reduce significantly the self-corrosion and in addition prevent formation of $Mg(OH)_2$. The most effective was the mixture of sodium salicylate-sodium nitrate. This work is a step further to the improvement of the Mg-air battery performance.

Porous carbons are important cathodes for Li-O_2 batteries. But most ways of preparing porous carbons are high cost and complex. We present a simple and low-cost route to prepare porous carbons from food-grade bacterial cellulose (BC). By carbonizing as-prepared aqueous hydrogel BC, usually the porosity of the nanofibre network is lost because of its partial melting, and a compact carbon is obtained. Porous carbons can be obtained when using alcohols to treat BCs. And the carbon resulted from 1-butanol treated BC possesses outstanding discharge capacity and good cycle life for Li-O_2 batteries. This work presents a tunable, cost-effective and scalable method for obtaining porous carbons from sustainable sources.

Constructed Wetland-Microbial Electrochemical Snorkel system for efficient denitrification

Joanna Rogińska, Marc Hebrant, Michel Perdicakis, Christelle Despas, Julien Tournebize, Frédéric Jorand, Mathieu Etienne
Université de Lorraine, CNRS, LCPME
F-54000 Nancy, France
joanna.roginska@univ-lorraine.fr

The exceeded nitrate concentration in surface waters is caused by the use of nitrogen fertilizers in agriculture and may bring several negative consequences, e.g. excessive eutrophication. One solution for remediation is to collect water draining from the fields in constructed wetlands (CW), in which nitrate can be used as terminal electron acceptor by bacteria present in the sediment. However, size of the wetland is often not sufficient for efficient treatment of the watershed, when the highest nitrate concentrations are observed.

Microbial Electrochemical Snorkel (MES)[1] is a simplified version of Microbial Fuel Cell in which anode and cathode are short-circuited. The anodic part of the system reacts with electron donors (organic and inorganic compounds) and the cathodic part reacts with electron acceptors (oxygen and nitrate) but no energy is produced by the device. The main advantage of MES is to maximize the current flowing between anodic and cathodic parts for a more efficient water treatment.

Currently, we are investigating MES in a constructed wetland with the aim to increase the denitrification rate. Stainless steel and graphite felt have been used as electrode material to build MESs which were compared with control experiments in wetland without any electrodes. After optimization of the device, a significant improvement was achieved as it is illustrated on Figure 1. These series of experiment were performed in triplicate with an initial nitrate concentration in the range of 33 to 40 mg $N\text{-}NO_3^-$/l. The best fit to adjust the model to experimental data was obtained by considering an apparent first order reaction with $C = C_0e^{-kt}$.

Here, we achieved k values for the CW-MES (0.117 ± 0.012 hour^{-1}) that are five times higher than the control experiment with CW only (0.022 ± 0.002 hour^{-1}). We are now investigating the electromicrobial mechanisms that allows such large increase in denitrification rate and we started evaluating on-field applications. This communication will summarize our latest results about denitrification with microbial electrochemical systems in constructed wetlands.

ludmila.simkova@jh-inst.cas.cz

Photoluminescent metal complexes have a broad application potential in various fields such as photocatalysis, photovoltaics, light-emitting devices, molecular sensors, bioimaging, etc., but among them the complexes of electron-deficient metals with LMCT excited states are rather scarce. We have observed phosphorescence of a new class of Zr and Hf metallocene complexes with intramolecularly tethered imine or pyridine moiety (obtained by protonation of the ketimide group or abstraction of chloride anion in parent neutral complexes [1,2]) both in the solid state and in solution at ambient temperature with relatively high quantum yields and luminescence lifetimes up to tens of µs.[3]

Because charge transfer in photochemistry and electron transfer in electrochemistry are in close relationship, and because redox stability is a very important property in this case, electrochemical methods are inevitable in this research. In order to understand the energetic as well as kinetic relationship between various excited states and redox states, a series of cationic 4 metallocene complexes (Ti, Zr, Hf) stabilized by pendant N-donor groups was synthesized and studied by electrochemical methods.

In the accessible potential range all studied compounds involved several reduction steps, suggesting a complicated mechanism. Almost all derivatives are reversible reduced in the first step. The influence of metal atom and the substitution of the ketimide or pyridine moiety on the potential is discussed. The results are compared with DFT calculations.

Semiconductors are commonly prepared using element at high temperature, in vapour phase and high vacuum conditions. Liquid solution using water, organic solvents, or ionic liquids are other possibilities to grow materials in the bulk form or as thin films. Electrodeposition can be performed with simple conditions, at room temperature and ambient pressure saving energy, money and performing green synthesis. Moreover, the electrodeposition can be easily scaled up from a small electrochemical cell to industrial level.

Today electrochemistry plays a crucial role in the material science thanks to methods that permits to control the deposition at atomic level, exploiting surface limited reactions like the underpotential deposition (UPD). The UPD is a well-known phenomenon but recently there is a renewed interest on it because of the possible applications in many technological fields from electrocatalysis (like water splitting) to thin film photovoltaic, display and LEDs, light detectors and lasers. Based on UPD process, it is possible to perform the electrochemical atomic layer epitaxy (ECALE), or E-ALD when the deposits cannot be rigorously considered epitaxial, alternating the deposition of a metal and of a non-metal element in a cycle. With the E-ALD it is possible to avoid the formation of three-dimensional crystallites and Stranski-Krastanov growth. Therefore E-ALD is a valid approach to obtain semiconductors on metallic substrate. In our laboratory, with this method, we successfully synthesized thin films of various 12-16 groups semiconductor compounds like ZnS, CdS, CdSe, CdTe, but also Cu_2S, $MoSe_2$ and Bi_2Se_3 on silver electrode [1,2].

Moreover, we explored also the possibility to performing controlled electrodeposition on silicon. Despite its diffusion in the microelectronic industry, the realization of Si-based devices is extremely challenging due to its indirect bandgap and a suitable candidate to integrate light in silicon and open the microelectronic world to the light remains to be found. Among semiconductors, other materials are emerging to face the important demand to produce novel optoelectronic devices integrated in Si platforms. The possibility of integrating various materials on the Si surface offers the opportunity to produce compact and cost-effective electronic circuits with numerous applications. Finding UPD conditions on Si is extremely difficult but operating in severe regimes of charge and time-controlled deposition it is possible to obtain an E-ALD-like deposit [3].

The PRIN ("Progetti di Ricerca di Rilevante Interesse Nazionale") is acknowledged for funding the project "Novel Multilayered and Micro-Machined Electrode Nano-Architectures for Electrocatalytic Applications (Fuel Cells and Electrolyzers)", grant number 2017YH9MRK.

Redox charge storage in two-dimensional transition metal carbides (MXenes)

Yury Gogotsi*, Tyler S. Mathis, Xuehang Wang and Narendra Kurra

A.J. Drexel Nanomaterials Institute and the Department of Materials Science and Engineering, Drexel University, Philadelphia, PA 19104, USA

Email:yg36@drexel.edu

Two-dimensional (2D) transition metal carbides known as MXenes, have received considerable attention for energy storage applications due to their tunable electronic and physical properties.[1-2] MXenes have high specific capacitances due to their redox-active transition metal surfaces, and binder-free MXene films have electronic conductivities much higher than typical supercapacitor materials (>1000 S/cm compared to <0.1 S/cm).[3-4] Furthermore, MXenes are capable of storing charge in a wide variety of aqueous electrolytes and it has been shown that MXenes are capable of electrochemically intercalating cations of various charges (K^+, Na^+, Mg^{2+}, Al^{3+}) into the interlayer spaces between their 2D nanosheets.[5-6]

There is increasing interest in researching materials with nanoconfined fluids for electrochemical energy storage applications due to the interesting modifications confined fluids can have on ion transport, ion desolvation and insertion, or solvent co-intercalation into host materials. Furthermore, layered materials with these confined fluids can demonstrate higher rates of charge storage and transfer due to decreases in the activation energy of charge-transfer at their solvated surfaces.[7] Since the surface of the MXenes has abundant surface functional groups (e.g., O, F, and OH), surface redox reactions with intercalated protons result in very high volumetric capacitance in acidic aqueous electrolytes. The high electronic conductivity and the water confined within the MXene nanosheets in this system also enables ion transport rates that are far superior to any other known pseudocapacitive material.[4] In organic electrolytes, simply changing the solvent of the electrolyte can dramatically alter the mechanism by which charge storing ions are intercalated into the MXene structure, resulting in significant changes in the amount of charge stored and the mobility of the intercalated ions.[8]

Different MXenes have been synthesized with a large variety of surface chemistries, many of which have demonstrated promising properties for energy storage applications. By further selecting the proper combination between ions, polarization conditions, and the type of MXene, the changeable interlayer space may allow for tunable ion intercalation and improved supercapacitor performance.

Electrochemical pH sensor for continuous monitoring in minimal invasive device

Sofia Rodrigues Teixeira[1], Paul Galvin[1]
[1] *Tyndall National Institute, Cork, Ireland, T12 R5CP*
sofia.teixeira@tyndall.ie

pH sensor is used in various applications utilizing redox reactions, encompassing both research and industrial fields. pH plays a significant role in multiple biological processes, like cell proliferation, endocytosis, ion transport and is also a factor in cardiopulmonary and neurodegenerative diseases, including cancer [1]. Minimally invasive techniques enable diagnostics and surgery to be performed through a small incision reducing the damage to healthy tissue leading to faster recovery times for the patient.

Iridium Oxide (IrOx) is one of the electrochemical materials for display devices [2], a popular alternative to conventional glass and other metal-oxide electrodes. Advantages of IrOx sensors include fast response time, reduced chemical interference, and long-term stability, furthermore, these electrodes exhibit functionality at temperatures up to 250°C, high pressures, in hydrofluoric acid, and in non-aqueous solutions [3]. When considering practical applications, the properties of IrOx are very sensitive to structure and composition, which are dependent on fabrication methods and conditions used [4]. Thus, the different characteristics of IrOx pH electrodes are mainly accounted for by different preparation methods.

A pH sensor was developed involving electrodeposition of IrOx films onto platinum films. Anodically electrodeposition of IrOx film were deposited on the electrode via standard electrochemical cyclic voltammetry using a three-electrode setup (Figure 1A). The number of cycles that are carried out corresponds to the level of deposition of IrOx on the electrode surface. Open-circuit potential measurements were performed to evaluate the potential electrode pH response at room temperature using a 2-electrode cell. Comparison of different working electrodes on the same chip and in different chips was carried out (Figure 1B). The sensors showed an excellent reproducibility with a linear super-Nernstian response around 69mV/pH unit in a wide pH range (pH 4−10). The present pH sensor includes excellent adhesion of the pH sensitive layer to the substrate and excellent reproducibility of sensor fabrication, which can lead to a new generation of diagnostic tools for the simultaneous detection of various biological analytes.

Room Temperature Electrodeposition of Titanium sub-oxides on Mild Steel Electrode towards Corrosion Protection

Zeliha Ertekin, Erhan Karaca, Merve Uğur, Kadir Pekmez, Nuran Özçiçek Pekmez
Hacettepe University, Faculty of Science, 06800 Beytepe, Ankara, Turkey
zelihaertekin@hacettepe.edu.tr

Titanium sub-oxides are mixed-valence compounds containing Ti^{3+} and Ti^{4+} ions, which provides several possible configurations in the crystal. The oxygen vacancies of the Ti-O system have important effects on interfacial electronic structures. Such compounds are also known as Ti_nO_{2n-1} (Ti_3O_5, Ti_4O_7, Ti_5O_9, Ti_6O_{11}, etc.), where $2 < n < 10$. Depending on the n value, their crystal structure, electronic structure, and color can change. In recent years, they have attracted considerable attention due to their excellent properties such as high electrical conductivity, remarkably visible light absorptivity, and chemical stability in aggressive alkali and acidic media. These properties make them suitable for a variety of applications such as cathodic protection, electrode materials, batteries, catalytic support for fuel cells, degradation of pollutants, and electronic and optoelectronic devices [1-3].

In this study, a rapid and simple electrochemical process without a calcination step to prepare titanium sub-oxide coating on mild steel (MS) surface is presented for the first time. The low-temperature synthesis of titanium sub-oxide is carried out on the MS electrode by cyclic voltammetry in acetonitrile solution containing titanyl perchlorate. The coatings obtained various potential intervals and cycle numbers are investigated by comparing with each other using EIS. According to the obtained resistances, the optimum experimental parameter is a potential range of 0.0 V and -2.2 V with 20 cycles. The broad reduction peak at about -1.9 V in the blank solution indicates the formation of Ti_nO_{2n-1} (Fig.1A). The morphology and chemical composition of the coating are studied by SEM-EDX, XRD, and XPS. XRD result indicates the presence of different oxygen-containing phases (Ti_3O_5, Ti_4O_7, and Ti_5O_9) together with Fe_2TiO_5 intermetallic phase. From XPS, the Ti(III) and Ti(IV) oxidation states are demonstrated in the electrodeposited Ti_nO_{2n-1} film on MS (Fig.1B). Corrosion performance of the Ti_nO_{2n-1} coated MS electrode is investigated using EIS, OCP, and Tafel measurements in 0.5 M H_2SO_4. It is determined that the resulting coating, synthesized in a solution containing $TiOClO_4.6H_2O$ on the MS electrode, provides five times more protection in 0.5 M H_2SO_4 medium. The results demonstrate that the electrodeposited Ti_nO_{2n-1} film on MS is a good alternative for practical application of metal-oxide based corrosion systems.

E-mail: lucie.kolacna@jh-inst.cas.cz

Conjugated aromatic systems are commonly used for organic electronics as “green smart molecules” free of any metal. Specific properties of these molecules are simply adjustable by chemical modification. Our project is focused on molecules comprising pyrene derivatives and/or other aromatics in combination with cyclobutene representing the tetrasubstituted double-bond bridge. Modifications and conjugations of mentioned molecules result in various extent of electron delocalization. Electrochemical data of pyrene, cyclobuten and their conjugates are essential for understanding the redox mechanism of these large delocalized systems.

Redox mechanism of conjugates was studied in non-aqueous aprotic solutions (acetonitrile and dimethylformamide) at mercury and glassy carbon working electrodes by means of polarography, voltammetry at rotating disc electrode (glassy carbon) and cyclic voltammetry at hanging mercury drop electrode and stationary glassy-carbon electrode. Electron paramagnetic resonance with *in situ* electrochemical generation at platinum working electrode in dimethylformamide was used for detection and characterization of primary and secondary radical intermediates.

Studied systems involved three types of reduction mechanism: I. pyrene with substituents exhibiting induction/mesomeric effect, II. pyrene in combination with other independent reducible centre, III. cyclobutene conjugates with substituents extending the delocalized system (pyrene and/ or other aromatics).

The reduction process of all studied compounds is not "electrode assisted" (mercury, glassy carbon). Potentials in DMF are systematically shifted to less negative values with respect to acetonitrile by approx. 70 mV. The reversibility is more pronounced in DMF, which means that the primary radical anions exhibit higher stability. During oxidation at glassy-carbon electrode, polymerization of pyrene and/or other components was observed.

Pyrene is reduced in two one-electron steps – first to a stable radical anion and subsequently to unstable dianion. Substituents shift the reduction potential in agreement with induction/mesomeric effect.
Direct interconnection of two pyrene molecules by a single bond results in twisted molecule with limited pyrene interaction, proved by formation of stable radical anions.
The cyclobutene bridge enters in conjugation with aromatic substituents (pyrene, tolyl or anisyl) extending planar delocalized system, which was confirmed by partial reversibility of its first reduction step to unstable radical. In the next step, cyclobutene is reduced by simple reduction to cyclobutane (proved by analysis of products of preparative electrolysis by NMR – MS), although the ring opening and splitting of the CH_2–CH_2 bond by the ECE mechanism was suggested in the literature [1, 2].

Pyrene derivatives are good chromophores and redox centres and studied molecules are suitable for construction of organic semiconductor materials. Analysis and interpretation of spectro-electrochemical data of pyrene derivatives and conjugates revealed intramolecular communication of electrons and redox mechanism of conjugates. This knowledge is basic for tuning the required redox properties by chemical modification.

The research was supported by GA CR 18-12150 S.

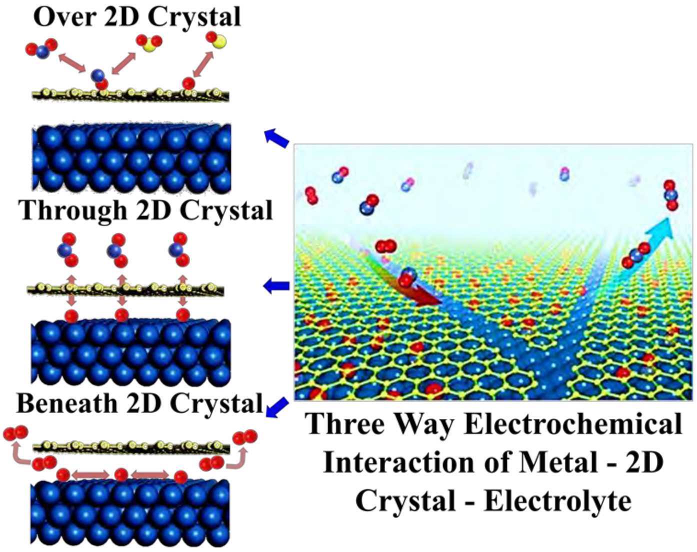
Three-Way Interactions of Two-Dimensional Crystals

Nakkiran Arulmozhi, Viorica Tudor, Grégory F. Schneider, Marc T. M. Koper*
Leiden Institute of Chemistry, Leiden University, PO Box 9502, 2300 RA Leiden, The Netherlands
e-mail address: m.koper@chem.leidenuniv.nl.

Graphene and related two-dimensional (2D) crystals, a new class of advanced materials, not only improves the performance of the current technological devices but also create new disruptive technologies[1]. From the interfacial electrochemistry's perspective, 2D crystals possess a porous double-sided surface and its integration into a device can lead to multiple interactions namely: i) an electrochemical interaction between the 2D crystal and the electrolyte[2]. ii) The protons (in the case of pristine 2D crystal[3]) or ions (in the case of defect-engineered 2D crystal[4]) permeation through the lattice of 2D crystals. iii) A confined electrochemical interaction in-between the region of 2D crystal and the conducting metal substrate[5].The three-way electrochemical interaction of 2D crystals makes it a unique material and performance tuning of these interactions can radically transform electrochemistry-based technologies.



Therefore, the primary goal of the talk is to present a detailed analysis of a model metal – 2D material – solution interface, i.e. Pt(111) – graphene – electrolyte interface[6], with an objective to emphasize and define the fundamental aspects behind the three-way electrochemical interactions. The strategy to examine the three-way electrochemical interactions of Pt(111) – graphene- electrolyte interface is to isolate the region for individual interaction and investigate them. The first part of the talk focuses on understanding electrochemical interaction between the graphene and the electrolyte (reaction over 2D crystals): A detailed electrochemical analysis of graphene oxidation kinetics and graphene oxide reduction kinetics will be presented. The second part of the talk will focus on electrochemical permeation of protons through graphene: A comprehensive analysis of temperature dependence of electrosorption of proton on to Pt(111) via graphene permeation in the aqueous electrolyte will be presented. Finally, the talk will focus on understanding the electrochemical reaction below graphene. A comprehensive electrochemical study of hydrogen evolution reaction (HER) on graphene – Pt (111) electrode in the aqueous electrolyte will be presented. These fundamental-level analyses of the three-way electrochemical interaction of 2D materials would be of crucial importance for both the scientific and commercial success of 2D material.

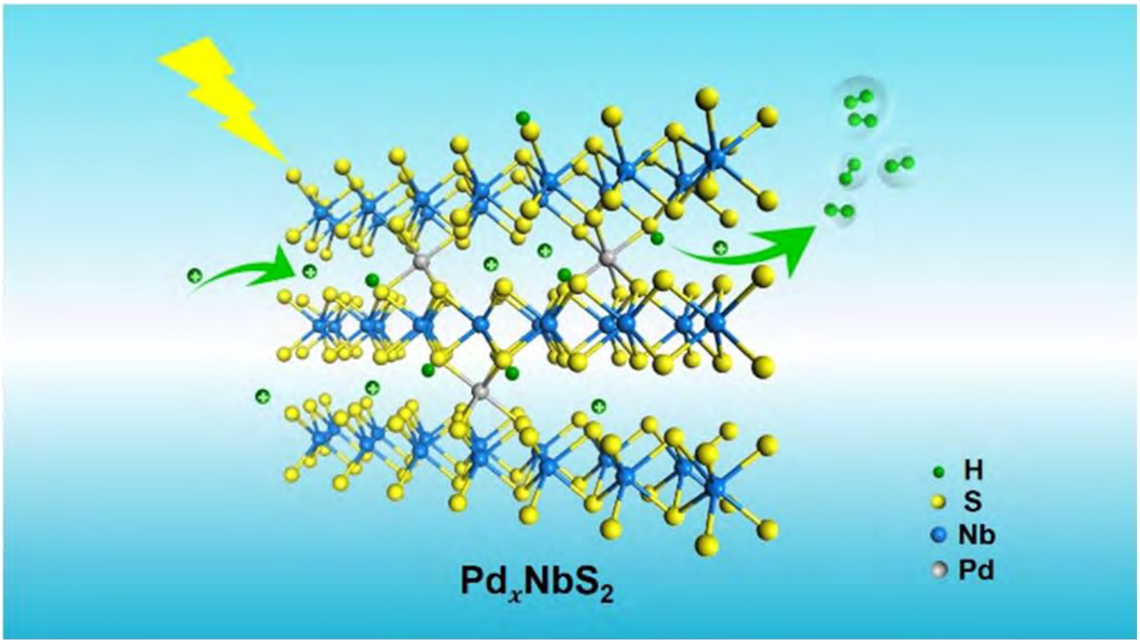
ABSTRACT: Exploring novel electrocatalysts with prominent performance is highly demanded for electrochemical hydrogen evolution. As one family member of layered transition-metal dichalcogenides (TMDs), metallic niobium disulfide (NbS_2) with intrinsic basal plane activity might be a promising candidate once its electrical and structural characteristics are optimized. Here, we develop novel electrocatalysts by incorporating palladium (Pd) atoms into the van der Waals gaps of NbS_2 to form new compounds Pd_xNbS_2 (x = 0-0.23). On the basis of single crystal structure refinement and theoretical calculations, the Pd atoms act as atomic pillars to expand the interlayer spacing of NbS_2 and boost the basal plane activity with a drop of Gibbs free energy for hydrogen adsorption to 0.06 eV on neighboring S atoms, resulting in more protons to adsorb and react. In addition, pillared Pd stabilizes the crystal structure by connecting the NbS_2 interlayers with $[PdS_6]$ octahedra. All these merits endow $Pd_{0.23}NbS_2$ with superior electrochemical activity and durability, achieving 10 mA cm^{-2} at a low overpotential of 157 mV with a negligible change in 12 h. This unique atomic pillar effect for optimizing the electrocatalytic performance of Pd_xNbS_2 demonstrates a functional and powerful strategy to develop efficient TMD-based electrocatalysts.



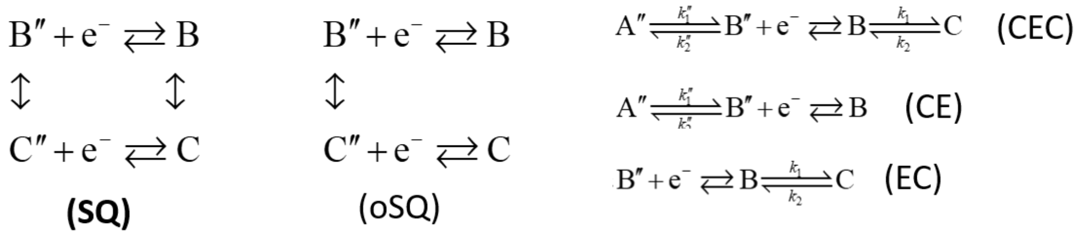
Guidelines for the Voltammetric Study of Electrode Reactions with Coupled Chemical Kinetics at an Arbitrary Electrode Geometry

Eduardo Laborda, Manuela López-Tenés and Angela Molina

Departamento de Química Física, Facultad de Química, Regional Campus of International Excellence"Campus Mare Nostrum",Universidad de Murcia, 30100 Murcia, Spain

elaborda@um.es

By suitable preliminary analysis of the boundary value problem, a remarkable generalization and simplification of the theoretical treatment of homogeneous chemical reactions affecting the interfacial charge transfer is revealed for any electrode size and shape [1,2]. Thus, the multivariable boundary value problem of complex reaction mechanisms [3], at both uniformly accessible (as(hemi)spheres) and non-uniformly accessible (as discs) electrodes, can be reduced to a single variable problem the mathematical form of which is equivalent to that of an irreversible E mechanism. This is obviously very advantageous for the mathematical resolution of the problem either by analytical or numerical methods.



In this communication, the use of the above theoretical approach is illustrated by treating the problem of the SQ mechanism and the simpler derived schemes oSQ, CEC, CE and EC [4,5]. The solutions obtained enable the comprehensive study of their voltammetric response as a function of the chemical rate and equilibrium constants and of the electrode size and shape. As a result, clues and experimental protocols for the identification and characterization of the charge transfer mechanism and for the determination of the corresponding kinetic and thermodynamic parameters are established. Also, the equivalence relationship between electrodes of different shape is critically examined within this context, finding that the constant relationship between the steady state current−potential response at microdiscs and micro(hemi)spheres (ratio between the current densities at electrodes of the same radius = 4/π) does not hold in the presence of chemical kinetic effects, even though the electron transfer is Nernstian.

Chromogenic materials are able to change their optical properties as a response to an external stimulus, such as light irradiation (photochromic materials), temperature variation (thermochromic materials) or electric potential (electrochromic materials).

Glazing employing electrochromic materials can change their optical characteristics of transparency and absorption of solar radiation according to users' needs by simultaneously reducing visible light and NIR transmission through the window. However, spectral selectivity has been becoming a key requirement in smart dynamic windows as it permits maximizing both visual and thermal comfort while minimizing energy consumption for heating, cooling, and lighting [1].

Herein, a dual band electrochromic system is presented, which consists of an engineered nanocomposite electrode capable of advantageously combining the broad band plasmonic response of nanocrystalline indium-tin-oxide (ITO) with high optical contrast of polyaniline (PANI). Their synergistical spectroelectrochemical features make possible the implementation of a four-state tunable electrochromic system (here referred to as "plasmochromic"), which permits selectively regulating optical transmittance in the visible and near-infrared range and exhibits excellent spectral selectivity across a potentials window of only 1.2 V, with a visible light *vs.* solar transmittance ratio tunable from 0.67 to 1.61.

Electrochemical and spectroscopic features of the two constituting components (*i.e.*, ITO nanocrystals and PANI) will be discussed, together with the study of how their single characteristics symbiotically combine each other in defining the performance of the resulting hybrid plasmochromic electrodes. Finally, a set of dual-band EC devices offering an excellent VIS/NIR spectral selectivity within a relatively small electrochemical window will be presented, discussing their main key features [2].

Oxidation ratio of conducting polymer in the conducting polymer-coated electrode

Yumi Yoshida, Emi Kusakabe, Kohji Maeda
Faculty of Molecular Chemistry and Engineering, Kyoto Institute of Technology
Matsugasaki, Sakyo, Kyoto 606-8585, Japan
yyoshida@kit.ac.jp

A solid electrode that can operate as both a reference electrode and a counter electrode—a reference/counter electrode—for an organic phase, Org, is necessary for the fabrication of a micro and/or thin layer cell with an organic membrane such as a liquid membrane-type ion-selective electrode, ISE, and a voltammetric cell with the interface between aqueous phase, W and Org.

A conducting polymer-coated solid electrode has been one of candidates for use as a reference/counter electrode in Org. The conducting polymer has low solubility in Org and functions as an ion-electron transducer. In 1987–1988, the conducting polymer-coated electrode was applied to an all-solid ISE in which the inner solution was replaced by the conducting polymer, and there are many reports on the all-solid ISE using the conducting polymer-coated electrode even in recent literatures. Recently, amperometric ISEs and the coulometric thin layer cell using the conducting polymer-coated electrode have been proposed and used for the realization of stripping voltammetry and absolute determination of redox-inactive ions. However, these ISEs and electrolysis cells with the conducting polymer-coated electrode have rarely been used in practical applications even though various applications of the conducting polymer-coated electrode have been proposed.

Low stability and poor reproducibility of the electrode potential are the most serious problems for the conducting polymer-coated electrode. Poly(3,4-ethylenedioxythiophene), PEDOT, is a chemically stable conducting polymer that improves the potential stability of the all-solid ISE; however, slow potential drift and a shift of the absolute value of the electrode potential in an aqueous standard solution have been observed for this ISE. The factors related to the potential stability and reproducibility of the conducting polymer-coated electrode have been extensively discussed based on the redox capacitance of the conducting polymer or the irreversibility of the ion transfer between the polymer and the selective membrane.

To get stable and reproducible potential for longer period, we adopted the potentiostatic adjustment of the oxidation ratio: the formal potential for the redox reaction of the conducting polymer was evaluated from the potential dependence of the absorption spectrum of the conducting polymer and was applied to the conducting polymer-coated electrode for adjustment of the oxidation ratio. The potentiostatic adjustment for long time made more homogeneous oxidation condition in the conducting polymer while chronocoulometric adjustment for short time made inhomogeneous oxidation condition. The potential stability and potential reproducibility of the conducting polymer-coated electrode under open circuit or current-flowing were examined in hydrophobic Orgs for longer period such as 200 h by focusing on the oxidation ratio of the conducting polymer. Oxidation to the conducting polymer by oxygen in air was also examined for 800 h. The partially oxidized PEDOT electrodes were applied to the two-electrode system thin layer cell for the ion transfer between aqueous sample solution and organic membrane [1].

Electrochemical detection of Prussian Blue Nanoparticles in flow

Joanna Dolinska, Marcin Holdynski, Marcin Opallo

Institute of Physical Chemistry, Polish Academy of Sciences
Kasprzaka 44/52 01-224 Warsaw
jdolinska@ichf.edu.pl

The last decade has abounded in research on the electrochemical behaviour of suspended nanoparticles. Most of them focused on their electrochemistry at an ultramicroelectrodes in quiescent conditions. Detection of single collisions of nanoparticles with the (ultra-micro)electrode surface was claimed[1,2]. This is important from the point of view of acquiring knowledge about single nanoparticles, but it requires sophisticated equipment and skilled personnel. For many purposes including analytical ones other techniques involving the larger size of electrodes can be used. This requires acceleration of nanoparticles, namely experiments in forced convection conditions. Recently we demonstrated electrochemical detection of nanoparticles exhibiting redox reaction: Prussian Blue nanoparticles at rotating disc electrode[3]. Here we would like to extend this study to flow conditions. For this purpose we prepared 3D printed system consisting channels, mixer, inlets, outlets, place to fix working disc electrode and chamber for counter and reference electrodes and (see scheme below). Such an approach allows for simple and quick design and optimization of the whole system including the position of the working electrode (perpendicular or parallel to the flow).

We will demonstrate that Prussian Blue nanoparticles can be detected employing both electrochemical reduction or electrochemical oxidation. The effect of the cell design, electrode material and flow rate will be demonstrated. These results, including the detection limit, will be compared with those obtained with a rotating disc electrode. [3]

Raman spectroelectrochemistry of conducting polymer films on reflective electrode: role of double excitation of the solution layer

A.A. Nekrasov, O.D. Yakobson, O.L. Gribkova
A.N. Frumkin Institute of Physical Chemistry and Electrochemistry, RAS
Leninskii prospect 31, Moscow, 119071, Russia
e-mail: secp@elchem.ac.ru

Raman spectroelectrochemistry is a powerful tool to monitor structural transformations during electrosynthesis and doping/dedoping of conducting polymers. However, the excitation laser beam passes several interfaces, where absorption, refraction and reflection processes may occur. These are: air/glass (the wall of spectroelectrochemical cell); glass/electrolyte; electrolyte/film (of conducting polymer); film/electrode. Noteworthy, the film of conducting polymer changes its thickness, absorption and refraction during the electrosynthesis and doping/dedoping. All these phenomena influence the shape of in situ Raman spectra and are also dependent on the incident angle of the laser beam. This influence was demonstrated on the example of in situ Raman monitoring of galvanostatic polymerization of aniline on Pt-electrode in aqueous solutions of the following polymeric sulfonic acids: flexible-chain poly(2-acrylamido-2-methyl-1-propanesulfonic acid), poly(styrenesulfonic acid) and rigid-chain poly-(4,4'-(2,2'-disulfoacid)-diphenylene-iso-phthalamide), poly-(4,4'-(2,2'-disulfoacid)-diphenylene-tere-phthalamide). Firstly, it was found that 532 nm laser radiation caused fluorescence in the solutions of phenyl-containing polyacids resulted in the Raman spectrometer overload. One can reduce fluorescence (Fig.a) by increasing the incident angle of the laser beam on the electrode up to 20° (perpendicular direction is taken as 0°). Secondly, some of the polyacids were found to have intensive Raman bands in the range of characteristic Raman frequencies (1000-1800 cm^{-1}) of polyaniline (PANI). In this case, subtraction of the solution background spectrum before starting the electropolymerization monitoring causes appearance of ever-growing negative Raman signals (Fig.b) as the PANI film absorbing the laser radiation grows on the reflective electrode. The above two issues are due to the double excitation of the thin solution layer before the electrode by the incident and reflected laser beams, the degree of this doubling decreasing as (1) the incident angle is increased and (2) the laser-absorbing PANI film grows. The distortive influence of the solution Raman spectrum on the real shape of PANI spectrum may be estimated and diminished by using the amplitude of ever-growing negative Raman signal in the area of water O-H vibration (near 3440 cm^{-1}) as a measure of the ever-decreasing reflectance of the working electrode. Using the developed approach, it was shown that evolutions of the relative portions of the imine nitrogen (near 1490 cm^{-1}) and the radical-cation nitrogen (near 1340 cm^{-1}) fragments in the Raman spectra of PANI recorded in the course of electropolymerization can be used as informative criteria for the explanation of the differences in the aniline polymerization rate in the presence of polyacids of different chemical structure.

daniele.cecconet@unipv.it

A fraction between 60 and 75% of domestic wastewater is represented by greywater, which can be defined as water coming from domestic sources, including kitchen sinks, washing machines, and hand basins excluding toilets, bidets, and urinals. Compared to unsegregated domestic wastewater, greywater contains a relatively lower amount of organic matter that needs to be removed in order to comply with the current regulations regarding water reuse for non-potable application.

Among different options for greywater treatment, membrane filtration and its coupling with biological treatment, membrane biological reactor, are particularly diffused due to the simplicity and compactness of the treatment. However, those technologies are highly energy consuming, and may negatively impact on the energy balance of a building.

Bioelectrochemical systems (BESs) have emerged in the last two decades as a multi-faceted platform for a variety of purposes, including organic matter removal, nutrients recovery, hazardous sites remediation, groundwater treatment. The first and most common declination of BESs is represented by microbial fuel cells (MFCs), able to remove organic matter and produce electrical energy.

In this work, 3 identical H-type MFCs were built, inoculated and then operated for the assessment of the suitability of greywater treatment for organic matter removal and energy production. Due to the large variability of conductivity in greywater, a single MFC was operated with low conductivity greywater (348 µS/cm), a second one with high conductivity greywater (1578 µS/cm); a third one was fed with acetate and used as control reactor. Each batch was repeated 3 times to ensure reproducibility. Organic matter concentration of greywater and acetate solution was measured at 489 mgCOD/L; each batch lasted 500 hours.

A similar organic matter removal was observed in the different MFCs, with values between 85% (greywater, high conductivity) and 90% (acetate fed), showing that the MFCs were able to oxidize the complex organic compounds present in greywater. As shown in table 1, the performances in terms of electrical production of the MFC fed with high-conductivity greywater were higher than in the case of low conductivity influent. In addition, the maximum voltage in the case of low conductivity greywater was reached more than 200 hours later compared to the high conductivity greywater-fed MFC.

Table 1. Organic matter removal and electrical production data from the third batch of the experimentation. NER: Normalized energy recovery; CD_{max}: maximum current density; PD_{max}: maximum power density; V_{max}: maximum voltage.

Test	NER_s (kWh/kg_{CODrem})	CD_{max} (mA/L)	PD_{max} (mW/L)	η_{COD} (%)	V_{max} (mV)
Greywater, low conductivity	0.15	0.84	0.29	87%	346
Greywater, high conductivity	0.21	0.98	0.40	85%	409
Control, acetate	0.34	1.14	0.54	90%	474

Low conductivity in wastewater usually causes increase of overpotentials, due to slow proton transport in the active biofilm, enhanced resistance in ion transport between anode and cathode, other than higher resistances originating from the diffusion boundary layer and electric double layer. The combination of these factors may have led to the observed decrease in MFC's energy production.

In conclusion, MFC technology showed to be able to successfully remove organic matter from greywater, allowing also the production of electrical energy. This findings may open a novel pathway for an on-site treatment of greywater for non-potable reuse coupled with energy recovery that may be directly used in the building in which greywater is collected and treated.

Bimetallic Organic Framework Deposited on Anodized TiO_2 Nanotube Arrays with Enhanced Photoelectrochemical Activity for Water Oxidation

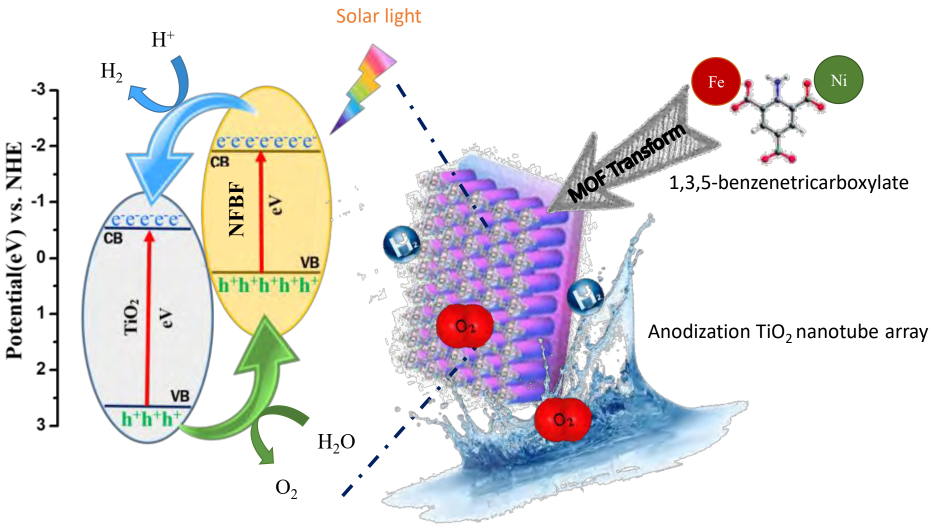
Fossil fuel reserves are dwindling and their unrestricted use has led to incontrovertible changes in the Earth's surface temperature and climate. Solar fuel generation through water splitting is an ideal route to store renewable energy sources and mitigate global warming. Metal organic frameworks (MOFs) have recently been used as solid supports in photocatalytic water splitting. Their porosity and structural versatility offer a tantalizing consolidation of the components needed for solar light harvesting and water dissociation. In this work, we report on the fabrication of iron-nickel bimetallic organic framework (FNBF) discretely deposited on top of anodized TiO_2 nanotube array (TNTA). They were synthesized by electrochemical deposition of Ni^{2+} and Fe^{3+} species onto TNTA surfaces and then chemically transformed (using a simple hydrothermal process) into MOF by using appropriate organic ligands. The structures of these photanodes was optimized and characterized by SEM, TEM, and XPS analysis. The optimized FNBF@TNTA photoanodes were then tested for water photo-oxidation. A photocurrent of 1.40 mA cm^{-2} was measured under 100 mW/cm^2 UV + Visible light intensity. The performances were found stable (a photocurrent of 1.30 mA cm^{-2} was measured after 180 minutes of continuous operation). These nanocomposite photoanodes successfully combine great light harvesting properties, a good conductivity and stability due to the carbon-based architecture, and show good oxygen evolution reaction activity under solar light. FNBF@TNTA photoanodes are promising materials for the development of water



Coupling microalgae and microbial fuel cells: process optimization for simultaneous wastewater treatment and energy recovery

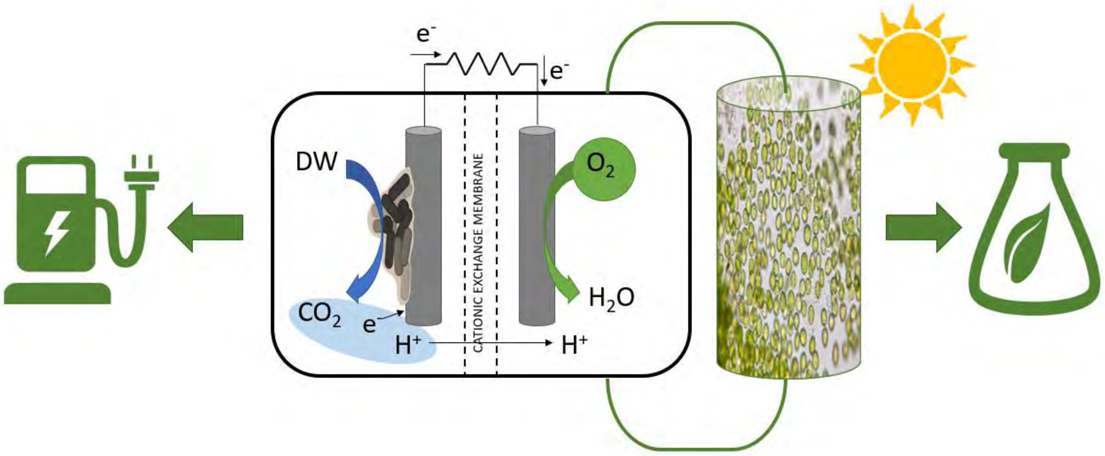
Increasing energy demands and greenhouse gases (GHG) emission from wastewater treatment processes prompted the investigation of alternatives capable to achieve effective treatment, energy and materials recovery, and reduce global environmental footprint.

Microbial fuel cells (MFCs) are a promising technology for wastewater treatment, characterized by electrical energy recovery and low emissions and sludge production. MFCs convert the chemical energy of organic pollutants (substrate) directly into electrical energy, thanks to electrochemically active bacteria (EAB) in the anodic chamber, potentially achieving higher conversion efficiency (44%) than with a conventional anaerobic treatment (28%). Microalgae, on the other hand, are well known as potential candidates in biorefineries for biofuels and biomaterial production, because of the many products that they can potentially produce with lower land occupation and no competition for human nutrition needs.

Coupling MFC technology with microalgal-based process in MFC-PBR (photobioreactor) systems could reduce GHG emissions from wastewater treatment facilities, capturing CO_2 emitted from industrial facilities or directly from the atmosphere and convert it in the desired terminal electron acceptor (TEA), oxygen. Microalgae production could enhance recovery of wastewater-embedded resources. Two identical MFC-PBR systems configurations were tested and compared with a control MFC, under different operating conditions (light/dark ratio, oxygen providing method), using both synthetic and agro-industrial wastewater as anolytes. COD removal efficiency (ηCOD) and energy production were monitored throughout the experimentation, reaching ηCOD values up to 99% and power density (P_d) up to 2.8 W m^{-3}. Energy losses were also evaluated to monitor how the presence of the microalgae affected the long-term operation of the system. The system equipped with microalgal biocathode proved to be capable to efficiently treat real wastewater, achieving values comparable to the control system. Oxygen provided by the algae improved the overall energy balance of this system by lowering aeration costs, which could be further enhanced by post-processing of the cathodic microalgal effluent.



Oxygen Supply Management to Intensify Domestic Wastewater Treatment by a Microbial Electrochemical Snorkel (MES)

Morgane HOAREAU, Benjamin ERABLE, Alain BERGEL
Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France
morgane.hoareau@toulouse-inp.fr

Keywords: Electroactive biofilm, microbial electrochemical system, bioremediation process, microbial fuel cell

Oxygen supply is the most cost-intensive part of the aerobic biological wastewater treatment plants. The Microbial Electrochemical Snorkel (MES) is a low-cost and low-maintenance solution that should considerably reduce this cost. A MES is generally in the form of a single electrode placed vertically in an environment where the composition of oxidizing and reducing species is spatially heterogeneous.

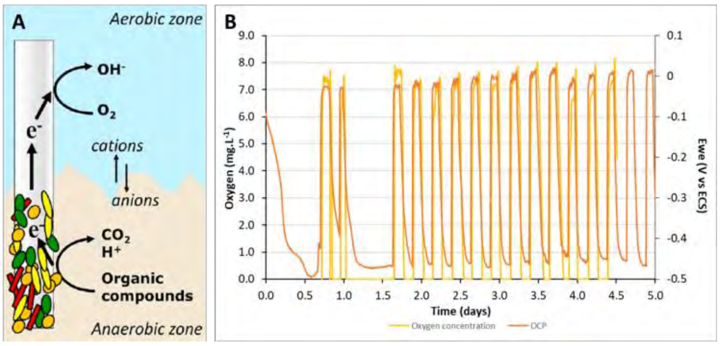


Figure 1 : (A) Principle of the Microbial Electrochemical Snorkel (B) Evolution of the dissolve oxygen concentration and the OCP

In the context of wastewater treatment, the lower part of the MES (Figure 1-A), is positioned in the anaerobic environment and ensures the oxidation of the COD (Chemical Oxygen Demand) present in the effluent to be treated [1,2]. Anaerobic bacteria spontaneously form an electroactive biofilm on the surface of that part of the MES and oxidizes the COD by transferring electrons to the electrode. This part of the MES acts as the electron acceptor (microbial anode). The upper part of the MES, located in the aerobic zone, ensures the evacuation of the electrons via the oxygen reduction reaction (cathode). The objective of the work was to optimize the oxygen supply in the upper aeration zone.

The challenge was to solubilize the amount of oxygen required for the extraction of electrons without disturbing the lower anaerobic zone. We have demonstrated that the efficiency of the COD abatement by MES depends on the open circuit potential (OCP) of the MES. Furthermore, the OCP and the soluble oxygen concentration are closely related (Figure 1-B). This correlation was used to optimize the operating protocol of the MES. Several types of reactors have been set up by varying the height of the aeration zone, the aeration mode, continuous or sequential, and its frequency.

The liquid phase of the reactors was aerated by air bubbling, which provides intensive gas-liquid transfer to ensure 100 % of O_2 solubility in the upper cathodic part of the MES. In response to aeration, the OCP of the MES increased by promoting the cathodic reaction until a high potential was reached around 0 V vs. SCE (Figure 1-B). When the OCP of the MES was high, oxygen availability was no longer rate-limiting and aeration was consequently stopped. The OCP then dropped after aeration had been stopped if the anode part of the MES is fully active and ensured efficient oxidation of the COD. Oxygen availability becomes rate-limiting again when the OCP of the MES is less than -0.4 V vs. SCE (Figure 1-B). This value was reached in around 30 minutes in our systems. When the OCP was lower than -0.4 V vs. SCE, there was no further COD treatment. In control reactors, COD abatement ceases as soon as aeration was stopped. The MES therefore made it possible to abate COD, even after aeration has been stopped, contrary to the control.

The aeration frequency was then optimized taking into account that too high aeration frequency can lead to aerobic oxidation of the COD (biological respiration), which is a nuisance to the desired bioelectrochemical oxidation. Finally, a sequential aeration with 30 minutes of aeration on top of the tank for 1h30 without aeration seemed to be the most appropriate.

The work is carried out within the framework of the ANR Biotuba project (ANR-17-CE06-0015-02).

Biological charge transport (CT) is the key step in many basic cellular processes, such as respiration or photosynthesis, and nature has developed highly specialized molecular building blocks to achieve it with unprecedented efficiency. Understanding the mechanisms behind biological CT, is key to elucidate the changes in its regimes caused by specific structural variations of the associated molecular machinery. Such knowledge will ultimately lead us to tailor its electrical properties and exploit them, in the near future, as high performance bioelectronic devices with a wide variety of applications in organic electronics, sensing, biomanufacturing etc.

To investigate CT in single-molecule bioelectronic devices, we exploit Scanning Tunnelling Microscopy-based approaches in the break-junction mode (STM-BJ)[1,2] under electrochemical control (EC-STM). It allows the trapping of individual molecules in a junction to characterize their main electrical signatures (*Fig. 1*).[2,3] We carry on our tunnelling transport studies in bio-inspired wires employing Azurin molecules (blue copper proteins) under electrochemical control. Azurin molecules present a classical metal-mediated *two-step tunnelling* transport, that results in a molecular conductance maximum when the electrochemical gate potential is adjusted to its characteristic redox midpoint value.[4] Such distinctive electronic behaviour allows to study deviations of the electron transport mechanism through the molecule, making Azurin a suitable test-bench for singe-molecule transport measurements.

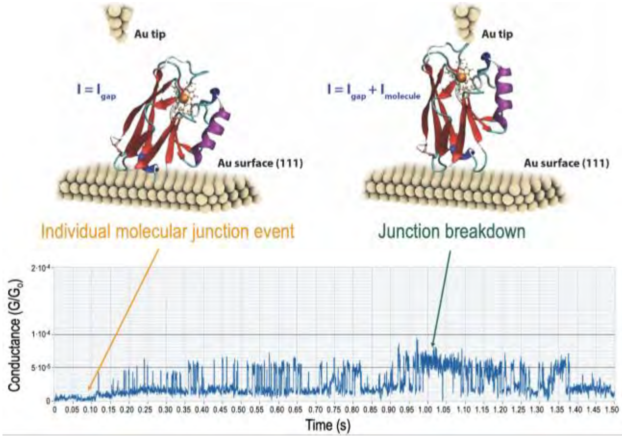

Figure 1. *Schematic representation of a metalloprotein molecule (Azurin) contacted between the STM electrodes and the captured current signal with single-molecule events which define the characteristic telegraphic-like stochastic switching.*

We will base this contribution by showing the work in progress on the development of a new hybrid platform with spectro-electrical single-molecule detection capabilities under ambient conditions. It aims to explore several key structural and physicochemical aspects, that remain unknown, during the single-molecule junction formation. This is possible thanks to the *operando* capabilities of the hybrid platform to work in the near-field Raman between the two STM electrodes (TERS) under electrochemical control. TERS represents a high ultra-sensitive non-destructive spectroscopic method with molecular resolution (*Fig. 2*). This new platform opens the gates to obtain detailed insights into the molecule's physical and chemical properties by simultaneously capturing the current during the spontaneous formation of a molecular junction, *i.e.* the evolution of spectro-electrochemical characteristics of the junction. In addition, due to the development of the new platform, novel singe-molecule effects under red-laser illumination (633 nm) have been revealed. Effects over the molecular conductance and transport mechanisms consequence to expose individual molecular junctions to a plasmonic field.

Catalysis of Redox-Neutral Reactions by Electron Exchange Between Electrodes and Organic Compounds

Robert Francke, Arend F. Roesel, Timo Broese, Adrian Prudlik, Michal Májek
Instiute of Chemistry, Rostock University
Albert-Einstein-Str. 3a, 18059 Rostock, Germany
robert.francke@uni-rostock.de

To most chemists the term ‘electrocatalysis’ is known as the facilitation of a heterogeneous electron transfer via a chemical interaction between the electrode and a substrate.[1,2] The opposite case, the utilization of a heterogeneous electron exchange to catalyze a chemical reaction (‘electrochemical catalysis’), is a much less known but yet a very powerful approach in electrosynthesis.[3] Here, the injection (or removal) of an electron into (or from) a substrate triggers a redox-neutral reaction (e. g. a molecular rearrangement) that may otherwise require harsh conditions and/or the use of reagents. Such processes involve the electrogeneration of an ionic or radical ionic species, which after a coupled chemical step either undergoes a backward electron exchange with the electrode (ECE^{b} mechanism) or triggers a chain process in the bulk solution. Under these circumstances, sub-stoichiometric amounts of charge are sufficient to achieve a full conversion and conceptionally, the electrons and holes can be understood as being catalysts.

In this contribution, the concept of electrochemical catalysis will be illustrated using the Newman-Kwart rearrangement (NKR) of *O*-aryl thiocarbamates **2** to the corresponding *S*-aryl compounds **3** as an example (see scheme below).[4] Generally, the NKR represents the key-reaction in the three-step synthesis of thiophenols **4** from phenols **1** and proceeds between 200 and 300 °C.[5] Electrochemical catalysis, however, allows for operation at room temperature and provides a complementary reactivity with respect to the arene substitution.[4] Recently, we have carried out a detailed mechanistic study using cyclic voltammetry, control experiments and quantum chemical calculations,[6] the results of which will be presented herein.

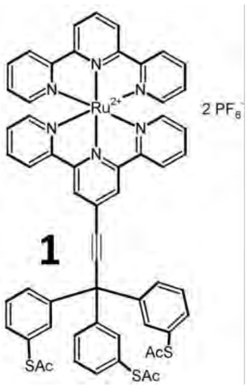
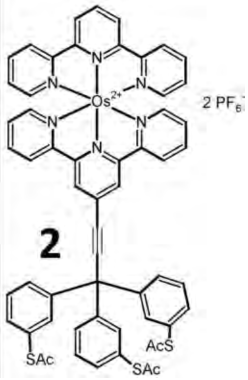
Organometallic complexes based on M(terpyridine)$_2^{2+}$ offer wide range of use for their photophysical and photochemical properties.[1,2] These molecules rank among the promising group of compounds for molecular electronics, new electrochromic devices and sensors. The aim of this contribution is a preparation and characterization of compact films of M(terpyridine)$_2^{2+}$ (M = Ru, Os) organometallic complexes on the electrode surface. Electrochemical behaviour of adsorbed molecules will be compared to their electrochemical properties in solution. One of the possibilities of molecular film preparation is structural addition of linker terminated by functional groups specialized for the formation of Au-S bond between molecule and gold electrode.[3] Tripodal arrangement of anchoring groups supports formation of fully compact self-assembled monolayers (SAMs) of redox active centers perpendicular to the electrode surface.[4]



1



2

The electrochemical properties of organometallic complexes **1** and **2** (for chemical structure see attached figure) were studied by cyclic voltammetry at various scan rate values in acetonitrile in non-adsorbed state on gold and glassy carbon electrodes and in the form of SAMs on the polycrystalline gold electrode. Cyclic voltammograms of **1** in non-adsorbed state show reversible voltammetric wave for Ru^{2+}/Ru^{3+} oxidation at E^0 = +0.910 V vs. Fc/Fc$^+$. Value of E^0 obtained for Os^{2+}/Os^{3+} oxidation of **2** was +0.562 V vs. Fc/Fc$^+$. These values are similar to E^0 values obtained for metal ion oxidation of the reference Ru(terpyridine)$_2^{2+}$ and Os(terpyridine)$_2^{2+}$ complexes.[2,5] Diffusion-controlled process was proved by a linear dependence of the oxidation peak current on the square root of the scan rate. Terpyridine ligands of **1** and **2** are reduced in two one-electron reversible processes and their E^0 values are shifted positively in comparison to M(terpyridine)$_2^{2+}$ complexes indicating easier reduction of newly prepared molecules **1** and **2**. SAMs of **1** and **2** were prepared by standard procedure.[4] Ru^{2+}/Ru^{3+} oxidation of **1** was observed at E^0 = +0.948 V vs. Fc/Fc$^+$, that of Os^{2+}/Os^{3+} oxidation of **2** was measured at +0.587 V vs. Fc/Fc$^+$. Adsorption of **1** and **2** was proved by linear dependence of peak current on the scan rate. The determined values of the surface concentration of **1** and **2** indicate that the molecules form compact monolayer, where all of the Au-S bonds are involved in the SAMs formation. SAMs of **2** are more compact compared to SAMs of **1** due to different management of Coulombic interactions within the SAMs.

Lithium ion batteries have been and are one of the major components in the portable electronics revolution, as well as in the transition to a more sustainable society based on electric mobility. To advance in this field, the research is strongly committed in the development of new nanostructured electrode materials, and in the deep understanding of the processes that are involved during charge/discharge.

Electronic and ionic transport at the electrolyte/electrode interface play a critical role during battery operation. In situ and in operando techniques represent powerful tools to investigate such phenomena. Electrochemical Impedance Spectroscopy (EIS) has been widely exploited to study the response of the electrode at different state of charge. This technique demonstrated that electrode impedance evolves during lithium intercalation mainly because of the formation of the solid electrolyte interphase. However, in the case of metal oxides EIS has also indicated that the inherent electronic properties of electrodes changes with the degree of lithiation. Despite excellent models have been proposed, EIS still does not enable a clear discrimination between the effect on the impedance of the charge transfer at the interphase and the electronic conductivity of the electrodes.

To address this challenging issue, here we report for the first time a systematic study on the electronic properties of electrode materials for lithium ion batteries at different state of charge by an electrolyte gated transistor set-up. This novel configuration allows to evaluate the evolution of the electronic characteristics of the materials in situ, i.e. during the lithium ion intercalation/de-intercalation. Specifically, a study carried out on Lithium Titanate and olivine and spinel cathodes is here reported and discussed.

Acknowledgments

The research has been carried out under the Executive Bilateral Program Italy-Quebec 2017-2019 "Electronic properties of nanostructured materials for energetics" (M02241, QU17MO01).

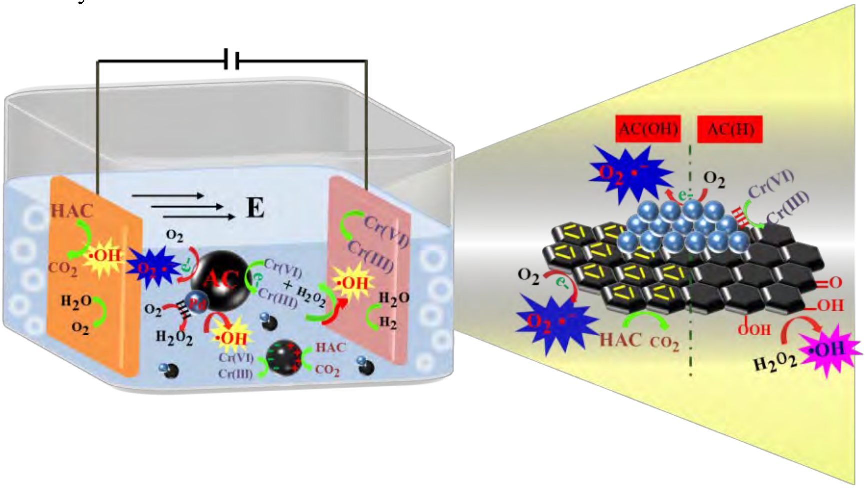
Abstract: Electrochemical advanced oxidation processes (AOPs) represent an efficient and promising strategy for dealing with the ever-growing water pollution. Meanwhile, carbocatalysis has long and widely been applied in the fields of synthesis and catalysis because of high activity and selectivity. In this work, we combined the advantages of these two methods and for the first time proposed a conceptual new, novel and promising approach of electrochemical-driven carbocatalysis as highly efficient AOPs for water remediation, which was simply performed by adding carbon-based particles into the electrochemical system. This method shows great potentials for the simultaneous removal of both humic acid (HAC) and Cr(VI) in water, in which HAC was effectively mineralized with a TOC removal efficiency as high as 90% and Cr(VI) was completely removed with a total Cr removal beyond 90%. The presence of carbon particulate materials and their physicochemical properties were first indicated to play critical roles in the developed electrochemical AOPs. These added carbonaceous particles such as activated carbon (AC) and a series of modified AC materials, on one side exerted an important carbocatalytic function with typical AOPs features and on another side, they behaved like numerous galvanic cells with quasi-homogeneous catalytic properties, greatly facilitating mass and electron transfers in the electrochemical system and resulting in a synergistic effect for the removal of combined pollutants. The physicochemical properties of these carbon particulate catalysts facilitated the simultaneous occurrence of adsorption and carbocatalysis, where a synergistic effect between adsorption and catalytic oxidation was confirmed in this electrochemical-driven carbocatalysis system. Moreover, the catalytic performances and mechanisms of this system were found to be dependent on the carbon structures (e.g., surface area, functional groups and hybridization structure, etc.). Very importantly, the energy-effective feature and the carbon materials stability showed a promising prospect of this approach with energy consumption much lower than the ever-reported electrochemical AOPs. This work details the first insight into electrochemical-driven carbocatalysis and provides a new, green and promising approach for effective water remediation, as well as gives new evidence for the synergistic effect between adsorption and catalytic oxidation.



Schematic mechanisms of carbonaceous particles-promoted electrochemical AOPs for simultaneous removal of HAC and Cr (VI).

Carbon paste electrodes are composed of at least carbon materials and pasting liquids. Frequently some additives are added to make modified carbon paste electrodes. Commonly, carbon paste electrodes are well known as bulk electrodes. However, electrochemical reactions occur in the surface of carbon paste electrodes. Therefore, carbon paste electrodes can be regarded as unique renewable membrane-based electrodes. The presence of both solid materials (carbon materials etc) and liquid materials (pasting liquids) in carbon paste electrodes endows them many unique features in comparison with pure solid electrodes.

We present here the application of carbon paste electrodes to enhance the stability of electrochemical generated intermediates and the electrochemical oxidation activity of azide as well as to expand electrochemical window and improve reproducibility for stripping analysis by pasting liquids (1-3).

There is a growing interest for the regeneration of the cofactor NAD(P)H due to its large-scale biosynthetic applications and its high price. Different methods including: chemical, electrochemical, photochemical, microbial, and enzymatic reactions have been developed for this aim. Among all the cited cofactor's regeneration methods, the electrochemical regeneration is a continuous electron-transfer process, where the regeneration of NAD(P)H is loaded only with an electrode. In this work, we focus on coupling efficiently hydrogen oxidation to NAD^+ reduction. To reach this objective, we combined the electrochemical regeneration of NADH mediated by a dissolved rhodium complex on the carbon felt electrode of the cathodic compartment[1], the application of continuous flow reaction, and the hydrogen oxidation using a GDE at the anodic compartment in a single system. The Nafion membrane between the anodic and the cathodic compartments allows transfer of H^+ from the anodic to the cathodic compartment. To optimize the proposed process, various factors have been varied e.g. rhodium complex concentration, NAD^+ concentration, pH, the activation procedure for the carbon-based electrode, as well as the cell operating conditions such as the hydrogen and the solution flow rates.

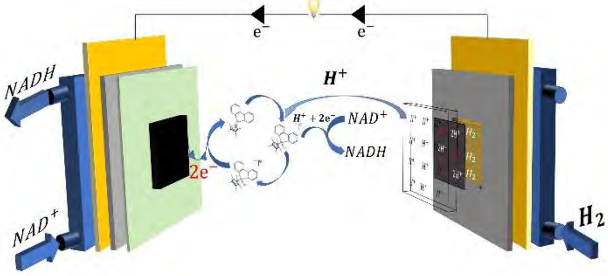

Figure 1. Functional scheme of the flow bioreactor

The efficient regeneration of NADH featured with a complete conversion and with a high faradaic yield can be reached by fixing different parameters for the used reactor: hydrogen and solution flow rates (20 mL/min), Ratio $[NAD^+]$ over $[Cp^*Rh(bpy)Cl]^+$ at 40, pH near 7 to avoid NADH and NAD^+ degradation), and with a carbon felt electrode activated in solution instead of a carbon felt thermally activated.[1]
Based on this optimized process, our actual work focuses on the covalent immobilization of the rhodium complex, that is economically desired on the laboratory and industrial scales, on the surface of a carbon felt electrode was achieved by following a two steps protocol described by us recently using a bucky paper electrode.[2,3] In addition, the rhodium complex covalent immobilization allows us to involve two reactions in the cathodic compartment: the regeneration of NADH simultaneously followed by an enzymatic reaction such as the bioconversion of D-sorbitol into D-fructose while immobilizing D-sorbitol dehydrogenase on another carbon felt. In addition, the bioconversion of D-sorbitol proves that the regenerated NADH is active and allows us to apply the regenerated cofactor as an electron carrier in enzymatic systems catalyzing stereo- and regioselective reactions having a great biotechnological potential.

Electrochemical void pinning and liquid metal effect on electromigration resistance in 2D aluminium and copper alloys

Andrei Ionut Mardare, Saeedeh Ravandi, Jan Philipp Kollender, Cezarina Cela Mardare,

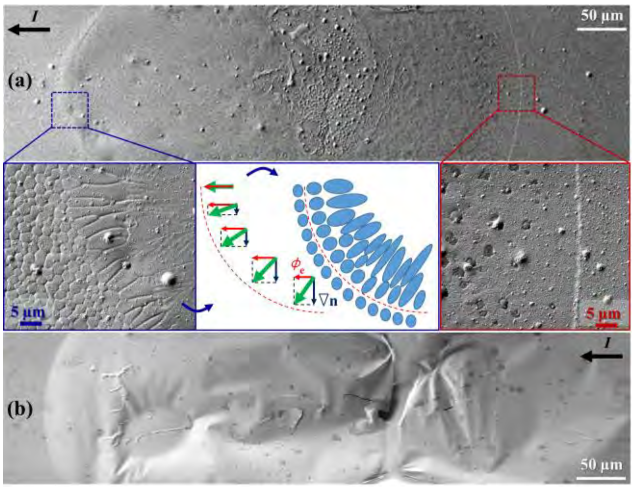
andrei.mardare@jku.at

Bidimensional (2D) conducting materials in form of thin and ultra-thin films are extensively used in our daily life. The proper functioning of every solid-state or electrochemical device relies on electrical current flowing through the working electrode. In extreme situations the current density passing through a 2D wire may lead to an irreversible morphological change resulting in an open circuit condition and total device failure. This occurs due to the effect of high electron fluxes on atoms residing in the conducting material that are forced to migrate along the wire in the current flow direction. Such electromigration phenomenon is present with different intensities in any electrical device and is enhanced in 2D electrodes due to the small cross-sections through which even low voltages may induce substantial current densities. The nowadays recognized model describing electromigration is based on the concept of voids and hillocks formation. During high electron fluxes atoms will migrate pilling up material close to anode while at the cathodic side voids with increasing size will form. Thus, one way of retarding or even blocking electromigration may be thought in decreasing the surface void mobility.



The current work addresses this issue. Various thin film combinatorial libraries based on Al and Cu were tested for this purpose. Two different approaches were involved. Firstly, anodic passivation of Al and Cu alloys was applied in an attempt to remove the free metallic surface available to voids and thus pin them down making the material migration more difficult. Additionally, amorphization of Al and Cu alloys was tested by alloying them with larger atoms such as Sm. The main advantage of an amorphous 2D conducting wire would be found in a complete lack of surface grain structuring impeding the void migration. Secondly, Al and Cu 2D test wires were alloyed with Ga in a combinatorial fashion and high throughput experimentation was performed for assessing the influence of the liquid metal atoms on the electromigration process. The dynamics of such electron flux induced atomic movement was modeled and the grain boundaries pinning by Ga was demonstrated. This is briefly illustrated in the figure for one Al-Ga alloy deposited on SiO_2 substrate (a) or polymer substrate (b) for flexible electronics applications. The direction of the current flow and hence anodic and cathodic regions of the 2D test wire are visible in the figure together with the central irreversibly damaged zone. In conclusion, several routes for improving electromigration resistance of Al and Cu 2D alloys were tested. Even though an electrochemical surface treatment did not prove a clear void pinning effect, still it remains an avoidable approach for improved devices. Additionally, the use of small Ga amounts alloyed with Al or Cu resulted in a clear enhancement of resistance against electromigration even in flexible electrodes deposited of polymeric substrates.

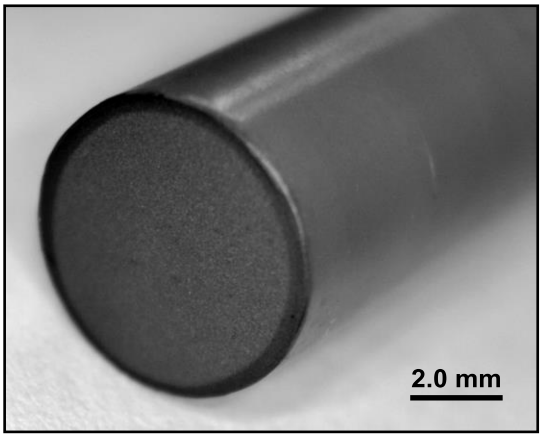
Microcrystalline Natural Graphite–Polystyrene Composite Film – Ten Years of Its Application in the Development of Electrochemical (Bio)Sensors

Vlastimil Vyskočil, Pavel Dvořák
Charles University, Faculty of Science, Department of Analytical Chemistry, UNESCO Laboratory of Environmental Electrochemistry, Hlavova 2030/8, 12843 Prague 2, Czech Republic
e-mail: vlastimil.vyskocil@natur.cuni.cz

A microcrystalline natural graphite–polystyrene composite film electrode (CFE, see the Figure) [1] represents a very promising alternative to electrode surfaces modified by carbon nanoparticles with profitable electrocatalytic properties (e.g., nanotubes or graphene) as well as to commercially available disposable screen-printed carbon working electrodes. Its simple, fast, and inexpensive preparation (surface of a classical solid working electrode in a glass or plastic electrode body is covered with a carbon ink suspension – a mixture of 0.09 g of micronized natural graphite with a particle size of 3.5–5.5 μm and 0.01 g of polystyrene in 0.5 mL of 1,2-dichloroethane), simple mechanical renewal of the electrode surface (by wiping off the old film with a filter paper and forming a new one), good reproducibility of measurements, elimination of problems connected with the "electrode history", and simple chemical modification are among the main advantages [2]. Recently, it has also been shown that the CFE is a suitable transducer for the preparation of electrochemical DNA biosensors [3].



In this contribution, a complex electrochemical and microscopic characterization of the composite film will be presented, and possibilities, advantages, and limitations of this beneficial electrode material will be demonstrated on a number of electroanalytical methods utilizing the CFE-based (bio)sensors for the determination of various biologically active organic compounds (drugs [2], agrochemicals [4], environmental pollutants [5,6]) and for the detection of DNA damage induced by mutual interactions between DNA and various xenobiotic agents (chemical carcinogens [3], hydroxyl radicals [7]).

This research was carried out within the framework of the Specific University Research (SVV 260560). Its financial support provided by the Czech Science Foundation (Project GACR 20-01589S) is gratefully acknowledged.

Abstract: Lithium ion battery (LIB) attracted massive attention because of its high energy density, light weight, and good capacity retention like characteristics. Li_2MSiO_4 (M = Fe, Mn, V, Cr, Co, Ni, etc.) attracted attention recently due to their high theoretical energy density ~ 333m Ahg^{-1}. However, these materials suffer with strong electrochemical capacity fading because of intrinsic Jahn-Teller distortion [1] in the active cathode material together with insulating characteristics. We synthesized phase pure Li_2MnSiO_4 material and doped chromium at Mn site to circumvent some of the issues with present cathode material. The Cr^{3+} doped $Li_2Mn_{1-x}Cr_xSiO_4/C$ (x = 0, .01, .03, .06) nanocomposites are synthesized using sol-gel method. A coating of graphitic carbon on nanostructured cathode material i.e. $Li_2Mn_{1-x}Cr_xSiO_4/C$ is achieved by using carbon precursor during synthesis, Fig 1. The carbon coating is used to increase the electric conductivity and reduce the particle size by restricting the growth after carbon covering. The detailed structural and microstructural characterizations are carried out using X-ray diffraction and scanning electron microscopic measurements. Thermogravimetric (TGA) measurements are carried out to understand the amount of carbon loading and thermal degradation of cathode materials. The cyclic voltammetry and AC impedance measurements are carried out to understand the electrochemical properties and ionic conductivity of synthesized materials. XRD measurements, Fig 1, showed orthorhombic crystal structure with $Pmn2_1$ phase space group. The crystalline size for pure Li_2MnSiO_4/C samples is the largest and decreases with increasing Cr doping at Mn sites for x=0.01 and 0.06 concentration. The carbon coating is substantiating by the observed C=O vibration modes in FTIR, which disappeared in the sample after TGA measurements (up to 900 ºC). The Cr^{3+} doping in $Li_2Mn_{1-x}Cr_xSiO_4/C$ is substantiated by the observed shifting in XRD, and FTIR peaks. The oxidized carbon reduces with increasing Cr^{3+} doping, as observed in FTIR [2]. The work will discuss the impact of Cr^{3+} in terms of structural stability, and electrochemical properties such as ionic conductivity and impedance characteristics.

Hydrogen is a promising "clean" fuel that produces only water when consumed in a fuel cell. However, it is explosive in nature (in air at concentrations of 4–75% by volume), which makes it a dangerous gas to store and transport. The detection of leaks of hydrogen is of utmost importance to ensure safety in future applications. Among other techniques that can be used for hydrogen detection, amperometric sensors are one type of technology that can be used for this purpose.[1] Room temperature ionic liquid (RTIL) solvents are gaining interest as replacement solvents in amperometric gas sensors as a result of their low-volatility, combined with other useful properties such as high chemical and thermal stability, wide electrochemical windows and good solvation properties. However, a challenge with RTIL solvents is the higher viscosity compared to conventional solvents can slow down diffusion and response times.

In the first part of my talk, I will discuss our work on a new design of modified electrode that can detect hydrogen very quickly upon introduction of the gas. The sensor consists of an array of gold microchannel electrodes, electrodeposited with platinum nanoparticles (PtNPs) to enable hydrogen electroactivity. Very thin layers (~9 μm) of room temperature ionic liquids (RTILs) resulted in an extremely fast response time of only 2s, significantly faster than the conventional electrodes studied.

In the second part of my talk, I will describe the modification of electrode surfaces with a metal-organic framework (MOF) as a low-cost alternative electrode material for hydrogen detection. A common MOF, HKUST-1, with copper nodes and 1,3,5-benzenetricarboxylic acid struts between them, was electrodeposited from aqueous solvents onto a glassy carbon (GC) electrode (see Figure 1). The MOF-modified GC electrode exhibited significantly enhanced activity towards the detection of hydrogen gas in the RTIL $[C_2mim][NTf_2]$. The response of HKUST−1/GC electrode in the presence of hydrogen was four times higher than a pure Pt electrode under similar conditions (Figure 1. Hydrogen appeared to become trapped in the pores of the MOF structures. This study highlights the successful application of cost-effective pristine MOF thin-films in combination with RTILs for low-cost gas leak-detection applications.

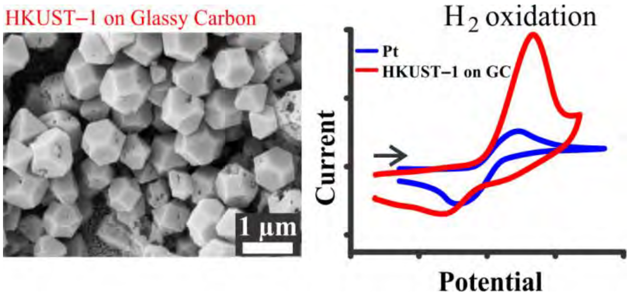

Figure 1. (left) Scanning electron microscopy image of the electrodeposited MOF, HKUST-1, on a glassy carbon electrode, (right) Cyclic voltammetry for hydrogen oxidation in an ionic liquid on the HKUST-1 modified GC electrode (red) compared to a conventional noble metal (Pt) electrode.

Organic electrodes For Energy Storage and Conversion

Yonggang Wang
Department of Chemistry and Shanghai Key Laboratory of Molecular Catalysis and Innovative Materials, Institute of New Energy, iChEM (Collaborative Innovation Center of Chemistry for Energy Materials), Fudan University, Shanghai 200433, China
e-mail: ygwang@fudan.edu.cn

Organic electrode materials are attracting extensive attention, because they offer new possibilities for high energy/power density, cost-effective, environmentally friendly, and functional rechargeable batteries.[1] Charge storage of organic compounds involves an n-type doping/de-doping mechanism (e.g., the reversible enolization C=O ⇌ C-O-M, where M is a small electrolyte cation such as Li^+, Na^+, or K^+) and/or a p-type doping/de-doping mechanism (e.g., the redox reactions accompanied by the reversible adsorption/desorption of large electrolyte anions).

In this talk, we will introduce our recent work about charge storage characteristics of organic electrode materials, including the electrode kinetics, electrochemical stability, chemical stability, and de-solvent at interface. According to these characteristics, we design the organic based aqueous Li (or Na) ion battery with a super-long life of 50,000 cycles, [2-3] organic based Mg (or Zn) ion aqueous battery for grid energy storage, [4-7] organic based battery operated at -70 °C,[8-10] and the new application of organic electrode as proton buffer electrode for decoupled water electrolysis.[11,12] Finally, the challenge and opportunity of organic electrode materials will be briefly discussed.

ulrike.krewer@kit.edu

Numerous interacting processes affect electrochemical reactions at technical electrodes. Mass transfer, reactions and double layer charging are strongly coupled, which makes the quantitative description of porous electrodes a challenging task. Therefore, a thorough understanding of the transport and reaction phenomena is indispensable for designing better electrodes and processes.

Dynamic techniques such as electrochemical impedance spectroscopy (EIS) are often used to disentangle the individual processes and gain a better understanding. However, not all processes can be identified by EIS. In such cases, additional information may be obtained by recording further quantities besides current and potential.

In this work we present a new method to observe the dynamics of the transport of volatile species in porous electrodes during electrochemical reactions in addition to current and potential. We call this technique species frequency response analysis (sFRA). Model-based analysis is used to extract transport and kinetic parameters from the experimental results.

We demonstrate the capabilities of the new method by investigating the electrochemical methanol oxidation reaction on a porous Pt/Ru electrode. Differential electrochemical mass spectrometry is used to measure the dynamics of current, potential and the flux of the gaseous reaction product CO2. A one-dimensional mathematical model of the processes in the electrodes is developed and employed to analyse the transfer function that relates current density with CO2 flux.

We show how reaction and transport phenomena can be separated in the sFRA Nyquist plot by the model-based analysis. Effective electrode transport parameters and kinetic parameters are determined and we demonstrate that particularly transport parameters can be estimated with a better sensitivity by sFRA than by EIS.

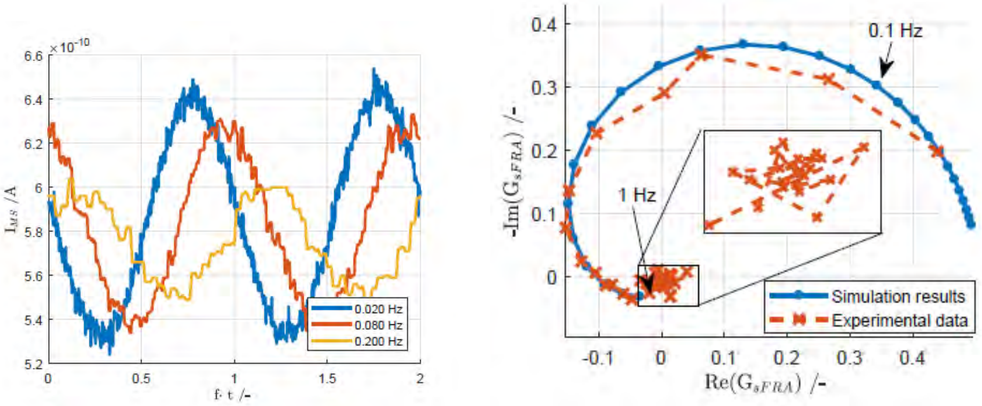

Fig. 1 Left: MS Signal over normalized time during sFRA measurement. Right: Nyquist plot of the sFRA spectrum [1].

The electrochemical behavior of a series of *S*-phenacyl-O-ethyl-xanthates (O-ethyl-dithiocarbonate acetophenone derivatives) in hydroalcoholic (MeOH/H_2O 4:1) and anhydrous media (ACN_{anh}/$TBAPF_6$) using carbon electrodes was studied. Cyclic voltammetry showed in hydroalcoholic media only two cathodic waves, whereas in ACN_{anh} one anodic and two cathodic waves were present. The first cathodic wave corresponded to the reduction of the phenylketone group, whereas the first anodic was attributed to the xanthate unit. Macroelectrolysis on graphite and vitreous carbon at anodic and cathodic potentials, let us to explore the synthetic potential of this electrochemical reactions. With some compounds in hydroalcoholic media and using carbon electrodes, polymeric material was deposited on the electrode impeding the reaction; this deposit was characterized by AFM and SEM-EDS. The electroreduction on Ti electrode overcome this problem and gave the corresponding acetophenones (>95%). On the other hand, in ACN_{ahn}, small quantities of the dimeric 1,4-dicarbonyl compounds X-$PhCOCH_2CH_2COPh$-X (7-15%), as well as the corresponding acetophenones (*ca.* 50%) were isolated. Oxidation macroelectrolysis showed a very complicated transformation without synthetic value. The reaction mechanism for the reduction and the homolytic dissociation into the phenacyl radical was confirmed by DFT calculations.

aldozarbin@ufpr.br

This work aims to present a novel, simple and efficient strategy to both synthesize and process complexes and multi-component electroactive materials as thin films, developed by our research group, based on the interface between two immiscible liquids [1-10]. This one-pot and single-step methodology takes advantage of the high interfacial energy at a liquid/liquid (L/L) interface to induces a spontaneous self-assembly of different solids, as a thin film (few nanometers in thickness) that can be easily deposited over different kind of substrates, plastics included. The technique allows the deposition of high homogeneous thin films of electroactive single- or multi-component materials (as different nanocomposites) that cannot be deposited using conventional routes. Here, we will present the fundaments of the liquid/liquid interfacial route (LLIR) to thin films, and demonstrate several examples of preparation and application in different fields. Films of carbon nanotubes- or graphene-based nanocomposites with conducting polymers [1-5], oxide/hydroxide nanoparticles [6-8] or Prussian blue analogues [9-12], as well as nanocomposites of 2D materials-based nanocomposites (as MoS_2 [13] or black phosphorous [14]) will be demonstrated, and their application as high-performance active components in transparent and flexible electrodes [4], transparent Na- [12,13] and K-ion [3,9] or alkaline [7,8] batteries , supercapacitors [2], electrochromic materials [1,5,9], photovoltaic devices [5,11], electrodes for HER, electrochemical sensors [1,7], among others, will be discussed.

Redox-enabling the electrical double-layer: redox-electrolytes vs. redox-materials

Volker Presser
INM – Leibniz Institute for New Materials & Saarland University,
Campus D2 2, 66123 Saarbrücken, Germany
volker.presser@leibniz-inm.de

Ion electrosorption, in combination with highly porous carbon electrodes, enables high power energy storage and recovery. As our understanding of the delicate nature of the electrical double-layer has improved, and with the use of advanced electrolytes with increased voltage stability, electrical double-layer capacitors have seen an increase in performance metrics. However, the charge storage capacity is fundamentally limited when excluding charge-transfer processes.

A straightforward approach is the compounding of carbon wit ha redox-active material (mechanical mixing). Electrodes based on composite materials are an easy way to transition from supercapacitor to battery seamlessly and allows cost-effective technology hybridization. The optimization must carefully consider material properties and performance metrics. For example, lithium manganese oxide benefits from a composite with activated carbon while lithium titanate already provides fast charge/discharge metrics to such an extent that no real benefit is gained from composite electrodes.[1, 2]

Another approach is the implementation of redox-active materials at the fluid/solid interface – basically, via nano-decoration of carbon surfaces with, for example, metal oxide materials. We discuss the benefits (and limitations) of doing so with advanced technology (esp. atomic layer deposition). In particular, the choice of carbon and its pore architecture is a crucial aspect of material hybridization.[3-7]

Finally, instead of using a solid/solid material combination, redox-activity can also elegantly be unlocked by combining highly porous carbon with redox-active electrolytes. The latter may contain a fluid/solid transition (electrodeposition), or the redox-ions may remain dissolved in the electrolyte during the entire charge/discharge process. Again, the carbon pore architecture is an important aspect to consider in addition to mitigating ion shuttling (which may cause rapid self-discharge).[8-10] Yet, the synergy of fast charge transfer and enhanced charge storage capacity accessible with redox-electrolytes make them a desirable domain for beyond-EDL-systems.

Strategies for enhancing Corrosion Protection by Organic Coatings

Michael Rohwerder
Max-Planck-Institut für Eisenforschung
Max-Planck-Str.1, 40237 Düsseldorf, Germany
rohwerder@mpie.de

Organic coatings are an important pillar of corrosion protection. Usually they are mainly viewed as passive barriers that prevent the access of corrosive species to the metal. However, they often have also an active function, as they often contain active pigments that can release corrosion inhibitors. For high passive delamination resistance, usually the metal has to be pretreated prior to application of the organic coating, e.g. by phosphating, in order to prevent cathodic delamination, which is the fastest delamination mode. The main function of such conversion coatings is to impede electron transfer to oxygen that has to diffused through the coating the interface between coating and metal. Novel approaches how inhibit cathodic delamination without use of any conversion layers will be discussed. Concerning active protection by organic coatings the focus of current research is on so called self-healing coatings, often also referred to as smart or intelligent self-healing coatings. For realizing such intelligent coatings showing high level self-healing performance the design strategies differ from those that have to be followed for achieving optimum passive performance. The basic principles of passive and active performance will be highlighted in detail and implications for developing novel strategies will be discussed and latest research examples will be presented.

Electrolyte Influence on the Electrochemical Oxidation of Terbium and its Stabilization in Aqueous Media

Lanthanides are used in various applications such as luminescent materials, magnets, catalysts, MRI reagents and (radio-)pharmaceuticals. Characteristic of their chemistry is the dominance of the trivalent oxidation state. As the 4f subshell is filled with electrons that are shielded by 5s and 5p electrons, 4f electrons are not participating in ligand interactions and chemical bond formation, resulting in similar chemical properties across the lanthanide series. The combination with their variable nuclear properties inspired their use in the field of nuclear medicine.

Apart from the generally dominant trivalent oxidation state, several lanthanides can occur in other oxidation states as well. For example, Sm, Eu and Yb have a relatively stable divalent state. Among these lanthanides, Eu(II) shows higher stability compared to Sm(II) and Yb(II) in aqueous media. There are several studies on the reduction of Eu by using either chemical, electrochemical or photochemical techniques for subsequent use in lanthanide separation. Whereas the most common electrolyte used in the reduction of Eu is chloride, recently reduction and stabilization of Eu(III) was achieved in concentrated nitrate media as well [1]. On the other hand the tetravalent state is well established for Ce ($E^0 = +1.72$ V vs. SHE), both in the solid state and in solution. Besides Ce, Tb ($E^0 = +3.1$ V vs. SHE) can also be oxidized to its tetravalent state, for example in mixed valence states in its oxide form. However, there is limited information on the oxidation of Tb(III) besides that it can be stabilized in concentrated carbonate solutions [2].

In this study, the oxidation of terbium is investigated via electrochemical methods. Tb(III) is oxidized in carbonate media via bulk electrolysis and the Tb(IV) product is identified via UV-Vis spectroscopy. A detailed parameter analysis is done to gain further insight in the reaction rate, stability and pH sensitivity of Tb(III) oxidation. Additionally, Tb(III) is oxidized in different electrolytes such as periodate and nitrate. Among all electrolytes the oxidation and stabilization is found to be the most efficient in concentrated carbonate solutions at relatively high pH. In addition, the kinetics of the Eu(III)/Eu(II) redox couple are studied using a rotating disc electrode. The gained insight in Eu(III) reduction in nitrate and chloride media, could also improve our understanding of Tb(III) oxidation. Once full control is achieved over the Tb(III) oxidation process, it could be applied in the separation of Tb from other lanthanides.

imarquez1@us.es

The combined study of the redox and acid/base properties of iron porphyrins is important to understand the effect of both the oxidation state of the metal center and the ionization state of the acid/base groups on the coordinative chemistry of heme.[1] In general, the interfacial electron transfer of metalloporphyrins is coupled to protonation / deprotonation processes involving their ionizable groups,[2] aimed at stabilizing one of the redox states involved in the process. Quantification of these proton-coupled electron transfer processes in hemin is useful to identify the molecular factors that control the redox potential of hemoproteins, and to rationalize the conformational changes induced by the exchange of ionizable ligands.[3]

Motivated by the discrepancy of the titration curves reported in literature for hemin immobilized onto graphite electrodes, we have revisited the effect of the solution pH on its voltammetric features. It has been found that its proton-coupled electron transfer is accompanied by binding events with the commonly used phosphate and acetate buffers that provoke significant deviations from the $1e^-/1H^+$ transfer expectations in the acid region. It is shown that these bindings involve the oxidized aquo-hemin complex and the ionized forms of the buffer, so that they are restricted to the pH interval where these particular forms coexist. A theoretical expression has been derived for the pH dependence of the redox potential taking into account the binding and acid/base speciation of the relevant species. Theoretical titration curves are characterized by an intermediate plateau, whose onset and extent vary with the buffer concentration in a similar way to that found experimentally. Fit of the theoretical expression to the experimental voltammetric titration curves allowed us to quantify the pK_a value of the iron-bound water molecule (3.85) as well as the hemin-acetate and hemin-dihydrogen phosphate binding equilibrium constants ($1.1\cdot10^4$ and $6.4\cdot10^3$, respectively), that reveals a greater affinity of hemin for the acetate anion than for dihydrogen phosphate. The negligible binding of hemin to the monohydrogen phosphate dianion is ascribed to both i) the electrostatic repulsion with the negatively charged propionate residues of hemin and ii) the low population of the aquo-hemin complex, since most of the water ligand has been replaced by hydroxide in the pH region of coexistence with monohydrogen phosphate.

Overall, this work provides a more complete speciation of immobilized hemin than previously considered, showing the substitutional lability of the aqua ligand in the oxidized state of the iron center and the reluctance of its hydroxyl counterpart to participate in an anion exchange with the buffer components.

Smart Electrochromic/Thermotropic Windows of Energy-Efficient Buildings based on Different Electrolytes

Verónica de Zea Bermudez
Department of Chemistry and CQ-VR, University of Trás-os-Montes e Alto Douro, 5000-801 Vila Real, Portugal
vbermude@utad.pt

Progress, economic growth, and well-being depend critically on energy. To meet environmental challenges and to address the energy demand of future generations, a global energy technological transition based on low-carbon alternatives and renewable sources is urgent. The ultimate target is to guarantee affordable, reliable, safe and universal access to energy. At least part of the energy solution lies in the building sector which accounts for about 40% of the primary energy use and related greenhouse gas emissions. Modern buildings use energy to provide occupants with thermal (heating, cooling and ventilation) and visual (lighting) comfort, and to power major appliances. Windows, a component of the buildings envelope, offer key opportunities in terms of energy saving, as they are responsible for ca. 10% of the total energy consumed in the building. The development of dynamic windows enabling the control in real time of sunlight transmittance (visible radiation) and solar heat gain (near-infrared (NIR) radiation) to internal or external conditions, or to the occupant's choice, and adapted to all types of climates, is extremely attractive. In particular, electrochromic windows have huge potential to reduce energy use, increase indoors thermal/visual comfort, and improve outdoors view [1].

Device systems with an archetypal five layer configuration comprising cathodically coloring tungsten oxide (WO_3), anodically coloring nickel oxide (NiO), two visible- and NIR-transparent conductive oxide layers (amorphous indium zinc oxide (a-IZO) [2-4] and indium molybdenum oxide (IMO) [5]), and an electrolyte layer were assembled. Three classes of electrolytes differing in the nature of the host matrix, dopant species, and synthesis procedure, were investigated: (1) Hybrid polymer/siloxane electrolytes prepared by the sol-gel process and doped with a protonic ionic liquid [2], a mixture of lithium and erbium salts [5], or a mixture of a lithium salt and an erbium complex [5]; (2) Polymer electrolytes composed of seaweeds-derived k-carrageenan polysaccharide and an erbium salt [3]; (3) Non-Newtonian nanofluid electrolytes based on glucose-derived carbon dots functionalized with a thermotropic ionic liquid [4,6]. The three electrolyte design strategies adopted resulted in sustainable electrochromic [2,3,5], thermotropic [4,6] or integrated thermotropic/electrochromic [4] devices with outstanding performance.

Powering Catalysis and Growth in Microorganisms Using Electrochemistry and Synthetic Biology

Caroline M. Ajo-Franklin, Sara Tejedor-Sanz, Moshe Baruch, Lin Su
Department of BioScicences, Rice University
6100 Main St., Mailstop 140, Houston, TX, USA 77005
cajo-franklin@rice.edu

Microorganisms precisely control biological processes, including biosynthesis and cell growth, by regulating the redox state of different biomolecules. These processes can be modulated by electrochemically coupling intracellular biomolecules to an external electrode, but current approaches afford only limited control and specificity. Here we describe using electrical current to reduce specific biomolecules, allowing control of biosynthesis and cell growth in two industrially relevant microorganisms, *Escherichia coli* and *Lactobacillus plantarum*.

To enable electrochemical control of *E. coli*, we used synthetic biology to introduce a heterologous electron transfer pathway. *E. coli* expressing *mtrCAB* from *Shewanella oneidensis* MR-1 consumed electrons directly from a cathode when fumarate or nitrate, both intracellular electron acceptors, were present. The fumarate-triggered current consumption occurred only when fumarate reductase was present, indicating all the electrons passed through this enzyme. Moreover, MtrCAB-expressing *E. coli* used current to stoichiometrically produce ammonia. Thus, our work introduces a modular genetic tool to reduce a specific intracellular redox molecule with an electrode, opening the possibility of electronically controlling biological processes such as biosynthesis and growth in any microorganism.

Complementing this approach, we discovered that *L. plantarum*, a lactic acid bacteria used industrially to produce fermented foods, can uptake electrons. This electron uptake occurs under anaerobic conditions when a terminal electron acceptor and its corresponding oxidioreductase are present. Unlike other anaerobic respiratory modes in *L. plantarum*, this current consumption does not require addition of co-factors such as heme or riboflavin. Electron uptake promotes cell growth and acidification of the media, both processes essential for food fermentation. We find that the *L. plantarum* metabolism is shifted towards ATP producing pathways in the presence of both a cathode and a suitable electron acceptor. This surprising discovery opens the possibility of using electrical current to drive industrial production of fermented foods using lactic acid bacteria.

A Voltammetric Study of Nitrogenase Catalysis Using Electron Transfer Mediators

Artavazd Badalyan, Zhi-Yong Yang, Lance C. Seefeldt
Department of Chemistry and Biochemistry, Utah State University
0300 Old Main Hill, Logan, UT 84322, USA
a.badalyan@usu.edu

The selective reduction of N_2 to NH_3 is a major challenge for industrial, biological, and synthetic chemistry.[1] In nature, the enzyme nitrogenase catalyzes the nitrogen reduction under mild conditions.[2] The molybdenum-dependent nitrogenase consists of two component proteins (Figure 1a): the molybdenum-iron protein (MoFeP) and the iron protein (FeP). MoFeP houses two unique cofactors, the electron carrier [8Fe-7S] (P-cluster) and the catalytic [7Fe-9S-1Mo-C-homocitrate] (FeMo-co). FeP contains a single [4Fe-4S] cluster and two MgATP binding sites. During the catalytic cycle, the FeP is reduced either by flavodoxin or ferredoxin (*in vivo*), or sodium dithionite or reduced methyl viologen (*in vitro*), and binds two MgATP molecules. Then FeP transiently associates with the MoFeP, transfers an electron followed by hydrolysis of two MgATP molecules and dissociation from MoFeP. The released oxidized FeP is reduced, the two MgADP are replaced by two MgATP, making FeP ready for another round of MoFeP reduction. In the presence of N_2, this cycle (called the FeP cycle) is repeated eight times to achieve the reduction of the N_2 to two ammonia molecules (eq 1). In the absence of N_2, nitrogenase catalyzes the reduction of protons to H_2 (eq 2).

$$N_2 + 16\ \mathrm{MgATP} + 8\ H^+ + 8\ e^- \rightarrow 2\ NH_3 + H_2 + 16\ \mathrm{MgADP} + 16\ P_i \qquad (1)$$

$$4\ \mathrm{MgATP} + 2\ H^+ + 2\ e^- \rightarrow H_2 + 4\ \mathrm{MgADP} + 4\ P_i \qquad (2)$$

In this study, a mediated cyclic voltammetry approach was developed that provides a quantitative analysis of electron flow through nitrogenase.[3] Conditions were optimized to reveal the catalytic reaction rate-limiting step. Analysis of the current response by an electrochemical approach yielded a catalytic rate constant (k_{cat}) of 14 s^{-1}, consistent with earlier studies. The current approach was used to resolve a long-standing conundrum in nitrogenase research, the apparent inhibition of electron flow through nitrogenase with increasing partial pressures of N_2. It was demonstrated using this voltammetric approach in the absence of the reductant dithionite that total electron flow through nitrogenase remains constant up to an N_2 partial pressure of 1 atm.

Scalable biofilm electrodes

Haluk Beyenal, Abdelrhman Mohamed
The Gene and Linda Voiland School of Chemical Engineering and Bioengineering, Washington State University, Pullman, Washington, United States
beyenal@wsu.edu

Bioelectrochemical systems (BESs) suffer from scale-up limitations. This is one of the major bottlenecks preventing the utilization of technology in practical applications. For example, Figure 1 shows how maximum current density changes with anode surface area in microbial fuel cells. It is clear that the current density is negatively correlated with electrode surface area. There have been many attempts to show scalability and improve current densities in BESs. However, most of systems reporting high current density when impractically small electrodes are used or in short term operations. It is possible to observe a higher power generating (or consuming) BESs in short term due to the capacitance of the electrodes. However, this is not practical. Previously our group published several research papers on scalability of BESs. Our recent works mainly focused on polarized biofilm electrodes and their scalability. We hypothesized that scalability of biofilm electrodes is controlled by mass transport. In this presentation, we summarize our recent work on the scalability of biofilm electrodes and the effect of substrate concentration on the current density of anodic and cathodic biofilm electrodes. We concluded that biofilm electrodes can be linearly scaled under controlled conditions, and we suggest a framework for scaling up BES for practical applications.

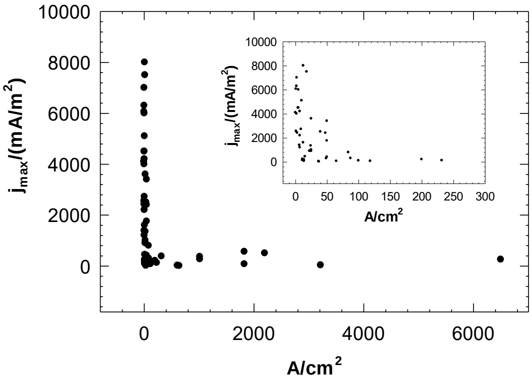

Figure 1. Maximum current density versus anode surface area. The inset shows the data for smaller anode surface areas. The data demonstrates that the bioelectrochemical systems scale at significantly low current densities.

Designing interphases for lithium, zinc and aluminum anodes

Qing Zhao*, Jingxu Zheng, Lynden L. Archer

Robert Frederick Smith School of Chemical and Biomolecular Engineering,
Cornell University, Ithaca, NY, USA
qz289@cornell.edu

The ever-growing demands of portable electronic devices accelerate the development of energy storage/conversion devices with high energy density.[1] Rechargeable metal batteries, applying high capacity and reactive metals (Li, Na, Zn, Al *et al.*) as anodes have been recently paid increasing attentions due to their high specific capacities (*e.g.* ~3850 mAh/g for Li) that are ten times higher than traditional graphite anode.[2] However, comparing with the graphite anode, the solid electrolyte interphases (SEI) formed on metal anodes are not stable, resulting in low Coulombic efficiencies of metal plating/stripping, and irregular shapes of metal deposition.[3,4] In specific situation, the growth of metal can even lead to a dendrite like structure, which shows potential risk to penetrate the separator and cause short circuit of batteries.

Various approaches have been developed to build stable interphases on metal surface, such as modification of electrolytes, preparation of 3D host for metal deposition, design of artificial SEI.[2] Here some emerging feasible strategies will be discussed to build stable interphases on metal surface, not only for lithium metal but also for other low cost metals such as Zn and Al.[5-7] In particular, for Zn and Al, the growth of metal can be orderly arranged by an interphase that shares similar crystal structures with deposited metal, named as epitaxial growth. Meanwhile, the demand of solid electrolyte interphase is different for various metals. For example, the Al metal naturally possesses a dense and high band-gap oxide layer, leading to sluggish kinetic of Al stripping. The design of ionic liquid based interphase on Al surface can replace the original oxide layer and facilitate the kinetics of Al anode.

Microbial fuel cell (MFC) is a developing technology for producing bioelectricity from organic compounds of waste materials that has cough the eye of scientists in recent years. In MFC, microorganisms as active biocatalysts decompose organic matters to electrons and protons [1]. Electrons by the anode as electron acceptor and by external circuit are transferred to cathode electrode to take part in oxygen reduction reaction. In spite of low cost feed in MFC, this technology is not still economic. Electrode materials are the high cost compartments of MFC. To decrease the cost of this technology, using low cost material is a solution[2]. Furthermore, exploiting the supercapacitive features of the MFC has been demonstrated a viable solution to boost power performance of supercapacitive MFCs [3]. Bacterial cellulose (BC) as a cheap biopolymer has been exploited as a flexible substrate for electrode fabrication. It is a porous media hydrogel pure cellulose produced by *Acetobacter* [4]. In this work, BC was coated by carbon nano tube (CNT) to become conductive and then coated electrochemically by polyaniline (PANI). It was used as anode in MFC. PANI as a conductive polymer has been utilized as anode modifier by the scientist[5]. In this research the capacitance behavior of PANI modified BC-CNT was studied before and after biofilm formation and also was compared with the effect of biofilm on BC-CNT's capacitance. For this purpose, impedance spectroscopy is a useful method which was run in the MFC. The results showed that for BC-CNT, the capacitance was decreased after biofilm formation while for the PANI modified electrode the capacitance was increased. Moreover, cyclic voltammetry and galvanostatic discharging demonstrated higher capacitance of PANI modified anode after biofilm formation. Additionally, power density of MFC showed higher performance of modified anode. Finally, FESEM images showed higher biocompatibility of PANI modified anode by higher density of formed biofilm on electrode surface. As a result, the PANI modified bioanode provided an active biofilm and resulted in higher capacitance which was verified by different electrochemical methods.

The Electron as a Probe to Measure the Thickness Distributions of Electroactive Films

Darren Buesen, Huaiguang Li, Nicolas Plumeré
Center for Electrochemical Sciences
Ruhr-Universität Bochum, 44780 Bochum, Germany
darren.buesen@ruhr-uni-bochum.de

Electron conducting films are ubiquitous in applications such as energy conversion, and their ability to fulfil their catalytic function can be greatly limited by inhomogeneities in their thickness or breaks within the film. Knowing the electroactive film thickness distribution would greatly facilitate optimization efforts, but techniques to measure this are lacking. Here, we present an electroanalytical method that provides the thickness distribution of the electrochemically accessible fraction of redox-active films in which the transfer of electrons is diffusional, i.e. by electron hopping. In this method, as the time scale of the experiment (the scan rate) is changed, the location of the diffusion layer boundary relative to the film roughness features is varied, allowing for the extraction of the film thickness distribution. In addition to being conveniently carried out in the solvated state, which is often the operational state of these conductive films, this approach is highly complementary to classical microscopy methods since it samples the entire modified electrode and is specific to the electroactive portions of the film. Therefore, this approach provides information on film morphology that is truly relevant for the catalytic processes being optimized, and thus can guide the optimization of catalyst integration in films towards macroscale cohesion and thickness homogeneity which are essential for optimal performances. The results of this research have recently been published[1], and are relevant to conditions of reversible electron transfer. Efforts are currently underway to extend the model to include quasi-reversible and irreversible electron transfer kinetics.

AA5005 is an aluminum alloy whose main alloying element is Mg. This alloy is employed for constructions, furniture, packaging, in the chemical industry and marine structures. These applications often involve the exposure to aggressive environments: for this reason, very often an organic coating is applied to extend the service life of the structure/manufacture. Among the different failure mechanisms which are responsible for the reduction of the service life of painted aluminium sheets, filiform corrosion frequently occurs in humid and saline environment. Filiform corrosion, which consists in small threadlike delamination tracks driven by differential aeration conditions, usually triggers from surface defects in the protective film in the presence of soluble ionic species in presence of a r.h. between 50 and 90% and relatively high temperature.

Among the different chemical conversion treatments of the aluminium substarte which can be employed to reduce the filiform corrosion phenomenon an alternative can be the use of Layered Double Hydroxides (LDHs) grown in situ over the AA5005. In this study, the effect of the synthesis parameters of Layered Double Hydroxides (LDHs) based thin layers on AA5005 is investigated in order to develop a filiform corrosion resistant solution. LDHs consist in a class of synthetic anionic clays having a layered structure based on magnesium hydroxide (brucite, $Mg(OH)_2$). LDHs are currently studied for different applications, such as additives in functional polymeric materials, as a mean for water decontamination, as osmotic membranes for water desalination and also for exchange and ionic species by absorption. In this work, Al/Mg based LDHs have been developed in autoclave under different synthesis conditions: the effect of the synthesis time and urea presence have been investigated. The morphology of the developed LDH layer have been investigated by SEM and AFM. The thickness and the structure of the developed coatings have been assessed by FIB-SEM. XRD pattern have been collected over the sample to check the LDH structure and to characterize the interplanar distance obtained by playing with the different synthesis parameters. The corrosion protection properties of the as synthetized layers have been investigated by means of polarization curves and electrochemical impedance spectroscopy (EIS).

In the second stage of the work, an epoxy clearcoat has been applied over the AA5005 plates covered by the different LDH layers (in terms of morphology, thickness and composition). The effect of the different LDH layers on the filiform corrosion susceptibility has been assessed in compliance with the ASTM D2803 − 09 standard. The effect of the different surface condition on the formation of filiform filaments has been unravelled.

Free Charge Density Gradients in Room Temperature Ionic Liquids and The Factors that Control Them

G. J. Blanchard, Yufeng Wang, Md. Iqbal Hossain
Michigan State University, Department of Chemistry
578 S. Shaw Lane, East Lansing, MI USA 48824
blanchard@chemistry.msu.edu

Free charge density gradients that extend over macroscopic distances (*ca*. 100 μm) have been seen in room temperature ionic liquids (IL). These gradients, the magnitude and sign of which is controlled by the surface charge of the support on which a film of ionic liquid resides, can be controlled in both magnitude and spatial extent by the molecular structure and organization of IL systems. Our recent work has demonstrated the ability to quantitate the magnitude of the gradient using molecular diffusion measurements. Both the structures of the IL constituents and the presence of diluent affect the gradient in a predictable manner. Current work is focused on identifying the best way to model these systems and devising nonlinear optical spectroscopic strategies for characterizing the charge density gradient.

Electrochemical Approach to Durability of Reinforced Concrete Structures

X.R. Nóvoa, A. Collazo, B. Díaz. C. Pérez
CINTECX, Universidade de Vigo, ENCOMAT group
Campus Universitario As Lagoas, Marcosende, 36310 Vigo, Spain
rnovoa@uvigo.es

The Eurocode-2 “Design of concrete structures” approved in 2004 introduces the concept of durability for construction works. Several parameters related to the mixing compositions or to the safety levels for chloride content are defined, that need of reliable methods for correct assessment of the structure’s integrity.

Corrosion of reinforcing steel bars is recognised as one of the main factors involved in the durability concept, which brings to the need for developing techniques and procedures able to assess corrosion initiation and development. The corrosion potential and polarization resistance are the main electrochemical techniques considered for on-site inspection, under the assumption that the cathodic process corresponds to oxygen reduction and the anodic process to steel corrosion. Although these assumptions are mostly true, they are not able to explain some transitions from passive to active states, as well as some corrosion potential evolutions.

This talk will review recent achievements in understanding the electrochemical response of the steel-concrete interface with the aim of evaluating the possibilities of the electrochemical impedance spectroscopy technique (EIS) for providing quantitative information on the rebar’s corrosion process, and also on the transport of aggressive ions through the concrete cover, thus dealing with durability assessment issues.

Multielectrochromic Conjugated Polymers Based on 2,5-Di(thienyl)pyrrole Derivatives

Jorge L. Neto[1], Luis P.A. Silva[1], Joel B. da Silva[1], Ana Júlia C. da Silva[2], Dimas J.P. Lima[1], Adriana S. Ribeiro[1]
[1] *Federal University of Alagoas, Campus A. C. Simões, 57072-970, Maceió-AL, Brazil*
[2] *Federal Institute of Alagoas, Campus Viçosa, Centro, 57700-000, Viçosa-AL, Brazil*
aribeiro@qui.ufal.br

Among various π-conjugated polymers described in the literature, a 'trimeric' π-extended system based on thiophene bonded to a central pyrrole moiety, namely 2,5-dithienylpyrrole (SNS), has receiving a great deal of attention, since its correspondent polymer can be obtained either by chemical or electrochemical polymerization [1,2]. Furthermore, the oxidation potential of the monomer is less anodic when compared to pristine pyrrole or thiophene and the so-obtained polymer films show multielectrochromic response [3,4]. 2,5-di(thienyl)pyrrole derivatives bearing dansyl (SNSD) or fluorene (SNSF) substituents were prepared by simple synthetic routes, and successfully electropolymerized or copolymerized with 3,4-ethylenedioxythiophene (EDOT) on ITO electrodes by using tetrabutylammonium tetrafluoroborate ($(C_4H_9)_4NBF_4$) / acetonitrile (CH_3CN) as electrolyte. The electrochromic properties of the so-produced polymer films, P(SNSD-co-EDOT) and PSNSF, were investigated by spectroelectrochemical techniques. P(SNSD-co-EDOT) films deposited on ITO with 1:5 feed ratio presented multielectrochromism with rainbow-like colors depending on the applied potential, whilst PSNSF films shows color variation from yellow in the neutral state to green and blue in the oxidized state, as can be seen in the track of the CIE 1931 *xy* chromaticity coordinates, Figure 1. Both polymer films also presented high absorption in the near infrared region, chromatic contrast (Δ%T) in the range of 11 – 40 % depending on the λ, coloration efficiency (η) from 110 to 350 cm^2 C^{-1}, fast switching time (< 1.0 s), and stability to redox cycling. Such properties make these materials potentially applicable as active layer in optoelectronic devices.

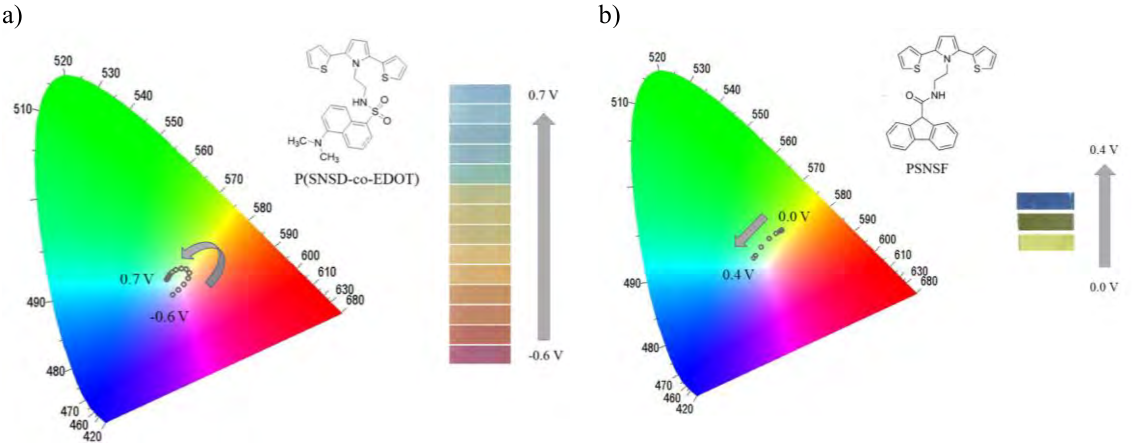

Figure 1. Calculated colour trajectory in the CIE 1931 color space and images of the a) P(SNSD-co-EDOT) film deposited on ITO with 1:5 feed ratio and b) PSNSF film deposited on ITO, registered during potential scan from -0.6 to 0.7 V and 0.0 to 0.4 V *vs.* Ag/Ag$^+$, respectively.

Microbial Electrochemical Technologies: False Leads, Open Perspectives and Ethics

Alain BERGEL
Laboratoire de Génie Chimique, CNRS, University of Toulouse (France)
LGC, 4 allée Emile Monso, 31432 Toulouse, France
alain.bergel@toulouse-inp.fr

For almost two decades, microbial electrochemical technologies (MET) have been opening up amazing perspectives in various application sectors: production of electrical energy from wastewaters, replacement of fossil fuels by bio-hydrogen, mitigation of global warming by the transformation of carbon dioxide into renewable fuels, etc. Basic knowledge on extracellular electron transfers and electroactive biofilms is growing rapidly, revealing fascinating aspects of microbial life but, in spite of great fundamental advances, the technological promises seem to be a very long way from being fulfilled.

The presentation points out some major bottlenecks that preclude the development of the large-scale MET applications that have been announced. This analysis shows that some initial leads are obvious dead ends. It also reveals research avenues that seem more reasonable (in the author's opinion).

First of all, as a basic principle, conventional electrochemical reactors require electrolytes of high ionic conductivity to be efficient. Designing electrochemical cells that should operate with urban wastewater, i.e. electrolyte with ionic conductivity commonly less than $0.5\ S.m^{-1}$, is consequently an unattainable challenge …at least in the absence of really groundbreaking concepts. An alternative that is sometimes evoked would consist in compensating for the poor efficiency of weakly conductive media by designing low-cost electrochemical reactors. Unfortunately, industrial electrochemical reactors are necessarily expensive and have to work at high current density to be economically efficient [1].

Saline and hypersaline electrolytes may offer interesting leads for the development of large-scale MET [3]. In this context, analysis of ion fluxes shows that increasing salt concentrations results in reduced mitigation of the bioanode acidification, which is a severe inhibiting step [4]. This should be a major research axis to be explored. When the objective is no longer to produce electrical energy or to perform electrolysis, but to treat effluents or to enhance some microbially-catalyzed redox reactions, possible low-cost MET options such as microbial snorkel [2] or interspecies electron transfer mediated by conductive particles, can be regarded with hope, even for implementation in media of low ionic conductivity.

Scaling-up MET for CO_2 reduction is definitively hampered by the proximity of the reduction potentials of CO_2 and water. A microbial electrosynthesis cell working at high current density consequently results in the evolution of hydrogen, which peels off the biofilm from the cathode surface. Microbially-catalyzed hydrogenation carried out in two separate steps is a much more promising process configuration [5].

Finally, the question is raised as to whether we should feign ignorance of some obvious deadlocks and propose appealing but unrealistic applications to scientific policy makers in order to be able to continue our work in this exciting research field.

enrico.marsili@nu.edu.kz

Electrochemical techniques allow monitoring of antimicrobial activity in early biofilms [1]. Biofilms of the unicellular fungal pathogen (*Candida parapsilosis* ATCC 22019) and a Gram-negative bacterium (*Acinetobacter baumannii* ATCC 19606) were grown on screen-printed electrodes (SPE) in potentiostat-controlled electrochemical cells and exposed to two dinuclear silver(I) complexes at a concentration equal to the minimum inhibitory concentration (MIC) determined against planktonic bacteria, in the presence of the exogenous redox mediator $[Fe(CN)_6]^{3-}$. $[Fe(CN)_6]^{3-}$ applied in this concentration (100 μM), does not block growth of the microbial biofilms at the concentration tested in this study, as appreciable current outputs, which depend strictly on biofilm growth, were obtained when the cells were grown in the presence of the redox mediator $[Fe(CN)_6]^{3-}$ only. The working electrode was maintained at constant electrochemical potential (0.4 V vs. Ag pseudo-reference electrode). Under these conditions, part of electron flow due to the oxidation of nutrient in the growth medium is transferred extracellularly to the electrode. We have previously shown that the instantaneous current output and the overall charge output after a defined time are correlated to the formation of the biofilm or its inhibition due to an antibiofilm agent in solution. Chronoamperometry (CA) results confirmed that complex 1 has antibiofilm activity against *C. parapsilosis*, as observed by the lower instantaneous current, while it has limited effect on the biofilm activity of *A. baumannii* (Fig. 1). This result also suggested that the minimum inhibitory concentration for biofilm is higher than that in the planktonic phase, being in accordance with the results obtained from the standard microtiter plate based in vitro assay. The CA for the other two strains did not show a well-defined pattern. The non-turnover cyclic voltammograms (CVs) at 0 h are similar with and without the antimicrobial complex 1, while the turnover CVs at 24 h in the presence of complex 1 is much lower than in its absence, as complex 1 affects the bacterial metabolism and reduces the extracellular electron transfer rate. The effect of complex 1 on biofilm formation was also determined through the crystal violet assay in this set up. The amount of biofilm on the working electrode was determined for *A. baumannii* and *C. parapsilosis* with crystal violet assay, which underestimates the attached biomass, due to the multiple washing steps [2]. Overall, electrochemical experiments show that much higher concentration of complex 1 is needed to exert a strong antibiofilm inhibiting activity, while the effect is observable at planktonic MIC concentration. The difference between the CA, CV and crystal violet assays shows that multiple analytical methods are needed to determine the true nature of the antibiofilm effect of a given antimicrobial agent.

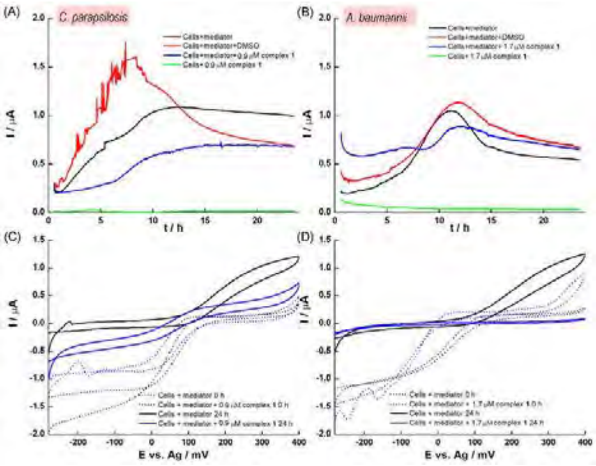

Fig. 1 CA of *C. parapsilosis* (A) and *A. baumannii* (B) biofilms in bioelectrochemical cells. Cells with $[Fe(CN)_6]^{3-}$ (black traces); cells with $[Fe(CN)_6]^{3-}$ and DMSO (red traces); cells with $[Fe(CN)_6]^{3-}$ and 0.9 or 1.7 μM of complex 1 in DMSO (blue traces). Cells with complex 1 in DMSO without $[Fe(CN)_6]^{3-}$ (green traces). CV of *C. parapsilosis* (C) and *A. baumannii* (D) at 0 h (dashed traces) and 24 h (solid traces). Cells with $[Fe(CN)_6]^{3-}$ (black trace); cells with $[Fe(CN)_6]^{3-}$ and 0.9 and 1.7 μM of complex 1 in DMSO (blue traces).

Husbanding Biological Heat to Optimise Energy Conversion in Bioelectrochemical Systems (BES)

Pavlina Theodosiou*, Elizabeth Heidrich
Newcastle University, School of Engineering, Cassie Building, Newcastle upon Tyne, NE1 7RU
*pavlina.theodosiou@newcastle.ac.uk
Elizabeth.heidrich@newcastle.ac.uk

Bio-electrochemical systems (BES) use bacteria as biocatalysts to decompose organic matter and generate electricity, in the case of Microbial Fuel Cells (MFCs), or generate hydrogen, in the case of Microbial Electrolysis Cells (MECs). Since the early 2000s, research around the subject has surged due to the capability of this technology to treat and convert wastewater into useful byproducts, i.e. green energy. To test the propensity of the technology in real world scenarios different pilot-scale studies have been deployed around the globe from different research groups.

These studies have shown that BES holds a great potential as a sustainable technology however, the performance of pilot scale studies (100-1000L) is 1-3 order of magnitude lower than the lab scale (0.1-0.2L) ones. Primarily the research towards addressing this disparity, has been focused for a long time on materials rather than the biology of the system itself. It has been observed that BES can show resilience and continue operating at temperatures below 20 ºC, where normal anaerobic sewage treatments struggle. Hence it is suggested that the heat energy produced during bioconversion of chemical energy to electrical energy is an important energy vector which has not been accounted for.

Thermodynamic calculations show that counter intuitively biological anodes when fed acetate in BES take in heat energy, i.e. they get colder, preliminary data shows this may be an observable phenomenon even in mixed cultures (Figure 1). However, the digestion of upstream substrates such as longer chain starches to glucose will produce heat, this was significant and measurable in 120L pilot scale study [1]. These data suggest that heat transfers are observable and substrate dependent. Further exploration of the thermodynamics, and in particular enthalpy, of the reactions involved in the anaerobic digestion of wastewaters is warranted.

Balancing the energy inputs and outputs will be important for the industrial credibility of BES technology. Additionally, linking heat energy to growth will offer deeper understanding of the biology of anaerobic systems. These are vital steps in the process of engineering efficient biological systems to extract energy, either through classical anaerobic digestion, or with BES. Through a new project (BIOHEAT), the authors will investigate the heat energy transfers in microbial systems in order that we are able to efficiently engineer and husband them.

The enhancement of the Raman signal is fundamental to analyze molecules since it overcomes the low sensitivity of Raman spectroscopy. Usually, the Raman signal has been improved with plasmonic nanostructures using the Surface Enhanced Raman Scattering (SERS) effect. For many years, this phenomenon has been studied and, even today, some critical aspects are not fully understood. In 2018, our group discovered a new phenomenon that was denoted as Electrochemical Surface Oxidation Enhanced Raman Scattering (EC-SOERS),[1] because it only takes place during the oxidation of a silver substrate under specific conditions. EC-SOERS is an electrochemical phenomenon because, as far as we know, the enhancement of the Raman signal can only be obtained when an anodic overpotential or current is applied to the silver electrode. Therefore, this effect can only be studied using spectroelectrochemistry.

The enhancement of the Raman signal was initially observed during the oxidation of a silver substrate, in acidic medium with small amounts of chloride[2]. The origin of EC-SOERS still remains unclear; however, this phenomenon has been successfully used for quantitative analysis of different compounds[3], such as, uric acid, citric acid or caffeine. Moreover, EC-SOERS exhibits a high reproducibility and also a remarkable selectivity that can be used to resolve complex mixtures, as has been demonstrated in the quantification of vitamin B3[4]. The enhancement factors calculated for EC-SOERS indicate that not only a chemical effect but also an electromagnetic effect influences on the enhancement of the Raman signal. Therefore, some type of plasmonic nanostructures are being generated during the oxidation of the electrode.

In this communication, we show the latest developments achieved in the study and application of EC-SOERS. On the one hand, the structures of the molecules plays a fundamental role in the enhancement of the Raman signal. On the other hand, new electrolytic mediums can be used to improve the selectivity in the determination of different molecules. Moreover, this phenomenon has been observed in very different conditions, giving evidence of a more general phenomenon.

This work shows the most recent advances obtained in the study of EC-SOERS, a phenomenon similar to SERS, but with clear differences that can be used to analyze compounds that sometimes are not easily observed in SERS.

Nowadays, neurodegenerative disorders (NDD) and cancer diseases, due to their increasing prevalence and prolonged duration, pose a major global health problem for worldwide population, and a tremendous financial impact associated with medical care for families and society. Despite this, their early detection and follow up are complex tasks, usually performed by techniques, which, although being sensitive and reliable, show some limitations regarding their costs, assay time, invasiveness, complicated protocols and trained personnel for their execution or interpretation. Therefore, the development of low-cost and accessible methods, compatible with point-of-care technology (POCT), for quantifying closely related biomarkers is of great interest.

In this field, electrochemical immunosensors are flourishing as promising alternative tools for diagnosing, prognosing and characterizing this heterogeneous group of diseases, while meeting the POCT requirements: simple but high-performance devices, ensuring sensitive and selective analysis in non-laboratory environments and with limited resources, with easy-to-use equipment and minimal analysis time. The analytical performance of these biodevices can be considerably improved by means of rational surface chemistries such as the use of diazonium salts and/or the coupling with smart nanomaterials, like gold nanoparticles (AuNPs). The latter constitute one of the most widely used nanomaterial in single or multiple-component nanostructures and nanocomposites, due to their unique properties. AuNPs/multi-walled carbon nanotubes (AuNPs/MWCNTs) nanocomposites and dendrimer-encapsulated AuNPs are particularly attractive options to be exploited in electrochemical biosensing due to their remarkable conductivity, catalytic ability, biocompatibility and high density of active groups for biomolecules immobilization.

In this presentation, the most relevant aspects of pioneering use of AuNPs/MWCNTs [1] and AuNPs-poly(amidoamine) (PAMAM) dendrimer nanocomposites [2], prepared in the laboratory, as nanocarriers of multiple detector antibodies and peroxidase (HRP) molecules or electrode modifiers, respectively, in electrochemical immunosensing approaches recently developed to determine biomarkers of emerging relevance in metastatic cancer (Receptor Activator of Nuclear Factor-κB Ligand, RANKL) and neurodegenerative diseases (tau protein) will be critically discussed. These approaches are based on sandwich immunoassay formats and involve the use of commercial reagents and disposable electrodes modified by electrochemical grafting with 4-aminobenzoic acid (*p*-ABA) and amperometric transduction using the H_2O_2/hydroquinone (HQ) system.

The excellent characteristics that these AuNPs-based nanostructures impart to the resultant immunosensing platforms in terms of sensitivity, selectivity, and operational and storage stability for determining the target biomarkers in the required clinical ranges will be critically discussed. Moreover, their potential to direct and accurate determine the endogenous target biomarker levels in human serum, plasma and brain tissues samples from colorectal cancer or NDD-diagnosed patients, simply by placing a 5-µL drop of the undiluted biofluid or containing 2.5 µg of the tissue extract over the immunoplatform, and involving simple-handling and short turnaround protocols (1-2 h) will be presented.

Our recent experimental results confirm that these electrochemical immunosensors are competitive with commercial methodologies in terms of simplicity and assay time, which along with the amenability to be implemented in single or multiplexed formats and using affordable, low-power requirement and portable instrumentation, make them very attractive tools to further advance in the consolidation of candidate clinical biomarkers in metastasis and neurodegenerative processes, and their implementation in POCT devices to perform decentralized and rapid routine determinations.

s.reeves@soton.ac.uk

InSb is an infrared detector material which would have enhanced properties and tunability if deposited at the nanoscale. Electrodeposition provides a bottom-up approach to filling high aspect ratio nanostructured templates which conventional gas phase deposition can struggle with. Weakly coordinating solvents are useful for this purpose due to low surface tension and the solvent not affecting the electroactive species or any of the intermediates during electrodeposition.

The suitability of using tetrabutylammonium halometallate precursors in dichloromethane has been demonstrated for a number of p-block elements [1]. The electrodeposition of $Ge_2Sb_2Te_5$ [2] and Bi_2Te_3 [3] from this system has also been demonstrated. This presentation will cover the electrodeposition of InSb from this system at different length scales. The electrochemical behaviours of the precursors, the different challenges associated with producing and using templates at each length scale, and the composition control of the resulting deposits, will be highlighted.

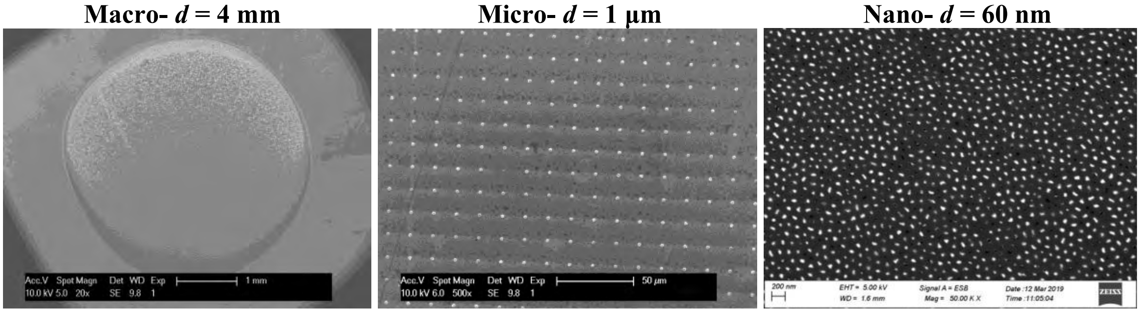

Figure 1: SEM images of InSb electrodeposits at different length scales

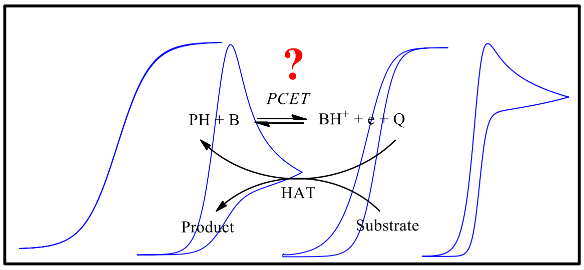
cyrille.costentin@univ-grenoble-alpes.fr

Proton Coupled Electron Transfer (PCET) catalysts will be presented in the framework of cyclic voltammetry (CV). Formal kinetic analysis of the various responses expected in the case of PCET catalyst following either stepwise or concerted pathways will be described. Both buffered solution and non-buffered aqueous media are considered. In the first case we show that, besides possible limitation by buffer diffusion, the PCET sequence may be rate limiting. CV wave shape, position and intensity are discussed in terms of thermodynamic and kinetic penalties associated to each mechanism. In the second case, we show that a non-classical *pseudo*-canonical cyclic voltammogram with hysteresis due to hydronium production is obtained for a Nernstian PCET catalyst with water as proton acceptor. Thermodynamic and kinetic penalties resulting from water based PCET specific pathways are analyzed. Then, we use this framework investigate the electrochemical catalysis of alcohol oxidation in water with a PCET catalyst, N-hydroxyphthalimide. We have found that the rate constant for benzyl alcohol oxidation is independent of *pH* strongly suggesting a true hydrogen atom transfer (HAT) as rate determining step. When water is the proton acceptor to generate the active form of the catalyst, i.e. N-oxyl PINO radical, the catalytic process follows a stepwise PTET pathway which kinetics partially limits the catalytic current.

Finally extension to heterogeneous PCET catalysts will be discussed with an application to an Oxygen Evolution catalyst.



All-in-one: removal of oxidizable (hydrocarbons) and reducible (sulfate) contaminants from contaminated groundwater in a single bioelectrochemical reactor

Due to their high sustainability and low energy footprint, Microbial Electrochemical Systems (MES) represent promising candidates for in-situ remediation of contaminated groundwater. Still, only few studies have verified the capability of such systems to address complex mixtures of organic and inorganic contaminants so far.

This study concerned the performances of a lab-scale "bioelectric well" [1–3], a membrane-less tubular reactor containing a carbon-based anode (e.g., graphite, biochar) and a concentric stainless-steel mesh cathode, having the two electrodes hydraulically connected, yet physically separated by a polyethylene mesh. This system was tested for the treatment of "real" polluted groundwater obtained from a petrochemical site (Italy), containing a complex mixture of oxidizable (e.g., BTEX, PAHs, and other petroleum hydrocarbons) and reducible (e.g., sulfate, nitrate) contaminants. The "bioelectric well" was initially operated in fed-batch mode, and a potential of +0.2 V *vs*. SHE was imposed to the anode. After an initial acclimation phase, the system reached high oxidation rates of toluene (i.e., the main groundwater pollutant), with a Coulombic efficiency typically exceeding 90%. Interestingly, the molecular hydrogen generated at the cathode was then fully exploited for the biologically-driven reduction of sulfate. In a later stage, the reactor was also operated in continuous-flow mode by means of a peristaltic pump and its performance under pseudo steady-state conditions was thoroughly characterized.

Finally, the analysis of the microbiome composition and the quantification of key functional genes corroborated the chemical data and provided further insights into the performance of this novel bioremediation technology.

Exotic Plasmonic Excitation of Electrons beyond The Normal Limit of Electrochemical Potential for Novel Photochemical Reactions

Kei Murakoshi
Department of Chemistry, Faculty of Science, Hokkaido University,
Sapporo, JAPAN
e-mail: kei@sci.hokudai.ac.jp

Plasmon-powered processes to expand the ability of the spectroscopy regarding sensitivities in space, time, and energy resolutions. As their characteristics on localization of surface plasmons into molecule scale, huge intensity gradient of electromagnetic field would break the limit of light-matter interactions via the modification of the selection rule of the electronic excitation process. I have discussed about the possibility for the surface-enhanced-Raman scattering (SERS) as the probe to monitor the exotic electronic excitation processes [1]. Based on the observation of a small number of molecules at the plasmonic metal nanostructures by SERS [2-4], possibilities leading to the future innovative photo-functionalities were demonstrated by showing improved properties at optical manipulation of electrons and molecules, and ions [5-7]. We have shown that the localized surface plasmons of the Au nanodimer structures prepared on defect-free graphene provide highly-confined electromagnetic field to generate holes and electrons of the electrochemical potentials beyond the limit of far field light illumination [8]. Novel non-zero wavevector excitation results in the generation of highly reductive and oxidative powers for electrochemical reactions. Recent findings also prove the modification of electronic distribution of electrons under plasmonic excitation [9]. These findings provide a novel way to breaking the limit of photochemical reactions using various plasmonic materials.

Electrochemiluminescence sensing and light generation confined in nanochannels

Klaus Mathwig
University of Groningen, Groningen Research Institute of Pharmacy, Pharmaceutical Analysis,
P.O. Box 196, 9700 AD Groningen, The Netherlands
k.h.mathwig@gmail.com

Electrochemiluminescence (ECL) is light emission which triggered electrochemically in solution: reactive ECL species are generated by at electrode surfaces and undergo an electron-transfer reaction in solution generating the excited state of a luminophore, it subsequently returns to the ground state and emits a photon. ECL is widely and commercially used for biodetection, specifically in clinical immunosensing. Many diseases and other biomarkers can be detected by labelling antibodies with luminophores. The method several advantaged: sensing is background-free and allows straightforward highly sensitive detection in a very broad measuring range.

We employ nanofluidic electrochemical devices for light emission by ECL [1]. Microfabrication of nanochannels using photolithography, deposition and dry etching techniques allows the confinement of the reaction volume to a well-defined channel of 10 femtoliters. There, smallest quantities of luminophores participate in reactions. Nanoscale distances to electrodes enable very efficient reactions and bright light emission as well as novel reaction pathways.

The microfabricated nanochannel is connected to a bulk liquid reservoir via two small access holes. Thus, the reaction volume inside the channel can be geometrically decoupled from the reservoir, and the composition of reactants within the nanochannel, i.e., their oxidation states, depends on the potential applied to the electrodes embedded in the channel walls.

We demonstrate that, unique for ECL in nanochannels, reactions and light emission can be controlled by different biasing and reaction schemes to yield very distinct emission patterns. In particular, driving a annihilation electrochemiluminescence of tris(bispyridine)ruthenium(II) $Ru(bpy)_3^{2+}$ leads to constant light emission along the entire nanochannel, while a co-reactant pathway in which $Ru(bpy)_3^{2+}$ oxidation is triggered by tripropylamine limits light emission to nanochannel access holes [1].

Coreactant ECL reactions at the nanoscale could be employed for sensitive biosensing, e.g., ECL-labeled detection in immunoassays.

**Email: xszhou@zjnu.edu.cn*

Using single molecules to build a field-effect transistor is the critical step forward realizing future nanodevices with high efficiency and low energy consumption,[1-2] which has motivated a lot of researches over the world to achieve this ultimate goal. Redox-active molecules that could be converted between the oxidized or reduced states upon different electrochemical potentials, have been widely studied to illustrate the electrochemical gating at single molecular level. Their conductance could switch on as the energy levels of electrode shift to resonance with molecules. With this unique family of redox-active molecules, ongoing interest is to obtain a higher on/off ratio of conductance. However, achieving a high on/off ratio between the conductance of molecular junctions remains a great challenge and more factors of this single molecule system, like the molecular backbone, are needed to be explored.

Here a feasible strategy that connecting the redox-active moieties with conjugated chains was proposed to improve the electrochemical gating efficiency of molecular junctions using STM break junctions technique.[3-5] Benefiting from the low energy offset of frontier molecular orbitals, C=C-Fc-Py shows about one order larger maximum conductance enhancement and 160% improvement of conductance on/off ratio compared to C-C-Fc-Py at the equilibrium potential of Fc^+/Fc (**Figure** 1).

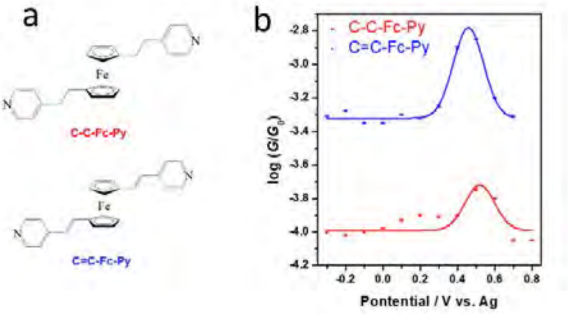

Figure 1. (a) Molecular structures of the investigated molecules. (b) The conductance of **C-C-Fc-Py** (red) and **C=C-Fc-Py** (blue) depends on the applied gate potential.

This research was supported by National Natural Science Foundation of China (Grant Nos. 21872126, and 21573298) and Zhejiang Provincial Natural Science Foundation of China (Grant No. LR15B030002) .

elisa.musella3@unibo.it

Layered double hydroxides (LDHs), also known as anionic clays, containing redox active transition metals are attractive compounds for electrochemical applications such as energy storage, sensors, fuel cells and catalysts for oxygen evolution reaction. [1] However, many LDH applications are still largely restricted due to their low electrical conductivity. Of course, this reduces the performances of electrochemical devices: in particular, supercapacitors need high currents flowing during fast charge−discharge cycles. These weak points can be overcome by combining LDHs with carbon nanomaterials, such as graphene. In the present work, we propose a one-step electrosynthetic protocol that produces nanostructured films of composites based on Ni/Al-LDH and reduced graphene oxide (GO).[2] This procedure contemporaneously allows for the LDH synthesis, the reduction of GO and its intercalation inside the layered structure. Up to date, the only interlayer anions introduced in LDHs coming from electrochemical syntheses are small molecules. This greatly constrains their applicability: in particular, our work could pave the way for further studies in the field of electrochemically induced intercalation chemistry. The films obtained have been thoroughly characterized by many techniques in order to verify the structure and morphology of the LDH/ERGO composites and to propose a theorization of the synthetic and growth mechanisms. Ultimately, we were able to employ these composites in the field of energy storage: the proposed hybrid super capacitor had a starting discharge specific capacity of 880 F g−1 which decreased and stabilized at 820 F g−1 after 300 cycles. The potential applicability of the device was also demonstrated by powering a red light-emitting diode. This work embraces the necessity of the development of systems with low environmental impact: in fact, we have proposed a binder-free device, safe, composed of hearth abundant element and able to work in aqueous electrolyte system with high performances. [3]

Cation-disordered Li_3VO_4 (LVO) has been identified as a promising negative electrode material for hybrid supercapacitors with theoretical specific capacity of 394 mAh g^{-1} (2 lithium accommodation) operating at a safe but still low potential range between 0.4 and 1.3 vs. Li/Li^+[1]. Recent our studies unveiled that cation-disordered LVO can be electrochemically obtained from the pristine cation-ordered LVO during initial cycling, which we termed as electrochemical activation process [1-2]. This electrochemical activation process induces the transformation of β-LVO from the pristine cation-ordered structure into an activated LVO, which has a Li^+/V^{5+} cation-disordered structure. Charge discharge curves also change from battery-like plateau to pseudocapacitive slope *via* such cation-disordering of LVO, along with its reaction mechanism change from two-phase to solid-solution reaction[2]. Yet, the preparation method of cation-disordered LVO has been a major issue as the electrochemical activation process is impractical from the industrial point of view. Such electrochemical process requires a precycling of β-LVO, which is difficult to control and inevitably produces undesirable irreversible capacity for a full cell assembling.

In this talk, we introduce two alternative processes to the electrochemical activation, *i.e.*, the direct synthesis of pseudocapacitive cation-disordered LVO materials (Figure 1). One is a simple mechanical milling of the pristine β-LVO powder, which brings about the full randomized Li^+/V^{5+} arrangement and thus enables to obtain thermodynamically metastable cation-disordered LVO phase without any precycling. Another is a partial substitution of V^{5+} with Si^{4+} in β-LVO, which results in a transformation of β-LVO into γ-$Li_{3+x}V_{1-x}Si_xO_4$. We present those two approaches, "fully" or "partially" cation-disordering, as new paths for transformation of battery-type materials into pseudocapacitive materials with improved electrochemical performances by simple cation mixing.

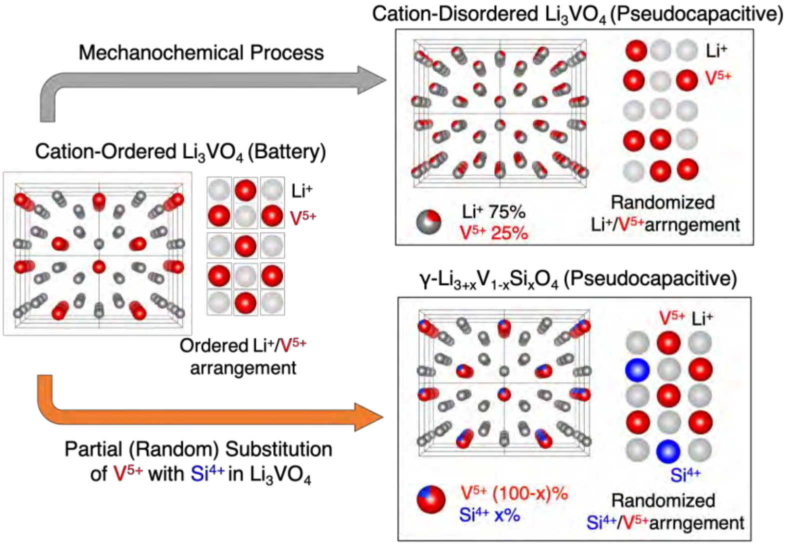

Figure 1. Schematic illustrations of two strategies for material transformation from "battery" into "psuedocapacitive" materials.

The commercialization of metal-air batteries requires efficient, low-cost, and stable bifunctional electrocatalysts for reversible electrocatalysis of the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER). The modification of natural coal by heteroatoms such as N and S, or metal oxide species, has been demonstrated to form very promising electrocatalysts for the ORR and OER. However, it remains elusive and underexplored on how the impurity elements in coal may impact the electrocatalytic properties of coal-derived catalysts. Herein, we explore the influence of the presence of various trace metals that are notable impurities in coal, including Al, Si, Ca, K, Fe, Mg, Co, Mn, Ni, and Cu, on the electrochemical performance of the prepared catalysts. The constructed Zn-air batteries are further shown to be able to power green LED lights for more than 80 h. The charge-discharge polarization curves exhibited excellent and durable rechargeability over 500 (ca. 84 h) continuous cycles. The promotional effect of the trace elements is believed to accrue from a combination of electronic structure modification of the active sites, enhancement of the active site density, and formation of a conductive 3-dimensional hierarchical network of carbon nanotubes.

Nanostructured mixed transition metal spinel oxide thin films as efficient electrocatalysts – composition, structure and properties

Sreena Thekkoot, Rehana Islam, and Sylvie Morin
Department of Chemistry, York University, 4700 Keele Street, Toronto, ON, M3J 1P3 Canada

Transition metal oxides have received renewed attention with their demonstrated usefulness as cathodes in dye-sensitized solar cells and as anodes in fuel cell [1, 2]. In addition, careful choice of the synthesis method and experimental conditions allow for the tailoring of the film nanostructure and surface area. However, it is clear from the literature [3,4] and our own work [5,6] that the experimental parameters used for the material preparation can greatly affect its electrocatalytic properties making it difficult to compare material performances. We have prepared various spinel oxides, namely $Cu_xCo_{3-x}O_4$ ($0 \le x \le 1$), $Ni_{1-x}Cu_xCo_2O_4$ ($0 \le x \le 0.75$), $Fe_yCu_{x-y}Co_{3-x}O_4$ and $Fe_yNi_{x-y}Co_{3-x}O_4$ (for y = 0.1 or 0.15 and x = 1 or 0.5 for both Fe-Cu and Fe-Ni containing oxides), using the thermal decomposition method. The films were analyzed, using several structural, chemical and electrochemical methods such as x-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive x-ray spectroscopy (EDX), cyclic voltammetry and X-ray photoelectron spectroscopy (XPS). The oxygen evolution reaction and electroreduction of hydrogen peroxide reaction were used as model reactions to determine the electrocatalytic activity of the electrodes.

The SEM analysis shows that the prepared thin films are quite porous and uniform. EDX analysis shows that a good correlation exists between stoichiometric and the resulting composition of the films. The formation of the spinel structure is confirmed by XRD analysis. For all our samples, the X-ray data also support the existence of the spinel structure. The addition of Cu to Co_3O_4 to form $Cu_xCo_{3-x}O_4$ resulted in an increase in roughness for x values from 0.25 to 1. When Ni is added to form the ternary oxides, the roughness more than doubles. For spinel oxides containing iron, nickel and cobalt, the roughness is much lower, i.e., around 80. Electrodes prepared by thermal decomposition method exhibit overall good catalytic activity towards oxygen evolution reaction and electroreduction of hydrogen peroxide. X-ray Photoelectron Spectroscopy (XPS), which probes the surface of the catalyst, was also used to understand the structure, composition and oxidation state of the metal ions in the ternary oxide materials. The high-resolution spectra for the Co, Cu and Ni 2p peaks indicate the existence of different Co^{2+}/Co^{3+}, Cu^{+}/Cu^{2+} and Ni^{2+}/Ni^{3+} ratio for these materials (the Fe signal was often too small in the XPS spectra to yield meaningful results). The analysis of O 1s spectra indicates that the main peak is composed of three components that can be assigned to lattice oxygen, adsorbed oxygen containing species such as hydroxides and surface bonded water. A detailed quantitative analysis will be provided in our presentation.

Electrochemical measurements show that for our samples, adding Cu to Co_3O_4 to form $Cu_xCo_{3-x}O_4$ and Ni to $CuCo_2O_4$ to form $Ni_{1-x}Cu_xCo_2O_4$ does not increase the material's electrocatalytic activity towards the oxygen evolution reaction, when the current is corrected for the real surface area. However, compared to Co_3O_4, our $Fe_{0.15}Ni_{0.35}Co_{2.5}O_4$, and $Fe_{0.1}Ni_{0.9}Co_2O_4$ ternary spinel oxides show significant enhancement with almost double the current density for the oxygen evolution reaction at 1 V under the same conditions. Our results will be compared with the morphology, structure, surface and bulk compositions, and electrochemical properties of spinel oxides films of similar compositions reported in the literature.

Several types of fuels can be used in biofuel cells (BFCs) to generate clean energy. However, the low power density obtained is one of the main problems that limits the application of enzymatic biofuel cells. One strategy to improve power density of BFC is to increase the degree of oxidation of the fuel, so a higher number of electrons can be harvested [1]. Hybrid system combines the advantages of metallic or small molecular catalysts with biological catalysts (enzymes) in order to provide a gain in terms of the energy withdrawn from the biofuel and generate electricity [2]. We will discuss two different hybrids systems for the electrooxidation of ethylene glycol. The first system combines metallic nanoparticles of PtSn deposited on multi-walled nanotubes functionalized with COOH (MWCNTs-PtSn) and the oxalate oxidase enzyme (OxOx). The second hybrid system investigated combines an organic catalyst (4-amino-TEMPO (TEMPO-NH_2)) and OxOx. Both catalysts (MWCNTs-PtSn and Amino-TEMPO) showed electrochemical activity towards ethylene glycol oxidation presenting a well-defined oxidation peak. However, the onset potential for the inorganic catalyst is shifted 200 mV towards less positive potentials compared with the TEMPO one, making MWCNTs-PtSn more advantageous for power generation applications. Addition of the enzyme OxOx enhance the current densities observed. Inorganic hybrid system (OxOx+MWCNTs-PtSn) double the current peak in the presence of the enzyme. Amino-TEMPO/OxOx the enzyme acts only when the concentration of EG is higher than 100 mmol L^{-1}. Comparison of both approaches shows that OxOx+MWCNTs-PtSn is 10 times more efficient that the homogenous organic catalyst furnishing a good prototype to produce energy devices. The chronoamperometric experiments also confirms the good active of the hybrid systems; both MWCNT-PtSn-OxOx and amino-TEMPO-OxOx presented an enhancement of ethylene glycol oxidation, 34 % and 23 %, respectively, compared with the system in the absence of enzyme. Product analysis by *HPLC* confirmed the multiples catabolic steps of EG oxidation, enabling the oxidation of EG to more oxidable compounds when the hybrid system is applied. Overall, this study illustrates the development of an enzymatic biofuel cell using hybrid systems combining either an organic catalyst or metallic nanoparticles and enzymes in order to obtain a novel hybrid anode architecture to ethylene glycol oxidation. It constitutes a simple methodology with useful application in the development of enzymatic biofuel cells.

Unconventional Electrochemical Precursor Stacks, Zn/Sn/Cu & Zn/Cu/Sn, for the Synthesis of CZTS

G. Panzeri, R. Dell'Oro, L. Magagnin
Department of Chemistry, Materials and Chemical Engineering Giulio Natta – Politecnico di Milano
Via Mancinelli, 7 – 20131 Milano (Italy)
luca.magagnin@polimi.it

Electrochemical stacked elemental layer (SEL) approach is one of the most exploited routes for the synthesis of Cu_2ZnSnS_4 (CZTS) [1]. This methodology typically involves the sequential deposition of the metallic layer followed by reactive annealing in a sulfur atmosphere. However, due to the limitations of aqueous chemistry, in the framework of electrodeposition the SEL approach has almost exclusively relied on the Cu/Sn/Zn sequence so far [1]. The zinc layer readily reacts upon the immersion in a copper/tin-based solution due to the difference between its reduction potential and that of the metallic dissolved ions. On the other hand, almost no limitations were observed for vacuum-based processes allowing to exploit different stacking order combinations [2], showing advantages with respect to the conventional one, such as the lower Zn and Sn loss after the high-temperature annealing. Therefore, the development of a suitable electrodeposition bath can bridge the technological gap between vacuum based and wet fabrication route in terms of possible stack sequences.

In our work, we investigated organic solutions based on ethylene glycol to overcome the intrinsic limitation of aqueous system [3] by reducing the reactivity between zinc and copper/tin ions in the solution. Displacement reactions are studied as a function of diethanolamine content in the bath, a suitable complexing agent for copper/tin ions. The solutions are characterized by cyclic voltammetry (CV), electrospray mass spectrometry (ESI) and, eventually, nuclear magnetic resonance spectroscopy (NMR). Zn/Sn/Cu and Zn/Cu/Sn stacks were fabricated by galvanostatic deposition and were characterized by scanning electron microscopy (SEM), electron dispersive spectroscopy (EDX), glow-discharge optical emission spectroscopy (GDOES) and X-ray diffraction (XRD). The copper-poor zinc-rich precursors obtained, were annealed in a sulfur atmosphere at 560 °C to obtain the CZTS, analyzed by Raman spectroscopy.

Biofilm electrodes are the living heart of the great majority of bioelectrochemical systems. Despite the recent progress, the further increase of the biofilm electrode performance is still a key issue for the future success of the deriving microbial electrochemical technologies. The current density of high-performing anodic microbial biofilms at flat, macroscopically smooth, electrode surfaces (e.g., at smooth polycrystalline graphite) reaches about 1 mA cm-^{2}, a further increase appearing hampered. Is this final limit in the performance of biofilm electrodes? Different approaches have been proposed to increase the electrode performance. They reach from surface structuring on a nanometer scale to a wealth of 3D electrode structures. How effective are such approaches? This presentation shows a systematic approach to the role of structural electrode dimensions on the short-term and long-term performance of biofilm electrodes. It also discusses opportunities by using promoting effects of unusual electrode materials, such as copper.

Abstract: Shock electrodialysis (or shock ED) is an emerging technology for water purification and separations based on splitting fluid streams on either side of a deionization shock wave propagating through a charged porous medium at overlimiting current. This talk will introduce the basic physics and design principles of shock ED and will demonstrate possible applications in water remediation. When the feed is dilute, shock ED can be used for deionization (>99%) with high (85%) water recovery, which we demonstrated by removing ions of cobalt and cesium from model radioactive water. We also observed high (>90x) selectivity for multivalent ions by the continuous removal of magnesium (Mg^{2+}) from a dilute solution of sodium chloride as well as from artificial seawater. Selectivity for toxic heavy metals (which are often multivalent) at low salinity guarantees an ultra-low cost of electrical energy (~\$0.01/m^3 feed), which could lead to a practical solution to purify drinking water from corroded pipes or contaminated sources. In addition to ionic separations, this talk will also explore exotic separations such as removal of biological contaminants (disinfection) and nanoparticles (dielectrophoresis).

The platinum-group metal-free catalysts (PGM-free) are the most performing and most affordable alternative solution to platinum catalyst into fuel cells. These catalysts are carbonaceous materials containing central atomic transition metals like Fe, Co, Mn coordinated to nitrogen bonded into the carbon matrix. The metal-nitrogen-carbon (M-N_x-C) in which the nitrogen coordination is 2, 3, 4 nitrogen is the most desired active site [1] to enhance oxygen reduction reaction (ORR) kinetics at all pH values [2,3]. Despite the intrinsic difference in active sites between PGM and PGM-free catalysts, PGM-free are able to deliver very satisfactory current density especially in a contaminated working environment where Pt is easily deactivated. This is particularly beneficial in Microbial Fuel Cells (MFC) application field, where wastewater can be exploited as a new source of energy. The Fe-N_x-C coordination ability to withstand very harmful contaminants has been studied in detail to identify the fingerprint of coordination contamination in the case of typical wastewater contaminants, namely nitrite, nitrate, chloride, perchlorate, sulfide, and sulfate. Rotating Disk Electrode (RDE) analysis, Koutecky-Levich analysis, and Tafel analysis have been exploited to identify specific trends at pH 7 in terms of Onset Potential (E_{on}), Halfwave potential ($E_{1/2}$), Limiting Current Density (J_{lim}), Number of Transferred Electrons (#e^-), Tafel slopes, and exchange current density (J_0) at the variation of contaminants concentration. The results showed a very peculiar trend in the case of direct active site poisoning with J_0 as the predominantly parameter able to exactly distinguish between specific and unspecific bonded contaminants.

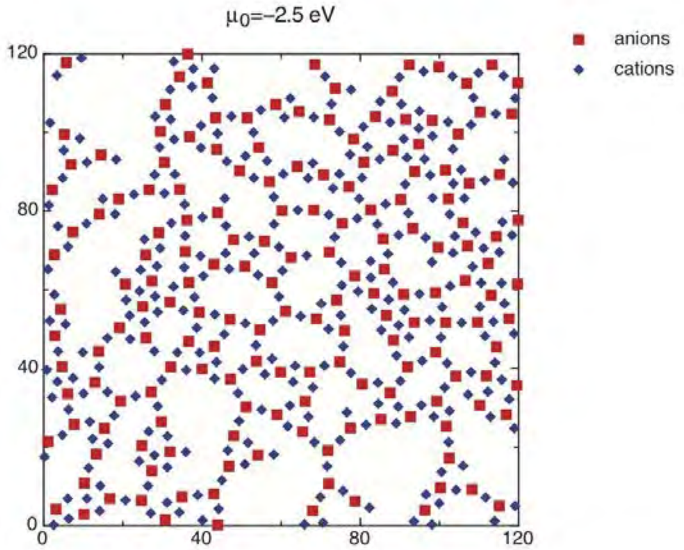
The Electric Double Layer in Carbon Nanotubes and -slits

W. Schmickler, F. Juarez, F. Flores-Dominguez, E. Santos, P. Quaino
Ulm University
Institute of Theoretical Chemistry, Ulm, Germany
Wolfgang.Schmickler@uni-ulm.de

The diameters of nanotubes and nanopores can be much smaller than the Debey lengths of electrolyte solutions. In this case, conventional double-layer theory cannot be applied. In order to understand the behavior of electrolytes under such conditions, we explore the interactions between ions, molecules, and carbon nanostructures such as graphene and nanotubes. Because of the low density of electronic states the adsorption or insertion of ions modifies the electronic properties of the carbon structures. In particular, they make semiconducting nanotubes locally conducting, converting them into degenerate n- or p-type semiconductors.

In contrast, the interaction of water with carbon structures is weak. In the case of narrow nanotubes, the image charge on the walls of the tube weakens the solvation of ions with water. Also, the presence of water hardly affects the interaction of ions across the walls of a nanotube.

On the basis of the elementary interaction of ions with carbon materials we have performed Monte Carlo simulations for an ensemble of ions inside a carbon nanoslit in the grand-canonical ensemble. Two regimes can be distinguished: A gas-like filling of the slit with a low density of ions, and a disordered, glass-like structure at high ionic concentrations. The two regimes are separated by a transition region reminiscent of a phase transition, in which transient, string-like structures are formed – see figure. Both the charge and the electrochemical potential are well defined in these ensembles. This allows us to calculate capacity curves without introducing adjustable parameters. The structure of these curves, in particular the number of capacity humps, depends on the details such as the hydrophilicity of the slit, and the charge number of the ions. A few typical examples will be presented.



Transient structures at the transition between a gas-like and a solid-like 2D ensemble of ions.

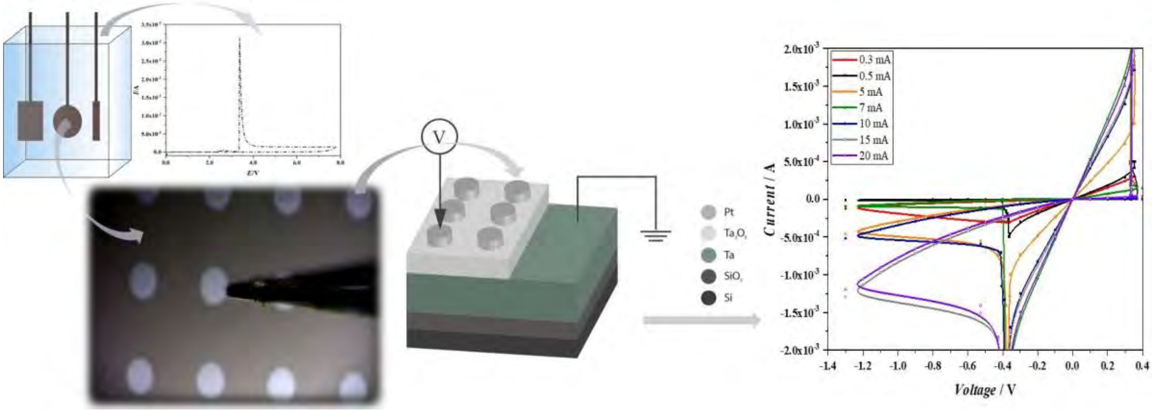
Influence of electrolyte selection on anodic memristors behavior

Ivana Zrinski, Jan Philipp Kollender, Cezarina Cela Mardare, Achim Walter Hassel,
Andrei Ionut Mardare
Johannes Kepler University Linz
Altenberger Straße 69
4040 Linz
ivana.zrinski@jku.at

As a borderline case amongst electroactive processes, the electrical field activated charge transport through a solid state material is responsible for the switching of a memristor between its different electrical conductivity states. These have a permanent character, thus the term of memory-resistor shortened as memristor is widely used. Among various materials, Ta oxide memristors play a very important role in the next-generation of thin film micro- and nano-electronic devices mainly due to applications in non-volatile redox-based resistive switching memories (ReRAMs) and artificial neural networks. Thus, there is a strongly motivated research interest for understanding the mechanism of device operation based on the electric field assisted formation of conductive filaments inside an insulating metal oxide layer. Due to its valve metal characteristics, anodic oxide formation on Ta is a reliable, controllable, reproducible, cost-efficient and industrially implementable approach for memristor fabrication. Such anodic oxide, also regarded as a solid electrolyte, is interposed between the Ta parent metal and a Pt thin film top electrode for defining a memristive device.



In this work, metal-insulator-metal (MIM) structures defined using thin and ultra-thin films of $Pt/Ta_2O_5/Ta$ were investigated in order to study ion migration during filament formation. Using sputtering, 330 nm thick Ta films were deposited on SiO_2/Si wafers. The metallic films were anodized potentiodynamically up to 20 nm thickness in three different electrolytes: phosphate buffer (PB) citrate buffer (CB) and borate buffer (BB) solutions with different rates of potential increase. Before electrical characterization, Pt top electrodes 200 µm in diameters were patterned on top of the oxide layer. The nature of anodic oxide was questioned from the point of view of anodization parameters. Electrolyte species may get trapped inside the memristive device due to anodization conditions and they can directly affect the filament formation during the memristive switching. Different compliance currents (I_{cc}) were studied during the memristor formation phase and their effects on final device properties are reported. The obtained memristors have shown very good switching properties, e.g. ability of long endurance, long retention ($>10^5$ cycles, $>10^6$ cycles with $I_{cc} < 150$ mA), low power consumption ($V_{set}/V_{reset} < \pm1.5$ V) and multiple switching levels. Thermo – electrical measurements were also performed resulting in reliable memristor formation dependence on the applied compliance current. The figure shows anodization process of Ta film with the schematic representation of the memristive devices and their *I-V* response.

In conclusion, the current study offers optimized routes for fabrication of anodic Ta oxide memristive devices offering possibilities for future sensing applications and large scale-up opportunities with the main advantage of a very simple and cheap fabrication procedure.

Electrochemical nitrite sensor based on PEDOT and hollow AuPt nanoparticles

G. Lucero, A. Bund
Fachgebiet Elektrochemie und Galvanotechnik, Technische Universität Ilmenau
Gustav-Kirchhoff-Str. 6, 98693 Ilmenau
gisella-liliana.lucero-lucas@tu-ilmenau.de

Nitrites are chemical compounds that can pose a threat to the environment and human health at concentrations above 3 mg/L in drinking and waste water (World Health Organization [1]). These compounds can react with amines and form N – nitroso compounds, some of which are potentially carcinogenic products, and can lead to cyanosis through the formation of methemoglobin by the reaction of nitrites and hemoglobin. Therefore, monitoring the concentration of nitrite in water is an essential task.

Traditionally, nitrite ions are detected and quantified by techniques that require complex devices, are time consuming or demand the pretreatment of the sample with some harmful reagents or the production of toxic compounds. These detection methods encompass colorimetry, chemiluminescence and chromatographic and spectrophotometric techniques.

Electrochemical sensors are an appropriate alternative for the detection of nitrite in water. Nanocomposites based on multiwall carbon nanotubes, graphene, conducting polymers and metal nanoparticles have been reported as nitrite sensors [2,3]; however, to the authors´ best knowledge, sensors based on PEDOT and hollow bimetallic nanoparticles have not been tested as potential materials for the electrochemical detection of nitrite.

In this work, hollow AuPt nanoparticles were synthesized by galvanic displacement and characterized by SEM, EDX and TEM/STEM. The results confirmed the hollow structure of the bimetallic nanoparticles (particle size: 20 -30 nm; Fig 1). EDX analysis revealed that the particles contain Au and Pt and showed the elemental profile through the nanoparticles. The nanoparticles were centrifuged, resuspended in water and co-deposited from a solution of the surfactant SDS, the monomer EDOT and $LiClO_4$ at 0.9 V. The performance of the composite PEDOT/AuPt was evaluated by differential pulse voltammetry (Fig. 2) in the range of 50 to 250 µM. The sensitivity of the sensor was 0.04 +/-0.01 µA µM^{-1}.

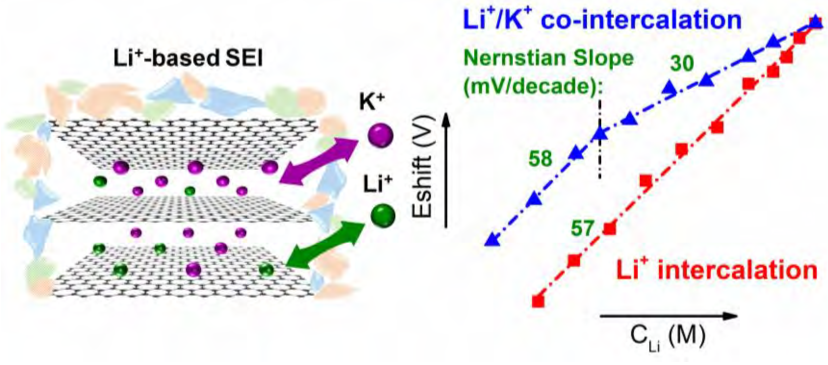
Alkali ion batteries (AIB) based on Li^+, and emerging technologies based on K^+, are important high-performance rechargeable energy storage devices. Alkali ion intercalation is fundamental to those battery technologies for a wide spectrum of potential applications that permeate our modern lifestyle, including portable electronics, electric vehicles, and the electric grid. In spite of its importance, the Nernstian nature of the charge transfer process describing lithiation of carbon has not been described previously.

Here we use the ultrathin few-layer graphene (FLG) with micron-sized grains as a powerful platform for exploring intercalation and co-intercalation mechanisms of alkali ions with high versatility. Using voltammetric and chronoamperometric methods and bolstered by density functional theory (DFT) calculations, we show the kinetically facile co-intercalation of Li^+ and K^+ within an ultrathin FLG electrode. Furthermore, distinct Nernstian-type responses for Li^+ only and Li^+/K^+ co-exist systems with respect to solution concentration were observed, with the previous one showing a single Li^+ charge transfer property upon (de)intercalation and the latter one showing a two-phase Li^+/K^+ co-intercalation behavior. Bulk ion diffusion coefficients in the carbon host, as measured using the potentiometric intermittent titration technique (PITT) were similarly sensitive to solution composition. While previous studies of co-intercalation on graphitic anode typically focus on co-intercalation of solvents and one particular alkali ion, this is to the best of our knowledge the first study elucidating the intercalation behavior of two monovalent alkali ions. This study demonstrates the concept of alkali ion co-intercalation for elucidating fundamental charge transfer processes for batteries *beyond Li-ion*, and establishes ultrathin graphitic electrodes as an enabling electroanalytical platform to uncover thermodynamic and kinetic processes with high versatility.



Spatially resolved model of oxygen reduction reaction in porous gas-diffusion electrodes

franzen@icvt.tu-clausthal.de

Chlorine is one of the most important basic chemicals, which is predominantly manufactured by the energy-intensive chlor-alkali electrolysis process. By introducing the so-called oxygen depolarized cathode (ODC), the electrical energy demand can be reduced by up to 30 % compared to the state-of-the-art membrane process. The ODC is designed as a gas diffusion electrode (GDE), due to the low solubility of oxygen at the high process temperature (80 °C). To improve the efficiency of GDE further it is necessary to understand the complex interaction of transport and reaction processes inside the electrodes.
In order to investigate these processes a stationary mathematical model is developed, which includes the physical transport processes inside the gas and liquid phase as well as phase transformation and electrochemical reaction kinetics at the three-phase boundary (Fig. 1, left).

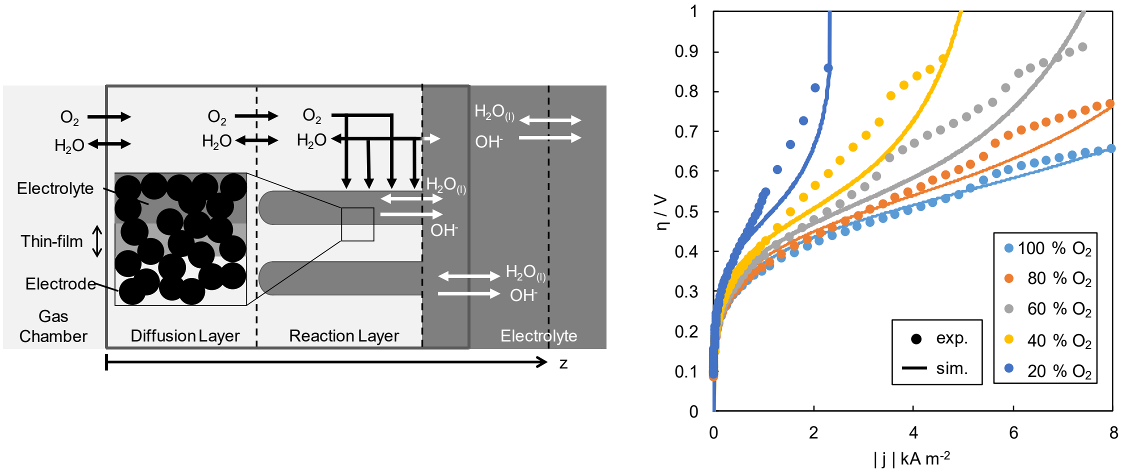

Fig. 1: Left: Schematic of the approach according to the TFFA model. Right: Measured and simulated polarization curves (80 °C, 30 wt.% NaOH) for different oxygen concentrations.

In contrast to earlier assumptions [1], recent findings by Botz et al. [2] showed the importance of the electrolyte transport inside the GDE which was underestimated in the current thin-film flooded-agglomerate (TFFA) models. In the improved version of the TFFA model, the electrolyte transport is considered adequately. The electrolyte properties inside the GDE and the resulting process parameters, such as the oxygen solubility, are spatially resolved, allowing a detailed glimpse into the physical and electrochemical processes inside the GDE.
The model is validated by a custom build test setup designed for stationary conditions. A large circulating electrolyte system, accurate gas dosing, as well as individual pressure and temperature control for the electrolyte and gas phase guarantee stationary conditions for long-term measurements. A wide range of process conditions can be adjusted and used for model validation. The results show a good agreement between measured and simulated overvoltages for different oxygen concentrations (Fig. 1, right).

Microbial electrolysis cell (MEC) is an emerging bioelectrochemical technology for hydrogen production from wastewater and other renewable resources, which major advantage is the relatively low voltage input (0.2–0.8 V) compared to the conventional water electrolysis (1.23–1.8 V). Because MECs use the same bioanodes as microbial fuel cells, the most critical challenge for their practical application is the development of cost-effective cathodes for near-neutral pH and ambient temperature conditions.

In this study, two- and three-component nanostructures, denoted as Fe_2Ni, Fe_3Ni Fe_2Co, Fe_3Co, CoNi, $CoNiFe_2$, and $CoNiFe_3$, were deposited on nickel foam (NF) by a new method called "Dip and Drying" (DDM) [1,2]. The DDM allows a fast self-deposition of nanoparticles upon the metal substrate at room temperature. The deposition was performed from mixed 0.1M solutions of $FeCl_2$, $FeCl_3$, $CoCl_2$ and $NiCl_2$, in different combinations for 30 minutes. The morphology and the chemical composition of the developed materials were analyzed by scanning electron microscopy (SEM) and X-ray photoelectron spectroscopy (XPS), respectively. The electrocatalytic activity of the modified electrodes for the hydrogen evolution reaction (HER) in neutral phosphate buffer solution (PBS) was explored by linear sweep voltammetry (LSV), cyclic voltammetry (CV), chronoamperometry (CA) and electrochemical impedance spectroscopy (EIS). The results obtained show that the nanocomposites, deposited from Fe^{2+} solutions, possess higher electrocatalytic activity than those from Fe^{3+}-containing electrolytes. The highest hydrogen production rate of 38±2 $ml.cm^{-2}.min^{-1}$ at -1.2 V (vs. Ag/AgCl) was achieved with Fe_2Co-NF electrode. Further studies, aiming at the practical application of this type of electrodes as cathodes in MECs, are going to be performed.

Electrochemical lab-on-a-chips (LoCs) are translational and mobile analytical micro-systems that enable rapid and label-free analyses of redox biomarkers, bringing benchtop medical diagnostic methods to the point-of-care. However, the selectivity of these LoCs towards the biomarkers-of-interest dramatically decreases in the presence of biofluids due to other redox molecules generating masking and overlapping electrochemical signals, requiring pretreatment steps to filter the interfering molecules and limiting the LoC's real-time analysis capabilities. Here we report a new electroanalytical technique that will enable biofluids analysis without pretreatment step and lies in the use of an array of microelectrodes that are modified by coating with bioelectronic films and generating a set of complex electrochemical signals that is analyzed by using intelligent machine learning algorithms (chemometrics) (Fig. 1A). We utilize electrodeposition method [1,2] to modify electrodes with bioelectronic nano-films (e.g., reduced-graphene-oxide and biopolymer chitosan). The modified array controls the electrochemical signal characteristics based on the diffusion and electron transfer rate coefficients of the redox molecules. We analyze biofluids in two detection modes: (1) direct detection of a specific biomarker and (2) simultaneous detection of multiple biomarkers by using machine learning algorithms. We demonstrate the proof-of-concept detection of: (1) amplifying antipsychotic clozapine electrochemical signal by using the reduced-graphene-oxide film that enables *in situ* detection in 20 µL of whole blood (within 5 minutes; limit of detection of 0.64 ± 0.04 µM, which is better than the clinical threshold) and will provide better schizophrenia treatment outcomes (Fig. 1B); and (2) utilizing an array of microelectrodes modified with various selectivities (chitosan and chitosan-carbon nanotubes) to different neurotransmitters and analyzing the set of signals generated from profiles of neurotransmitters by using a machine learning algorithm (artificial neural network and partial least square regression) enables their simultaneous differentiation (dopamine limit of detection of 9.3 mM and norepinephrine limit of detection of 6.7 mM) in undiluted urine (Fig. 1C).

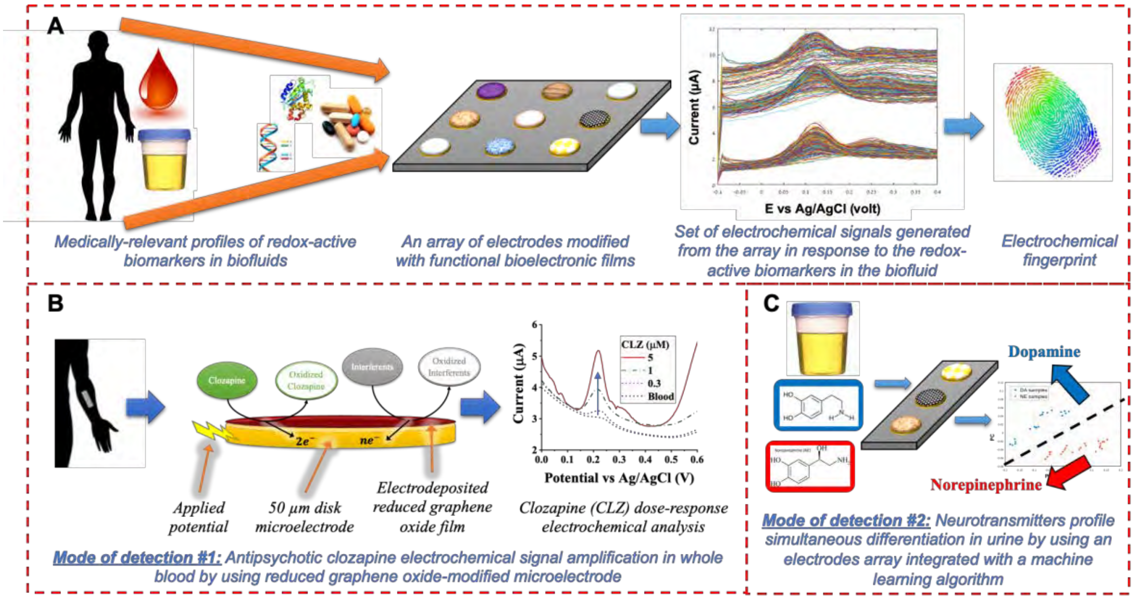

Figure 1: (A) Electrochemical lab-on-a-chip integrated with functional bioelectronic films for real-time and *in situ* probing of redox biomarkers in biofluids. (B) Amplification of antipsychotic clozapine electrochemical signal. (C) Intelligent electrodes array for neurotransmitters profiling.

Abstract

The paper provides insights on the less costly and eco-friendly green technique used for the synthesis of gold metal nanoparticle from banana (Musa paradisiaca) peel extracts. Electrospinning method was used to fabricate a stabilized nanocomposite polyacrylonitrile functionalized with green synthesized gold (PAN/Au) into nanofibers. The nanoparticle and its nanocomposite were characterized by using spectroscopy and surface morphology techniques. Surface characterization techniques like transmission electron microscope (TEM) was used to determine the shape and size of the nanoparticles. Other spectroscopy characterization was done by using UV-Visible spectroscopy, and X-ray diffraction (XRD), respectively. The spectroscopic studies for the gold nanoparticles were conducted at various volumes, concentrations, and synthesis time. The nanoparticle diameters were calculated to be on an average of 9 nm. Shape uniformity, stability and particle size distribution of the nanoparticles and nanocomposite were confirmed by TEM and Zeta Potential study. The electrochemical characterization of synthesized nanoparticles Au and its nanocomposite PAN/Au was carried out by using cyclic voltammetry (CV), Furthermore, the nanocomposites of gold nanoparticles doped in polyacrylonitrile nanofibers showed improved electrochemical information as compared to the monometallic nanoparticles, unmodified PAN molecule, and the bare glassy carbon electrode. These properties exhibited by the nanocomposite PAN-Au suggests that it can be used as electrochemical sensors for the detection of biological molecules such as neurotransmitters.

Preparation of Covalently Attached and Robust PANI Nanorod Arrays Using an Oriented Mesoporous Silica Film as Hard Template

Wahid Ullah, Neus Vilà, Gregoire Herzog, Alain Walcarius

Université de Lorraine, CNRS, LCPME, F-54600 Nancy, France.
wahid.ullah@univ-lorraine.fr

Polyaniline (PANI) is a thoroughly studied conducting polymer known for its structural diversities, high electrical conductivities, doping/de-doping and protonating/deprotonating chemistry, facile synthesis and environmental stability. Distinguishable among the family of conjugated polymers, it offers interest for numerous applications including sensors, energy harvesting and storage, memory devices, filtration membrane or anticorrosive coating.[1] For practical applications the structural design and fabrication at nanoscale (with controlled size and shape) is important for tuning their physical properties. Polyaniline nanostructures have been synthesized in different morphological shapes including nanofibers, nanorods and nanotubes, by using various synthetic methods such as template synthesis, emulsion, self-assembly and interfacial polymerization.[2] Aligned and ordered nanostructures are expected to exhibit better electrochemical and electronic properties than the randomly oriented nanoscale materials, as exemplified for polyaniline nanostructures showing high and reproducible performance as material of device.[3.]

One of the major issue is the PANI stability when deposited by drop-casting or electropolymerized over the surface. The lack of proper chemical bonds between the polymer chains and the conducting substrate, limits the practical applicability of PANI regardless of its excellent chemistry. It is thus necessary to get stable and covalently bonded PANI nanostructures.

In this work, PANI nanowires have been electropolymerized on ITO substrate covered with a mesoporous silica membrane and containing aniline molecules covalently attached at the bottom of the pores. The oriented mesoporous silica thin film was generated on ITO by electrochemically assisted self-assembly.[4] The ITO surface was first derivatized with aminophenyl molecules by in situ electrografting, according to a reported procedure,[5] followed by potentiostatic polymerization of PANI (for selected times) from a bath containing aniline in sulfuric acid media [6].

The electrografted arylamine molecules stabilize the PANI nanorods arrays and acts as catalysts during electropolymerization (see Fig. 1 indicating faster filling of mesochannels observed for the aniline-grafted sample, and mechanically stable deposits upon silica removal). The PANI nanowires exhibit excellent electrochemical redox behavior inside the silica pores and after removing the template. Its redox behavior was further studied by spectro-electrochemistry. Other physico-chemical methods including X-ray photoelectron spectroscopy, grazing-incidence small-angle X-ray scattering and transmission electron microscopy, were also used to characterize the materials.

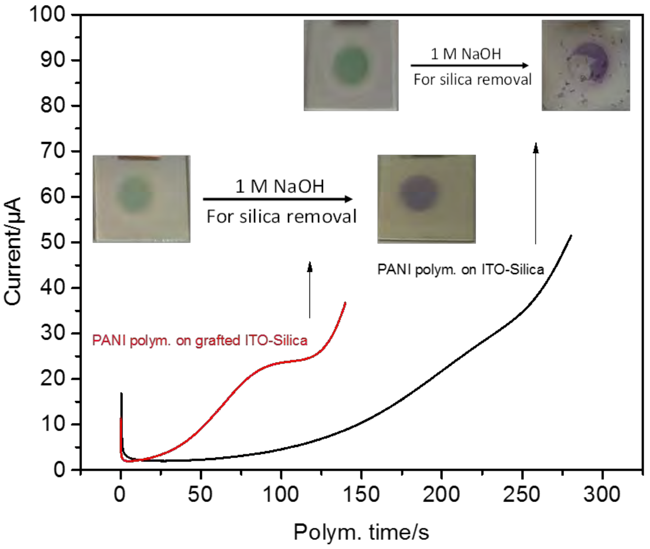

Fig.1. PANI polymerization steps on ITO-silica film and their relative stability after treatment with 1 M NaOH for silica template removal

Mg(II) porphine (MgP, Fig. 1_left) can be polymerized by its oxidation in acetonitrile (AN) solution. If the potential is sufficiently low (below 0.4 V vs. Ag/10 mM $AgNO_3$ in AN for potentiostatic deposition) an electroactive polymer film is steadily growing [1]. It is known that MgP oxidation under mild conditions should lead to single bond's formation in *meso-meso* positions. It implies that a porphine monomer unit may form from 2 to 4 such bonds inside the polymer.

Recently this process has been studied via both spectroelectrochemical [2], EQCM and redox-charge [3] methods in order to determine the average number of such bonds and consequently to establish the polymer structure.

The former technique monitors the variation of the UV-visible spectrum of the monomer solution in the course of its oxidative electrolysis, with separation of the monomer and solute oligomer contributions. It provides the relation between the electrolysis charge and the amount of the oxidized monomer. Their ratio reflects the charge consumption for formation of bonds inside the polymer and solute oligomers as well as for their transition to the oxidized (conducting) state.

Even though the latter contribution may be evaluated on the basis of the redox-charge variation of the deposited film in the monomer-free solution, one cannot find the number of bonds per monomer unit since a significant fraction of the oxidized monomer gives solute oligomers and polymer particles in solution or on the bottom of the cell.

Supplementary information for determination of the monomer fraction inside the polymer film on the electrode surface is available from the EQCM technique via measurements of the variation of the film's mass in the course of both its deposition and redox-charge variation in contact with background solution.

Data for all these three methods have been combined via the set of equations based on the mass and charge conservation laws.

Their solution has shown that the variation of the redox-charge of the film is accompanied by exchange with the background solution by not only counterions but also by solvent molecules, due to the film rigidity at this time scale. This analysis has confirmed a very high yield of the film deposition at the electrode surface: about 90% of all MgP monomers oxidized in the course of the oxidative electrolysis were transformed into monomer units inside the film. The average charging degree of the monomer unit inside the film at the deposition potential has turned out to be in agreement with our previous estimates, about 0.15. At last, the average number of the bonds between monomer units inside the film is around 2.3-2.4. It means that the polymer in general has got a chain structure (Fig. 1_right) but with a significant number of interchain links (around 3 to 4 links per 10 monomer units of the chain).

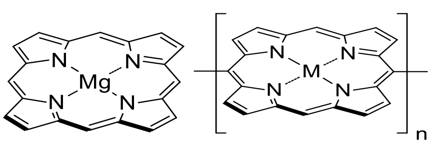

Fig. 1. Left: MgP monomer. Right: Mg(II) polyporphine deposited at very low oxidation potential, pMgP-I

Copper nanowires as higly sensitivite electrode for nitrate ions in water

Bernardo Patella, Roberta Russo, Carmelo Sunseri, Giuseppe Aiello, Rosalinda Inguanta
University of Palermo, Viale delle scienze Bd. 6
Bernardo.patella@unipa.it

Agricultural and livestock sectors are the main sources of nitrate ions contamination in water and foodstuff. [1]. High nitrate concentration is dangerous for both environment (algae overgrowth) and human health. Nitrate ions can be converted in different harmful nitrogen based compound such as NO_2^-, NO, N-nitroso compounds [2] that are responsible of several diseases such as cancer, Parkinson [3-4]. For these reasons, the Environmental Protection Agency, has established the maximum amount of nitrate ions in drinkable water at 44 mg/l, limit that is valid in many European countries [5]. Generally, spectroscopy techniques are the most used because allow to carry out analyses with high precision and reaching low LOD but it requires skilled workforces and specific instrumentations, besides the procedure is long and hard [6]. In this frame, electrochemical sensors can be used as easy, fast, cheap and not-lab-depended technology to detect nitrate ions with high selectivity and sensitivity. Copper is one of the more sensitive material to detect nitrate due to its low overpotential for reduction of NO_3^- to NO_2^- [7-9]. In this work, we have developed a Cu-NWs based electrode obtained by template galvanic deposition into nanoporous membrane. The overall process is cost effective, scalable, fast and Cu NWs of well anchored to a copper current collector can be easily obtained. Using this kind of nanostructured electrode, the surface area of the sensor is of about 70 time higher of bare ones and this is a special property for electrochemical devices. A low LOD of about 9.1 µM, (≈ 100 times lower than EPA limit) and a wide linear range were found. The effect of many interferents (Mg^{2+}, CO_3^{--}, Cu^{2+}, Pb^{2+}, Zn2+, Ni^{2+}, Hg^{2+}, Ag^{+}, Al^{3+}, SO_4^{--}, Na^{+}) was studied and nitrate ions were also successfully detected in real water samples (river, rain and drinking water).

Ascorbic Acid detection using linear sweep voltammetry on flexible electrode based on gold nanoparticles and reduced graphene oxide

Francesca Mazzara, Bernardo Patella, Giuseppe Aiello, Carmelo Sunseri, Rosalinda Inguanta
Department of Engineering
University of Palermo, Viale delle Scienze, 90128 – Palermo (Italy)
francesca.mazzara04@unipa.it

In the last years, sensors are taking more and more relevance in many fields such us, sport [1], environmental [2], health [3]. In the food field sensors can help to maintain the quality index for example by measuring the freshness, the allergens and the content of the contaminants or to improve the food-status monitoring by minimizing the waste and increasing the shelf-life.

In this work, an electrochemical sensor for ascorbic acid determination is shown whit a real validation for its determination in milk.

Ascorbic acid (AA), also known as vitamin C, is a water-soluble compound with antioxidant properties. It can be found in nature in many fresh fruits and vegetables like oranges, potatoes and cauliflower [4]. Due to its antioxidant properties, it is widely used in the food industry. It may be added to many foods and beverage to improve keeping qualities and it can be also used as a color/flavor stabilizer. Moreover, AA can be employed as a browning inhibitor to increase antioxidant food capacity. It plays a fundamental role in many biological functions such as iron absorption, collagen synthesis, immune system activation, osteogenesis [5]. Most plants and animals synthesize ascorbic acid from carbohydrate precursors including glucose and galactose. Humans and other animals are unable to produce this vitamin and thus it is necessary to be taken from the diet [6]. A lack of AA can cause scurvy pathology that affects collagen synthesis. Ascorbic acid deficiency leads to symptoms of weakness, anaemia, gum disease and skin problems. An excess of AA leads to gastric irritation and renal problem. Moreover, it can react with the heavy metals as pro-oxidant, increasing the oxidative stress in human cells.

For all these reasons, it is important to evaluate ascorbic acid concentration in food and beverage. In this work indium tin oxide (ITO) coated on flexible polyethylene terephthalate (PET) substrate electrode was modified with reduced graphene oxide and gold nanoparticles by simple co-electrodeposition performed at room temperature. All samples were characterized by electron scan microscopy and EDS analysis. Because the AA oxidation highly depends on the pH of the sensing solution, a systematic investigation on the effect of this parameter was performed.

The as prepared electrode was used as electrochemical sensor to selective detection of ascorbic acid using linear sweep voltammetry. Promising results were obtained. In particular, a linear range from 20 to 150 µM of ascorbic acid and a limit of detection of about 3.1 µM was found. The sensors have a reproducibility of about 5.5% and also show high selectivity towards different milk interferents such as chlorine, calcium, magnesium, sulphate ions, sodium and glucose. Ascorbic acid was detected also in different commercial milk samples demonstrating the possibility to quantify this analyte in real samples with a very cheap method.

The chemo-mechanical effect in solids refers to dimensional change due to change in stoichiometry. Dimensional change due to electrochemically-induced compositional change has been termed the electro-chemo-mechanical (ECM) effect. The mechanical instability inherent in this effect is clearly deleterious for batteries or fuel cells, but, as recently suggested, has potential for use in actuation[1]. The structure of an actuator device that operates on the ECM principle comprises a micrometer thick solid electrolyte (SE) sandwiched between two ECM-active, working body (WB) layers. An electrochemical reaction must occur in these layers, causing them to alternately expand or contract. In order to facilitate the ECM response, the WB layers should have mixed ionic and electronic conductivity and a large chemical expansion coefficient.

We have constructed a 2mm diameter thin film membrane ECM actuator device comprising 20mol% Gd doped CeO_2 (20GDC) as the SE and [$TiO_{2-\delta}$\20GDC] composites as the WBs. Selected area electron diffraction measurements showed the composite to be nanocrystalline, a morphology that promotes interfacial oxygen ion diffusion. Synchrotron X-ray absorption measurements detected a mixture of Ce^{3+}/Ce^{4+} (~[0.4]/[0.6]) and Ti^{3+}/Ti^{4+} (~[0.1]/[0.9]) oxidation states in the WB. The deformation of the ECM actuator was observed to be in the bending regime producing large vertical displacements (~3 μm) and ~4 MPa stress. The stress/voltage ratio yields a pseudo piezoelectric stress coefficient of e_{31}=1.26 C/m^2, comparable to common lead free piezoelectrics such as lithium niobate, lithium tantalate and alkali niobates.

Three-dimensional (3D) printing has been exponentially applied in chemistry with relevant applications in material science and electrochemistry. Fused deposition modelling is the most affordable 3D printing technique and thus has been widely used for the fabrication of electrodes for energy storage and sensors. Commercially-available conductive filaments made of polylactic acid (PLA) containing graphene or carbon black as conducting agents have been proposed.[1] However, recent publications have reported the presence of metallic impurities (Fe, Ti and Al) in commercial filaments of graphene/PLA, such as Black MagicTM, which can be accessible after a chemical treatment of the 3D printed surface with dimethylformamide (immersion for 15 min). These impurities affect the electrochemical properties of the 3D-printed material, such as for water splitting.[2] In this context, we demonstrate the electrochemical synthesis of iron hexacyanoferrate (Prussian blue) by cyclic voltammetry in the presence of ferricyanide using iron impurities present in such 3D-printed graphene/PLA electrodes as the iron source. It is well known that Prussian blue (PB) films can be formed electrochemically in the presence of iron (III) cations and ferricyanide. In this procedure, the iron (III) source is provided by the bulky 3D-printed G/PLA electrode after electrode immersion in dimethylformamide for 15 min to remove the excess of PLA and expose iron sites. After continuous voltammetric cycles in a 0.1 mol L^{-1} KCl solution, PB films were grown. Figure 1 shows PB film formed after 50, 100, 150 and 200 cycles. X-ray fluorescence revealed the presence of iron after solvent treatment, in agreement with previous works[2] and Raman spectra confirmed the presence of PB at the modified surface. The generated PB/graphene/PLA electrodes was evaluated for H_2O_2 detection under flow conditions and applying 0.0 V vs Ag/AgCl/KCl_{sat}. The results showed a remarkable performance of this novel platform in the detection of H_2O_2 within a linear range from 1 to 1000 μmol L^{-1} and with a limit of detection of 0.56 μmol L^{-1}. These results are well compared with previously reported electrochemical sensors based on PB-modified electrodes.

How Can Details of Processes of Conducting Polymers Be Uncovered by Means of In-situ Combined Electrochemical Techniques

Csaba Visy
Department of Physical Chemistry & Materials Sciences, University of Szeged
H-6720 Szeged, Rerrich tér 1. Hungary
visy@chem.u-szeged.hu

Since the discovery of electronically conducting polymers, not only their large-scale of potential applications has been evidenced, but many of them have been already put on realization. To improve functioning of such polymer based devices, the multi-faceted cognition of these materials is indispensable. Especially, the elucidation of their redox switching between non-conducting and conducting states is of prime importance. In situ electrochemical techniques are widely applied to study this phenomenon, because they deliver extra information about the processes from an additional aspect, such as spectral modifications, mass, structural, volume and conductivity changes, occurring in parallel with either the electropolymerization process or the redox transformation of the film. A recent book [1] was dedicated to the advantages of such combinations. Moreover, recent technical developments have led to combination of two in situ analytical methods to extend further the understanding of the redox behavior of conducting polymers by furnishing information on the self-same polymer film from several aspects at the same time by employing two in situ electrochemical techniques in a hyphenated mode.

This contribution intends to present examples how fundamental questions can be answered by designing and performing adequate experiments.

Answer to the question and longtime uncertainty whether the chain growth takes place via a coupling between two cation radicals or in a reaction of the cation radical with the monomer could be answered by UV-VIS spectroelectrochemistry.

A series of spectrally followed polymerizations revealed that the film has to be left to relax before its first electrochemical reduction, in order to avoid irregularities and irreversible damages. Parallel EQCM, in situ conductance and pH changes indicated that still existing protonated segments are transforming during the relaxation.

An extraordinary cation exchange behaviour evidenced by EQCN measurements has been found with poly(3,4-ethylenedioxythiophene), synthesized in the presence of chloride or fluoride ions. Thus, the idea of simple charge compensation role of the counter ions has to be completed by eventual specific interaction of the charge carrier with the dopant.

Voltabsorptiometric data during the first section of the return from the conducting state indicated a dissociation-type step in both anodically and cathodically doped films.

Role of the formation of optically distinguishable charge carriers in the development of the conducting state have been studied by using the hyphenation of spectroelectrochemistry with in situ conductance. It has been evidenced that fast redox switching – essential for practical applications - is expected only with polymers doped by immobile anions.

Sophisticated use of these techniques are not restricted to studies on conducting polymers, but can be extended for all kinds of electroactive layers.

800 E Kirkwood Avenue, Bloomington, Indiana, USA
lanbaker@indiana.edu

Transport process across the blood-brain barrier (BBB) takes place by either transcellular pathways or passive paracellular pathways. At cell-cell junctions, paracellular pathways consist of tight junctions (TJs) regulated by TJ proteins to protect the brain from harmful substances in the blood. However, some drugs related to neurological cares are known to transiently upset TJ proteins which disrupt the integrity of the BBB, such as hyperosmolar agents, the drugs of a major treatment for intracranial hypertension resulted from brain trauma. Thus, it is of great importance for people to fully understand the effects of these drugs on TJs to inform current therapies of possible side-effects. To measure the effect of a specific drug on paracellular transport, techniques using Ussing chamber and two-path impedance spectroscopy can be utilized to monitor paracellular conductance/resistance. While informative, they are not able to collect characteristic responses from a single cell, or the permeability change at small but important subcellular structures like tricellular TJs (tTJs). In this study, we utilized potentiometric-scanning ion conductance microscopy (P-SICM) conductance mapping to provide nanometer scale analysis of the response of the TJs at Madin–Darby Canine Kidney strain II (MDCKII) cells to hyperosmolar agent mannitol, from which tTJs and its counterpart bicellular TJs (bTJs) can be visualized and differentiated. We discovered that hyperosmolar condition (termed hyperosmolality here) leads to increased conductance at tTJs without significant alteration in conductance at bTJs. To quantify this effect, an automated computer vision algorithm was designed to extract and calculate conductance components at both tTJs and bTJs. Additionally, lowering Ca^{2+} concentration in the bath facilitates tTJ disruption under hyperosmolality. Strengthening tTJ structure by overexpressing immunoglobulin-like domain-containing receptor 1 (ILDR1) protein abrogates the effect of hyperosmolality. We posit that osmotic stress physically disrupts tTJ structure, as evidenced by super-resolution microscopy. Findings from this study not only provide a high-resolution view of TJ structure and function, but also can inform current osmotherapy and drug delivery strategies for brain diseases.

Applications of scanning electrochemical microscopy for high-resolution imaging and chemical sensing of corrosion reactions and corrosion protection strategies

Ricardo M. Souto
University of La Laguna
Department of Chemistry, P.O. Box 456, 38200 La Laguna (Tenerife), Canary Islands, Spain
rsouto@ull.es

Scanning electrochemical microscopy (SECM) has become a very powerful tool for the investigation of solid-liquid interfaces in corrosion processes. Corrosion processes are initiated in micrometer and sub-micrometer ranges, and they are usually very heterogeneously distributed on the surface of the reacting metals. In situ and real time monitoring thus requires the use of spatially resolved techniques such as scanning electrochemical microscopy (SECM). The movement of an ultramicroelectrode (UME) in close proximity to the interface under study allows the application of various experimental procedures that can be classified into amperometric and potentiometric operations depending on either sensing faradaic currents or concentration distributions resulting from the corrosion process. Quantitative analysis can be performed using the UME signal thus revealing different sample properties and/or the influence of the environment and experimental variables that can be observed on different length scales. In this way, identification of the earlier stages for localized corrosion initiation, monitoring of water and specific ions uptake by intact polymeric coatings applied on metals for corrosion protection as well as lixiviation, and detection of coating swelling -that constitutes the earlier stages of blistering-, have been successfully achieved. Prominent examples will be selected to illustrate the selection of operation modes and the problems encountered when working with practical samples.

Hybrid (iso)porphyrin – polyoxometalate copolymer for photo(electro)chemical applications: from flat to mesoporous ITO electrodes

Laurent Ruhlmann,* Yiming Liang, Zhaohui Huo, Antoine Bonnefont

4 rue Blaise Pascal, 67000 Strasbourg, France
lruhlmann@unistra.fr

The development of hybrid polymers incorporating POMs is a promising approach to elaborate new functional materials. To expand the practical applications, their association to a visible-light photosensitizer is needed. In this context, we have developed a method of electropolymerization of POMs based on nucleophilic attack onto the electrogenerated porphyrin dications.[1-2] The formation of hybrid POM-porphyrin copolymeric films (Fig. 1, film I) can be obtained by the electro-oxidation of porphyrin in the presence of the POM bearing two pyridyl groups (Py-POM-Py) [3]. This process is feasible for various type of POMs such as Dawson, Lindqvist or Keggin type POMs [4-6].

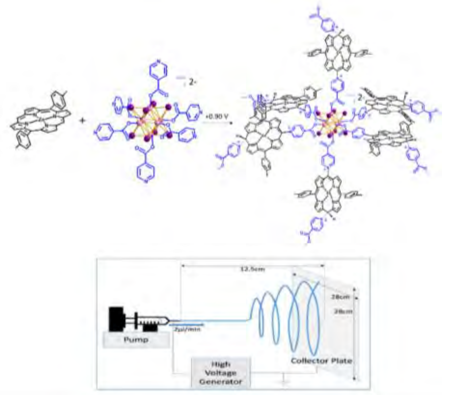

Figure 2 Top: 3D poly-Isoporphyrin-POM copolymer. Bottom: Electrospinning configuration used for deposition. of ITO nanofiber layers.

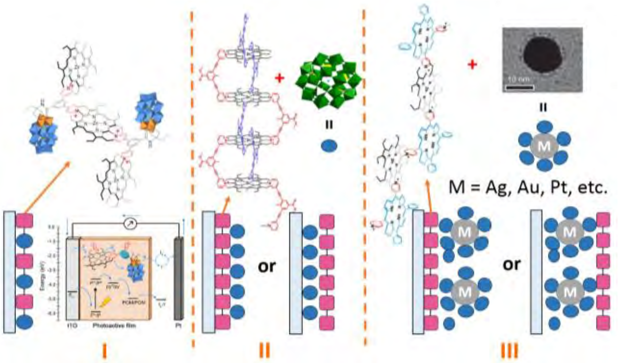

Figure 1 Various type of porphyrin-POM films.

Stable isoporphyrin [7] – POM copolymers (Fig. 2) have been also develop recently showing interesting efficiency even upon the NIR illumination. A second methodology is also proposed to form hybrid POM-porphyrin films (Fig. 1, films II or III): first the formation of cationic polyporphyrin electropolymer. Then, by metathesis reaction, the (partial) exchange onto the surface of the initial counter ions by the POM^{n-} or by the nanoparticles stabilized with POM^{n-} (POM^{n-}@M, M = Ag, Au, Pt, etc.).[8] The photovoltaic performances of these hybrid materials have been investigated by photocurrent transient measurements under visible-light illumination [9-11] given by now good efficiency. In order to increase the efficiency, mesoporous ITO electrodes (nanofiber formed by electrospun or porous ITO electrode obtained using a colloidal co-assembly approach) have been used and will be discussed (Fig. 2).

Magnetic Field-Driven Extraction of Peptides for Potentiometric Biosensing

Jiawang Ding, Enguang Lv, Wei Qin

Yantai Institute of Coastal Zone Research (YIC), Chinese Academy of Sciences (CAS);
Yantai, Shandong 264003, P. R. China
E-mail address: jwding@yic.ac.cn

Potentiometric sensors based on polymeric membrane ion-selective electrode (ISE), with attractive advantages of portability, robustness, and resistance to interference from turbidity, have been well developed in the field of biosensors [1]. Peptides have simple and defined structure and exhibit specific and strong affinities to a variety of analytes. Moreover, in contrast to antibodies, peptides are intrinsically more stable in harsh environments [2]. In principle, peptides can be positively or negatively charged, which could induce a potentiometric response on the polymeric membrane ISEs. Inspired by the potentiometric responses of polyamino acids [3], we envision that a general and direct potentiometric sensing platform can be designed by using peptides for both molecular recognition and signal transduction. In this presentation, direct potentiometric assays based on magnetic field-driven extraction of peptides into polymeric membranes will be reported.

The *cytochrome bd oxidases*, family of unique prokaryotic enzymes from the pathogenic respiratory chain, catalyze the reduction of molecular oxygen in water and oxidation of quinols. It is also found that these proteins play the crucial role in bacterial adaptivity and resistance to oxidative stress which makes *bd oxidases* the promising target for future antibiotics [1]. Here, we developed the enzyme-based electrochemical sensor for the screening of a compound library in order to find effective inhibitors of *bd oxidase* quinone-binding site. The application of the biosensor gives additional information on the catalytic behaviour of *bd oxidase*, immobilized on the 3D gold nanoparticles network which was previously modified by self-assembled monolayer of 6-mercaptohexan-1-ol and hexanthiol. The stability of protein films was tuned by adding lipids, varying the protein concentration and different thiols bound to the surface, so the screening results were obtained with good reproducibility [2].

The developed electrochemical sensor was successfully applied for the natural antibiotic Aurachin D and its synthetic derivatives screening, molecules that resemble the quinone scaffold. It was shown that the halogen substituent at 3-position is not influential, however, the length-dependent isoprenoid chain in this position plays crucial role in activity of potent inhibitors. Additionally, the role of Ubiquinone as cofactor was investigated for better understanding of the *bd oxidase* catalytic mechanism.

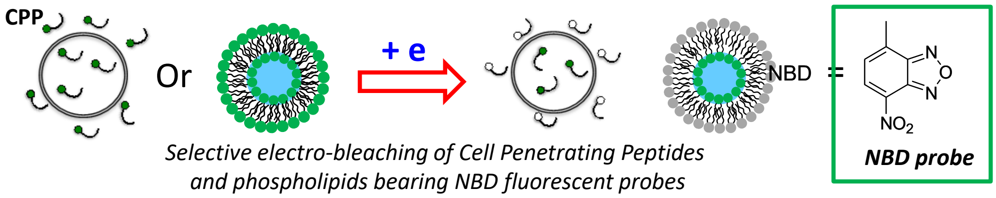
olivier.buriez@ens.fr

Transport of bioactive molecules across cell membranes is a central issue for living organisms since they encompass crucial processes including cell signaling and communication, cellular excretory activity and drug delivery. In this context, the development of instrumental methodologies possessing both high temporal and spatial resolutions to investigate transmembrane trafficking is still requested. The combination of amperometry and fluorescence is a representative example of the benefits brought by sensitive and time-resolved techniques in the exploration of vesicular exocytosis.[1] Based on this strategy, we recently explored the implementation of electrochemical commands to control fluorescence in order to study the passive transport of bioactive molecules across membranes.[2-4] Accordingly, we have shown that the fluorescence emitted by NBD-labelled biomolecules (NBD=7-nitrobenz-2-oxa-1,3-diazole) can be quenched electrochemically, a key property to study the trafficking of cell penetrating peptides (CPP). More specifically, we showed that such an electrochemical command is a powerful approach to discriminate internalized and non-internalized peptides incubated with purely lipidic nanometer-size vesicles. Interestingly, this strategy has also proved efficient to selectively switch off the fluorescence emitted by NBD-labelled phospholipids localized only on the outer leaflet of vesicles.



Selective electro-bleaching of Cell Penetrating Peptides and phospholipids bearing NBD fluorescent probes

stanislav.trashin@uantwerpen.be

Photosensitizers and photocatalytic reactions attract lots of attention due to a high demand for green technologies in organic synthesis, water and air purification, energy conversion. Moreover, new photosensitizers find applications in photodynamic therapy, artificial photosynthesis, biochemical studies as ROS generators, and in newly emerging fields such as photoelectrochemical sensing. Thus, discovering photosensitizers with advanced performances and evaluation of factors influencing their activities are crucial.

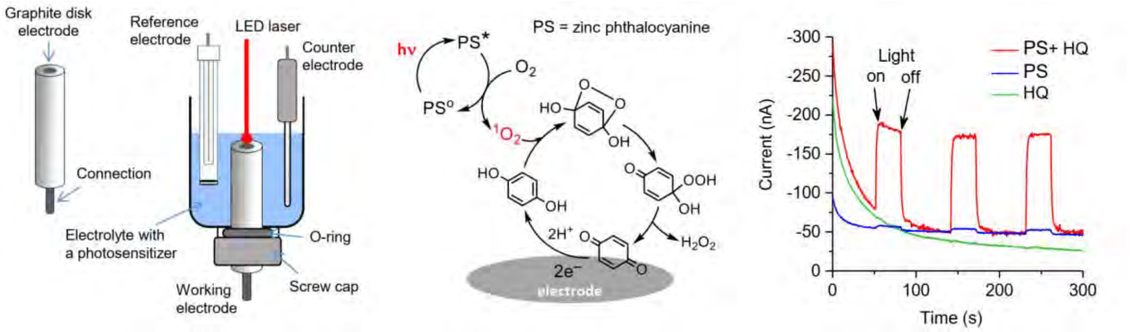

Fig. 1. Schematic illustration of the photoelectrochemical cell and the redox cycling mechanism

In the presented study [1], we developed a fast amperometric method to test the photocatalytic activity of type II photosensitizers dissolved in methanol making use of the redox cycling of hydroquinone (EC_{cat}-mechanism, Fig. 1). Within the suggested detection scheme, photocatalytic oxidation of hydroquinone is followed by amperometric reduction of the oxidized product (benzoquinone) at a graphite electrode giving rise to a photocurrent that can be linked to the rate and quantum yield (Φ_Δ) of singlet oxygen ($^1O_2$) generation. The method is suitable for measuring high $^1O_2$ quantum yields ($\Phi_\Delta >0.5$) as well as low yields ($\Phi_\Delta <0.05$) in the same experimental conditions and time scale. Moreover, the system does not require accumulation of a reaction product since the amperometric signal develops near instantly when the light is on, which enables dynamic monitoring of a photosensitizers' activity at varying conditions in a single experiment.

Besides the demonstrated application in characterization of photosensitizing activity, this work also represents the first example of one-pot coupling of electrochemical and photosensitized reactions in an organic medium.

Nitric oxide reductases (NORs) are a transmembrane metalloenzyme and catalytically reduce NO to N_2O in the microbial denitrification process. This enzymatic reaction occurs at a binuclear active center of the non-heme Fe_B and the heme b_3,[1] and the reaction mechanism remains unclear even though it has been intensively studied using physicochemical techniques including protein film electrochemistry.[2]

We have combined protein-film electrochemistry (PFE) and surface-enhanced infrared absorption (SEIRA) spectroscopy of a cytochrome *c*-dependent NOR (*c*NOR). The cNOR isolated from *P. aeruginosa* was immobilized on a SEIRA-active gold film electrode on hemicylindrical Si prism via self-assembled monolayer (SAM) of functional group-terminated alkylthiols and then the addition of phospholipids produced a protein-tethered lipid bilayer membrane (ptBLM), which was tracked by time-resolved SEIRA spectroscopy. The formation processes of BLMs were surely dependent on the existence of protein immobilized on SAMs. Potential-dependent SEIRA spectra at the *c*NOR-immobilized Au electrode, where the enzyme was almost exposed to the aqueous electrolyte solution, enabled us to assign the reduction potential of the binuclear active center, which revealed that heme b_3 involves the enzymatic NO reduction.[3] However, the effect of surrounding BLMs has not been included in the previous study. To gain further mechanistic insights, potential-dependent SEIRA spectroscopy at the ptBLM-immobilized Au electrode under NO is underway.

Biodiesel, a biofuel, have faced a constant increase on its production by attending the demand for sustainable fuel. The increase on its production have led to an excess of glycerol, a co-product of biodiesel production, in global market in a way that its use as fuel and/or precursor for value-added chemicals can be consider at the same time that high pure hydrogen can be produced in a electrolyzer.[1] Noble metal as Pt, Au, Pd and Ag have demonstrated its activity to oxidize glycerol[2] but the materials cost turns their use unviable[2]. Thus, to enable this type of device, it is extremely important the development of low cost electrocatalysts.

Perovskite oxide materials can be considered as an option of electrocatalysts. This kind of material has demonstrated being active as catalyst for glycerol reform in heterogeneous catalysis[3] and as electrocatalyst for glycerol and methanol oxidation for solid oxide fuel cell (SOFC).[4,5] Thus, in this work, we present the first findings of $LaNiO_3$ and $LaCoO_3$ as electrocatalysts for glycerol electrooxidation reaction (GEOR) suggesting a reaction pathway supported by *in situ* FTIR and sample collection *online* coupled to HPLC.

Figure 1(a1 and a2) shows the voltammetric profile of GEOR on both materials. $LaNiO_3$ (a1) and $LaCoO_3$ (a2) are active for GEOR and $LaCoO_3$ does not suffer with poisoning during cycling. The obtained currents for $LaNiO_3$ are c.a. 250 times higher than those for Ni/C[6].

Figure 1(b1 and b2) shows the *in situ* FTIR results. Bands due to the formation of formic (1580, 1380 and 1350 cm^{-1}) and glycolic (1580 and 1075 cm^{-1}) acids during GEOR are observed for both electrocatalysts. In the case of $LaCoO_3$ the presence of oxalic acid (1308 cm^{-1}) can also be observed. *Online* HPLC experiments corroborates the *in situ* FTIR results demonstrating the formation of formic and glycolic acid, being formic acid formed in higher amounts on $LaCoO_3$.

These results show that perovskite oxides are active for GEOR, producing high specific currents and the generation of formic and glycolic acids.

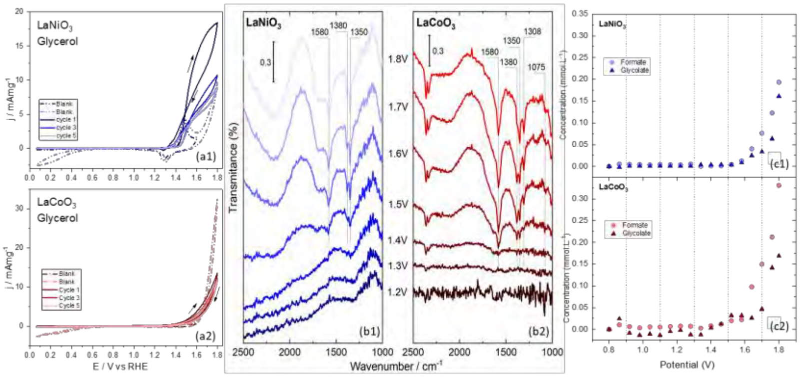

Figure 1: Voltammetric profile for GEOR on $LaNiO_3$ (a1) and $LaCoO_3$ (a2) (blank in dashed line). FTIR spectra of $LaNiO_3$ (b1) and $LaCoO_3$ (b2) collected in SNIFTIRS (reference 0.8V). Formate and glycolate formation detected by *on line* HPLC for $LaNiO_3$ (c1) and $LaCoO_3$ (c2). All results in a solution of $0.1 molL^{-1}$ glycerol in $0.1\ molL^{-1}$ NaOH.

An enzyme-free H2O2 sensor based on poly(2_aminophenylbenzimidazole)/gold nanoparticles coated pencil graphite electrode

Mine ŞEN TEKER[a], Erhan KARACA[a], Nuran ÖZÇİÇEK PEKMEZ[a] *, Uğur TAMER[b], Kadir PEKMEZ[a]

a Hacettepe University, Department of Chemistry, 06800 Ankara, Turkey
b Gazi University, Faculty of Pharmacy, Department of Analytical Chemistry, 06330 Ankara, Turkey
erhankaraca@hacettepe.edu.tr

A poly(2-aminophenylbenzimidazole)/ gold nanoparticles (P2AB/AuNPs) coated disposable pencil graphite electrode (PGE) was fabricated as an enzyme-free sensor for the H_2O_2 determination. P2AB/AuNPs and P2AB were successfully synthesized electrochemically on PGE in acetonitrile for the first time. The coatings were characterized by scanning electron microscopy, X-ray diffraction spectroscopy, Energy-dispersive X-ray spectroscopy, Surface-enhanced Raman spectroscopy, and UV-Vis spectroscopy. AuNPs interacted with P2AB as carrier enhances the electrocatalytic activity towards reduction of H_2O_2. The analytical performance was evaluated in a 100 mM phosphate buffer solution at pH 6.5 by amperometry. The steady state current *vs.* H_2O_2 concentration is linear in the range of 0.06 to100 mM (R = 0.992) with a limit of detection 3.67×10^{-5} M at - 0.8 V *vs.* SCE and no interference is caused by ascorbic acid, dopamine, uric acid, and glucose. The examination for the sensitive determination of H_2O_2 was conducted in commercially available hair oxidant solution. The results demonstrate that P2AB/AuNPs/PGE has potential applications as a sensing material for quantitative determination of H_2O_2.

Elucidating reactions of individual nanoparticles by electrochemical dark-field microscopy

Albeit nanoparticles, especially silver and gold, are frequently used to date in medicine and sportswear due to their antibacterial and anti-inflammatory properties, their physical properties, chemical reactivity and degradation are still poorly understood. Single noble metal nanoparticles can be studied with dark-field microscopy based on their localized surface plasmon resonance (LSPR). H, it is possible to observe their optical appearance (color) and scattering spectrum by hyperspectral dark-field imaging. Hyperspectral imaging can be used to observe a change of the LSPR *operando* due an applied potential and a subsequent electrochemical reaction by monitoring the scattering intensity and spectrum

With this new technique, further insights into reaction dynamics and processes or structural transformations of nanoparticles during their electrochemical reaction can be obtained [1-3]. Hence, this knowledge can be used to gain more information about the *operando* properties of nanoparticles itself and the effect of the dielectric environment in the vicinity of the surface of the particles.

Electrochemical energy conversion and storage (EECS) devices are expected to play a crucial role towards the achievement of a sustainable energy system at the global level. Among EECS, a particularly high relevance will be enjoyed by proton exchange membrane fuel cells (PEMFCs). In these EECS, the electrooxidation of hydrogen by oxygen yields a direct current without the emission of greenhouse gases [1]. The process is highly efficient, but is bottlenecked by the sluggishness of the oxygen reduction reaction (ORR) [1]. To ensure that the PEMFC achieves a performance level compatible with the intended application, the ORR must be promoted by suitable electrocatalysts (ECs). Platinum is the most promising material for the active sites of such ECs. However, to place PEMFCs closer to market and to prevent supply bottlenecks the total amount of noble metal needs to be curtailed.

This work overviews the development of a new family of low-Pt ECs for the ORR, whose active sites are found on the surface of sub-nanometric clusters (SNCs) where Pt is alloyed with a first-row transition metal (*e.g.*, Ni, Cu) that operates as a *“co-catalyst”* and raises the intrinsic performance of each active site much above the Pt baseline [2].

The SNCs increase the utilization of Pt atoms included therein by up to *ca.* one order of magnitude with respect to the Pt nanoparticles (NPs) adopted in state-of-the-art ORR ECs, thus raising the specific power yielded by the PEMFC. Values as high as 14 kW/g_{Pt} are achieved, that exceed the target set by the DoE for 2020 (*i.e.*, 8 kW/gPt).

The support of the low-Pt ECs described herein exhibits a *“core-shell”* morphology, including a hierarchical graphene-based (H-GR) *“core”* that is covered by a carbon nitride (CN) *“shell”*. H-GR consists of highly defective graphene nanoplatelets and carbon black NPs [3], to facilitate mass and charge transport. The CN *“shell”* includes less than 5 wt% of N (to prevent the introduction of ohmic drops) and though C- and N-based ligands makes up *“coordination nests”* that, together with defects of the graphene, stabilize the SNCs resulting in an outstanding durability of the ECs.

This report takes into consideration the various families of low-Pt ECs based on H-GR supports developed so far by our group, and compares the interplay between the preparation parameters (in particular the type of support) and the physicochemical properties with the electrochemical behavior and the performance in a single PEMFC tested under operating conditions.

Increasing Microbial Fuel Cell Power Densities Requires a Better Understanding of Factors that Impact Electrode Performance

Ruggero Rossi, Bruce Logan
The Pennsylvania State University
Department of Civil and Environmental Engineering, University Park, PA 16802, USA
rxr57@psu.edu, blogan@psu.edu

Improving power generation of microbial fuel cells (MFCs) requires that the systems are optimized to reduce resistances that limit system performance. Through quantification and analysis of these factors we were able to modify the cell design, and produce a maximum power density of 7.1 ± 0.4 W m^{-2} in 100 mM phosphate buffer (PBS), the highest power density ever generated for an MFC to our knowledge. The reactor was a flow-through cell with an anion exchange membrane (AEM) separating anode and cathode (all 7 cm^2) in a membrane electrode assembly (MEA) configuration. Through analysis of factors impacting the electrode resistance, we minimized the total internal resistance by using a felt anode, AEM, and cathode tightly packed together specifically to enhance the hydroxide ions transport from cathode to anode and minimize pH imbalances and solution resistance (R_Ω). Therefore, in 50 mM PBS the MFC produced one of the highest power density recorded in such media, with 5.7 ± 0.4 W m^{-2} (at 29 ± 1 A m^{-2}, internal resistance of 7.2 ± 0.6 mΩ m^2), and 25% higher in 100 mM PBS.

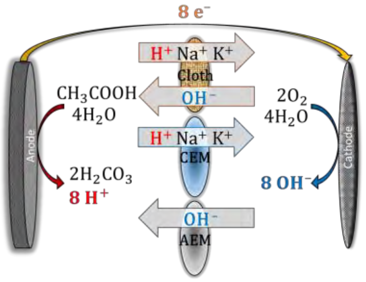

Fig. 1. Comparison of the ion transport in MFCs with a cloth separator, CEM, or AEM. Note that the cathode reaction is balanced by release of hydroxide ions and not consumption of protons. Only the AEM can selectively enhance hydroxide ion transport from the cathode and thus control charge balance through OH^- transport rather than H^+ ion transport.

In contrast to other MFCs using a cation exchange membrane (CEM) in MEA configurations, an AEM facilitate hydroxide ion transport. The carbon felt anode and an air cathode (no catholyte) were pressed onto the AEM, ensuring an electrode spacing similar to the membrane thickness (106 ± 1 μm) and facilitating transport of only the hydroxide ions produced at the cathode by the oxygen reduction reaction (ORR) while water diffuses through the membrane (Figure 1). Cation transport was severely limited by using an AEM while hydroxide anion transport was enhanced by the localized concentration gradient and the electric field at high current densities. Oxygen intrusion in the anolyte was limited by maintaining a low humidified air flowrate. To further minimize internal resistance the anolyte flow was directed through the felt anode to improve overall performance. Maintaining the anode and cathode close together contributed in minimizing R_Ω to only 1.09 ± 0.02 mΩ m^2, compared to R_Ω > 14 mΩ m^2 for a cubic MFC with brush anode and air-cathode [1]. To maximize overall power production in MFCs, the protons produced at the anode and the hydroxide ions produced at the cathode need to be transported towards the other electrode, to effectively obtain a neutral pH and avoid acidification of the anodic biofilm [2].

Our MFC design using an AEM placed directly on the cathode minimized the total solution resistance, selectively transferred hydroxide ions from the cathode to the anode, and thus better neutralized protons produced at the anode lowering internal resistance and substantially improving the reactor performance.

On the thermodynamics of electroactive microorganisms

Benjamin Korth
Department of Environmental Microbiology, Helmholtz-Centre for Environmental Research – UFZ
Permoser Str. 15, 04318 Leipzig, Germany
benjamin.korth@ufz.de

Electroactive microorganisms (EAM) are capable of performing extracellular electron transfer (EET). It represents a unique metabolic trait enabling the exchange of electrons via cytochromes across the cell membrane with solid electron conductors (e.g., electrodes). Although EAM attracted considerable interests over the last decade, their thermodynamic characterization is still in its infancy. However, assessing the energy fluxes during EET is a prerequisite for deciphering their ecological role and for leveraging their biotechnological potential. Yet, a comprehensive thermodynamic analysis of EAM requires a profound understanding of their energy conversion.

Therefore, the peculiarity of the electron-transport chain (ETC) and the energy harvest of EAM is discussed. As metabolically received electrons are transferred across the cell membrane, a certain share of ETC components is located in the periplasm and at the outer membrane. Thus, they cannot contribute to the generation of proton motive force across the inner membrane subsequently utilized for ATP synthesis. Consequently, the question arises, to which extent the anode potential influences the energy harvest of EAM. By applying a previous developed model for electroactive biofilms[1], it is illustrated that the anode potential indeed influences the reaction conditions for substrate oxidation. However, this is solely a kinetic effect while the thermodynamic frame of EAM is not affected by the anode potential[2]. Therefore, energetic assessments require an adapted approach compared to classical thermodynamic calculations.

Furthermore, bioelectrocalorimetric studies with *Geobacter anodireducens* enrichment cultures are performed for measuring the heat dissipation during EET. By analyzing redox titration experiments, the so far unknown microbial electrochemical Peltier heat (mePh) was revealed. It represents an entropic effect at the cytochrome/solid electron acceptor interface for direct EET and amounts in the studied model system to a heat formation of −27±6 kJ per mole of transferred electrons[3]. The mePh constitutes a metabolic trade-off as it decreases biomass yield but provides driving force for growth. To further assess this novel effect, alternative electron acceptors are analyzed.

Bioelectrochemistry to improve biological gas desulfurization

Annemiek ter Heijne, Rieks de Rink, Margo Elzinga, Dandan Liu, Jan Klok, Cees Buisman

Environmental Technology, Wageningen University & Research
Bornse Weilanden 9, P.O. Box 17, 6700 AA Wageningen, The Netherlands
Annemiek.terHeijne@wur.nl

The biological gas desulfurization process under haloalkaliphilic conditions is widely applied in industry for removal and conversion of H_2S from sour gas streams, such as biogas and natural gas. his continuous process consists of two steps: 1) Selective absorption of H_2S into a (bi)carbonate solution in an absorber column and 2) conversion of sulfide to elemental sulfur by sulfide oxidizing bacteria (SOB) in an aerated bioreactor. One of the challenges in this process is to increase the selectivity for sulfur formation, by decreasing the production side-products thiosulfate and sulfate, to reduce the requirements of NaOH to keep alkalinity. To increase this selectivity, the continuous biological desulfurization process was extended with an anaerobic bioreactor, which was placed in between the absorber and aerated bioreactor. It was hypothesized that both the biological formation of sulfate as the chemical formation of thiosulfate would reduce as a result of incubation of the SOB under the sulfidic conditions in the anaerobic reactor. With the anaerobic bioreactor, a selectivity for sulfur formation of 97% was achieved, compared to 75-80% without anaerobic bioreactor. This lead to a reduction in NaOH consumption and bleed stream formation of 80-90%. A surprising finding was the ability of SOB to remove part of the sulfide from solution in the anaerobic bioreactor. We hypothesized that SOB can shuttle electrons from sulfide from the anaerobic bioreactor to the aerobic bioreactor.

To study the hypothesis of electron shuttling, we performed batch experiments to study two processes: 1) the removal of sulfide from solution and 2) the release of electrons from SOB at the anode in an electrochemical cell. We used bioreactor solutions from two biological desulfurization systems; one from a full scale plant) with absorber and aerated bioreactor, and one from a pilot plant) with additional anaerobic bioreactor. We found that SOB removed all sulfide from solution when exposed to concentrations up to 0.2 mM^2. After SOB were transferred to an electrochemical cell, they released electrons to an anode in absence of free sulfide. Average current densities of 0.48 and 0.24 A/m^2 were measured for bioreactor solutions with two different types of SOB, at +0.1V vs Ag/AgCl. Current was negligible for reactor solutions without SOB. The recovered charge increased with more positive anode potentials. We hypothesize that SOB can oxidize sulfide to sulfur under anaerobic conditions and store electrons in e.g. the form of reduced quinones and cytochromes.

Another challenge in the desulfurization of sour gas streams is the presence of organosulfur compounds (thiols). These compounds inhibit SOB and as a result, gas streams with a high thiol concentration cannot be treated in an efficient way. We developed a bioelectrochemical process for the degradation of thiols to sulfide at the cathode. Methanethiol, ethanethiol, propanethiol and dimethyl disulfide were supplied separately to the cathodes of bioelectrochemical systems. These systems were controlled at a constant current density of 2 A/m^2 and 4 A/m^2. We observed removal of thiols, and a considerable part of the total sulfur added in the form of thiols was recovered as sulfide: 18% for methanethiol and ethanethiol, 17% for propanethiol and 22% for dimethyldisulfide. No sulfide was formed in electrochemical nor biological control experiments, demonstrating that both current and microorganisms are required for the conversion of organosulfur compounds. With further development of this process, the applicability of the biodesulfurization process can be extended to sour gas streams with high thiol content.

The combination of high pH and high salinity, the fact that bacteria can produce electricity in the absence of free sulfide, and the possibility to degrade thiols at biocathodes, offers new opportunities for design of biological desulfurization systems and bioelectrochemical reactors.

Electrochemical Deposition of Composite and Hybrid Materials

Ori Geuli and Daniel Mandler
Institute of Chemistry, the Hebrew University of Jerusalem
Jerusalem 9190401, Israel
Daniel.mandler@mail.huji.ac.il

The formation of well-controlled composite and hybrid material layers is challenging. One would wish to control not only the thickness but also the organization on the nanometer and micrometer scale, and the composition of such coatings. Furthermore, for many applications the layer should be deposited on complex geometries, such as screws, springs, tubes, etc. Finally, the incorporation of organic materials, such as drugs, makes it even more challenging and avoids the application of high-temperature methods, such as CVD, high-temperature spraying and more.

Electrochemistry is an ideal method for controlling the deposition of a wide variety of materials on conducting surfaces. Yet, typically electrochemical deposition is based on the oxidation or reduction of molecular species on the electrode surface and the formation of less soluble species that therefore, deposit instantaneously on the electrode. This does not allow good control on the formation of nanomaterials and even less composite and hybrid materials.

We have developed during the last years a different approach that is based on the deposition of nanomaterials and macromolecules from their dispersion onto the electrode surface upon applying an electrochemical potential.[1-4] This approach, which we term from "nano to nano" is based on destabilizing the dispersed nanomaterials in the solution causing them to precipitate because of applying an electrical potential. As the potential drives the deposition, it allows controlling the thickness and composition of the deposit, in case that co-deposition takes place. This enabled us to form graded layers, to co-deposit organic and inorganic materials, polymers and nanoparticles and much more. Moreover, deposition could be accomplished on a variety of surface topographies, and therefore, was applied for coating medical implants, grids and conductive patterns.

The lecture will give an overview of this exciting field and discuss future perspectives.

Signal Amplified Sandwich-type Photoelectrochemical Assay Based on Polypyrrole/g-C_3N_4/WO_3 Inverse Opal Photonic Crystals Triple Heterojunction

Xueming Dang, Huimin Zhao*
Key Laboratory of Industrial Ecology and Environmental Engineering (Ministry of Education, China),
School of Environmental Science and Technology, Dalian University of Technology

Dangxueming1989@126.com

Photoelectrochemical (PEC) analysis, as a promising and fast-growing technology, has attracted widespread attention for biomedical molecules and environmental pollutants detection due to its high sensitivity, low cost and low background noise [1]. In PEC sensors, the photoactive materials are core component, which play a vital role in the conversion of excitation photoirradiation to responsive electrochemical signal [2]. In recent years, tungsten oxide (WO_3), known as a visible light response semiconductor, has been widely used in the field of PEC detection, owing to its chemical and thermal stability [3]. However, the detection sensitivity of pure WO_3 photoelectrode is still limited by its relatively low photoelectric activity with the high photo-generated carriers recombination rate and low light absorption efficiency. Notably, to overcome above issues, the construction of heterojunction can be an efficient strategy in the inhibition of photo-induced electron-hole pairs recombination [4]. Especially, the formation of inverse opal photonic crystals (IOPCs) in photoactive materials can enhance the optical response of PEC system, attributing to the light trapping structure with uniform and periodic pores surrounded by solid walls [5]. Therefore, a novel sandwich-type PEC sensing platform based on polypyrrole/g-C_3N_4/WO_3 inverse opal photonic crystals (PPy/g-C_3N_4/WO_3 IOPCs) triple heterojunction was proposed in our studies [6]. The sandwich-type recognition system can not only enhance the sensitivity, but also favor the assembly the heterostructure. Benefiting from the appropriate cascade band-edge levels, the heterojunction among PPy, g-C_3N_4 and WO_3 highly accelerate the separation of photo-generated charges. Meanwhile, WO_3 IOPCs can greatly increase the light absorption of PEC detection electrode. With the simultaneous combination of these techniques, the developed PEC sensor possesses great photoelectric property and exhibits high sensitivity with low limit of detection (LOD) as 0.004 nM ($\approx$ 1.99 ng L^{-1}) towards oxytetracycline (OTC) in water. The excellent selectivity and satisfactory detection results in real sample further revealed the potential of the signal amplification strategy integrating the semiconductor IOPCs with its heterojunction structure assembled through sandwich-type detection model for PEC analytical application.

The levels of metabolites generated in human metabolism are related to human health conditions can be used for disease diagnosis. Herein, we introduce our latest research works focusing on creating electrochemical sensing platforms for three metabolite molecules, which can be used as a disease biomarker individually, i.e., inosine (INO), hypoxanthine (HX), and dopamine (DA). For the detection of cardiac ischemia biomarkers, INO and HX, a layer-by-layer (LbL) process involving a positively charged polyelectrolyte and negatively charged enzyme self-assembled on a screen printed carbon electrode (SPCE) was designed; LbL assembled polysaccharide chitosan and enzyme purine nucleoside phosphorylase [1] for INO, whereas poly(diallyldimethylammonium chloride) coated carbon nanotube-graphene complexes and enzyme xanthine oxidase for HX [2]. In addition, a combined use of poly(L-methionine), carbon nanotube-graphene complexes, and Au nanoparticles [3] on SPCEs was developed for DA of which level is related to Parkinson's disease and pheochromocytoma. Surfaces of three different electrode configurations were carefully characterized using various surface sensitive analytical tools including scanning electron microscope, atomic force microscopy, energy dispersive spectroscopy, and X-ray photoelectron spectroscopy. Under optimized conditions, each electrochemical sensors described above were applied separately to analyses of INO, HX, and DA in buffer and human biological fluid sample solutions using cyclic and differential pulse, and square wave voltammetric techniques. The sample analysis results were finally validated by comparing to those using liquid chromatography-mass spectrometry and/or commercially available assay kits.

Antibiotic drugs are widely used in our society and healthcare system. Unfortunately, the massive use of drugs causes anti-microbial resistance. The antibiotics Vancomycin hydrochloride (Van) is a typical 'last resort' antibiotics, which is used to treat a number of different bacterial infections. It is most effective against Gram-positive bacteria such as Methicillin-resistant Staphylococcus aureus (MRSA), which can cause very severe and sometimes fatal infections and is one of the major problems in clinical routines. Administration of Van is recommended intravenously to treat serious infections by Gram-positive bacteria such as in complicated skin infections, bloodstream infections, endocarditis, bone and joint infections, and meningitis caused by Staphylococcus aureus.

For the correct dosing of Van during therapy, companion tests of blood concentration levels are recommended, a technique called theranostics – therapy with combined diagnostics. Theranostic monitoring is important to avoid possible side effects due to excessive overdosing such as nephrotoxicity or ototoxicity. Underdosing should be avoided as well, since Van as one of the last possible medication options should effectively kill bacteria in patients with severe health condition. Since monitoring of Van has to be done daily or even several times per day, this is a typical application for a theranostic device for point-of-care usage. A biosensor for Van at bedside could help to provide patients always with the right dose, thereby increasing the effectiveness and reducing the side effects of drug treatment.

Here we realized an ultralight analytical biosensor system that, (i) provides an automated fluidic control on-chip, and (ii) combines optical and electrical detection mechanisms, for fast and accurate monitoring of Van in point-of-care settings. Optical detection of Van is carried out based on quenching of nanoparticles catalyzed chemiluminescence (CL) in a concentration-dependent inhibition process. Going beyond enzyme based CL detection schemes such as enzyme linked immunosorbent assays (ELISA), our method makes use of novel Van-specific silver nanoparticle (AgNP) assemblies, produced in a self-assembly based bio-nano conjugation. CL-quenching assays for Van detection require very low sample volumes (20 µL) and show high reproducibility and sensor dynamic ranges (10-15 µg/mL) covering clinically relevant concentration ranges on Van dosing. In parallel, we integrated a metal-microelectrode arrays (MEA) based electrochemical impedance spectroscopy sensor for electrical detection of Van. Here, Van-specific antibodies were immobilized within a fouling resistant polypyrrole matrix on gold microelectrodes using chronoamperometry. Van binding to the antibodies leads to a change in impedance signal, which can be measured in real-time using a miniaturized impedance analyzer and can be reaffirmed from the CL based optical detection.

With this novel Lab-on-a-chip device, we realized a generic opto-electronic biosensor platform, which could be easily adapted to other biosensor assays for point-of-care scenarios, when fast, accurate and automated biomolecule detection is needed.

Nitrosyl-BODIPY dyes: spectroelectrochemical and computational investigations

M. O. F. Goulart [1*] A. K. A. de Almeida[1], T. A. do Nascimento [1], T. L. Silva[2], A. P. A. Pereira[1], S. M. G. Melo[3], L. C. D. Rezende[3], J. C. S. Da Silva[1], F. S. Emery[3]
[1]Instituto de Química e Biotecnologia, UFAL, Maceió, Al; [2]Departamento de Química, UFAL/Arapiraca, Al.; Faculdade de Ciências Farmacêuticas, USP, Ribeirão Preto, SP, Brasil. mofg@qui.ufal.br

BODIPY is an outstanding class of fluorescent dyes with wide applications in biological/analytical/environment research. In this work, the electrochemical properties of new nitrosyl BODIPY dyes (**1-3**) were studied in degassed ACN + n-Bu_4NPF_6, along with computational studies. Compound **1** displayed the usual reduction behavior for unsubstituted BODIPY, while in the oxidation region it showed two irreversible waves (Epa1 = 1.61 V; Epa2 = 1.92 V) (Fig. 1A), probably due to the formation of radical cation and dication, respectively. The addition of the acceptor nitroso group, in compound **2** (Fig.1 B) and **3** (Fig. 1C), leads to a different profile. The reduction is much easier, ca 460 mV more positive for compound **3**. The first to be reduced is the nitroso group, due to the proximity to the positively charged N (EpIc$_3$ = -0.281 V), and non-bonding interactions with the electronegative borondifluoride, differently from compound **2**, with a β-nitroso group, where the reduction occurs in the BODIPY core (EpIc$_2$ = -0.408 V). In the oxidation region, the irreversible peaks for compound **2** (Epa = 2.00 V) and **3** (Epa = 1.96 V) respectively, may be related to the formation of radical cations in the NO group. ωB97xD/cc-pVTZ results had shown that the HOMO orbitals are mainly formed by the π orbitals of nitroso group, with a small contribution of orbitals from atoms of the ionic form of pyrrole ring of BODIPY moiety. A possible chemical interaction between the lone pair of fluorine of BODIPY core and π electrons of nitroso ligand for compound **3**, can be the reason for the slightly higher oxidation susceptibility for it. Comparing the IP calculated by the Koopman's theorem for values for compound **2** and **3** is possible to note that these values are approximately the same (~0.06 eV difference). As shown by electrochemical/computational profiles, the location of the group (α or β) strongly affects the electronic structure, and consequently, their reactivities.

Conducting diamond compact composition electrode materials are obtained by graphite transformation to diamond at high pressure and temperature in two- and three-component Pt–C and Pt–C–B growth systems; their physical and chemical properties are studied [1]. The diamond electrode added with Pt in the two-component growth system Pt–C behaves in the chloride-ion anodic oxidation reaction like a purely platinum one, with due allowance for the platinum actual amount at the electrode surface. Results of voltammetric studies are in good agreement with the electrochemical impedance spectroscopy data obtained in f-sweep and E-sweep modes. The boron doping of the diamond grown in the Pt–C–B system produced electrodes electroactive with respect to the chloride-ion anodic oxidation reaction; the electroactivity increased with the increasing of the platinum content at the electrode surface. The adding of platinum (a catalyst) was shown being more efficient (in the chlorine anodic evolution reaction) when the platinum was deposited right onto the electrode surface, rather when introduced to its bulk during the compact synthesis.

Knowledge-based AI for Smart Design of Functional Nanoparticles in Non-vacuum Reactive Environment

Byungchan Han, Hoje Chun, Hyunwook Jung, Choa Kwon
Department of Chemical and Biomolecular Engineering, Yonsei University
50 Yonsei-Ro, Seodaemun-Gu, Seoul, 03722, Korea
bchan@yonsei.ac.kr

Nanomaterials have been played a key role in wide range of electrochemical energy devices such as Li-air batteries, photovoltaic devices, and fuel cells. Innovative design for highly functional nanoparticles has been, however, delayed. In molecular level computational electrochemistry new research paradigm has been established, which substantially incorporates IT-based artificial intelligence (AI) technology into machine learning algorism. Using the new computational methodology high-throughput screening of promising nanoparticle candidates has been attempted for various desired applications.

Whether the frontier approach is successful or not is significantly controlled by the reliability and accuracy of input database. It is true that substantial amounts of the data are come by previous literatures and often ab-initio calculations with idealized model systems. The conditions in which the data were generated may be so different from the operando circumstances of the target materials. To secure extreme-level integrity of the database the in-situ measurement of nanoparticle structures should be carried out, from which the reliable correlation of the structure-performance-design principle can be identified.

We combined in-situ TEM measurement of nanoparticle with ligand in liquid and AI-based neural-network approach to precisely establish three-dimensional (3D) structure database. The information includes sizes, lattice distortions, and defects with picometer resolution under non-vacuum conditions. From the 3D liquid-cell electron microscopy atomistic interaction potential and surface reactivity are analyzed using density functional theory calculations and machine learning techniques. The approach is indeed 'knowledge-based' AI, which can be expected to make groundbreaking ways toward the quantum nanoarchitecture.

In the synthesis of inorganic materials, reactions often yield non-equilibrium kinetic byproducts instead of the thermodynamic equilibrium phase [1]. Why is that? And why, on the other hand, compounds predicted as thermodynamically stable often cannot be synthesized experimentally? Understanding the competition between thermodynamics and kinetics is fundamental for answering these questions and towards the rational synthesis of target materials [2]. In this presentation, we will highlight the use of in situ synchrotron x-ray diffraction to yield insights on the real time behavior of powder precursors during synthesis. We investigate the multistage crystallization pathways of the important two-layer (P2) sodium oxides $Na_{0.67}MO_2$ (M = Co, Mn) [3]. We find a series of fast non-equilibrium phase transformations through metastable three-layer O3, O3' or P3 phases, before formation of the equilibrium two-layer P2 polymorph. A theoretical framework to rationalize the observed phase progression will be presented, demonstrating that even though P2 is the equilibrium phase that we target, the first phase to form will be the one with the most negative compositionally-unconstrained reaction energy from the powder precursors. In other words, the first phase to form is guided by thermodynamics and it does not necessarily have the composition corresponding to the overall precursor composition in the reaction vessel. Afterwards, the first phase may develop according to kinetic or thermodynamic arguments, depending on the system of choice. Further examples will be presented for industrially-relevant $LiNiO_2$ and related compounds [4], where lithiation pathways can be instead more straightforward than sodiation ones; nonetheless, the high resolution of synchrotron XRD allows to observe detailed structural information revealing a complex behavior where metal vacancies play an important role. The insights we present constitutes a step forward towards unraveling the complex interplay between thermodynamics and kinetics during synthesis. Moreover, they can guide the choice of precursors and parameters towards the optimization of the solid-state synthesis of ceramic materials.

All-organic redox-flow batteries (RFBs) as an emerging branch of energy technology offer a modern and benign solution for buffering energy obtained from renewable but intrinsically intermittent sources. The "heavy duty" nature of battery application dictates a persistent need for new battery chemistries where precisely tailored physicochemical properties of redox electrolytes are utmost preferred [1]. In light of this, verdazyl free radical compounds stand for promising candidates for symmetrical all-organic RFBs due to variety of synthetic ways to adjust their structure as well as unique bipolar feature, enabling a single redox molecule for both negolyte and posolyte. Concurrently, an irreversible exchange of electrolytes within a cell gets appropriately prevented [2].

The presented work comprises preliminary screening of verdazyl compounds library in respect of bulk diffusion coefficient and heterogeneous electron transfer rate constant as the key redox electrolyte parameters, by means of cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS). In line with this, within a given set of symmetrical electrolytes, the best performing verdazyl-based radical was identified for RFB experiments in order to compare an electrochemical behavior (CV) within an actual cell and prerequisite data and thereafter confirm a viability for energy storage (galvanostatic cycling experiments) as well as to characterize a redox electrolyte from different angles within a single cycle ("state of the charge" experiments). Due to the fact that structure of the redox-flow cell significantly differs from the electrochemical one used throughout the preselection, a study of the present setup transition was conducted as well.

In the scope of long-term galvanostatic cycling experiments, symmetrical verdazyl electrolyte demonstrated good stability and high Coulombic (>97%) as well as energy efficiencies for more than 100 charge/discharge cycles. On this account, obtained results highlight verdazyl-based electrolytes as promising and versatile energy material and implies a wide field for further synthetic development and optimization in the field of RFBs.

kaiyufu@stanford.edu

The emerging biosensing devices largely extend our capability to measure and monitor the biomolecules in living organisms. Yet most commercially available detection platforms are either simplified for a handful of abundant molecules in vivo, *e.g.*, glucose and electrolytes, or designed with time-consuming sample pretreatment for low-abundance targets. There is an urgent quest to integrate the advancement of analytical chemistry and nanotechnology to solve the long-existing problems for biodetection. In this talk, I will first present a novel electrochemical detection platform that consists of high-density nanoscale electrodes, *viz.* nanopore electrode arrays (NEAs), for single entity detection by integrating into lab-chip device setting. I will describe a robust fabrication method to achieve nanopores with zero-dimensional structures and discuss how permselectivity and ion migration are well-positioned to explore in situ molecular separation and detection. Next, I will present a real-time sensing technology to measure neurotransmitters in the living brain using the nanoporous electrode. So far, the widely used technique for *in vivo* brain measurement is through fast-scan cyclic voltammetry, which cannot measure non-redox active species, and requires frequent drift-correction and complicated data analysis. The biosensor developed in this work is capable of continuously measuring the neurotransmitters from the cerebrospinal fluid of the animal brain. This biosensor is designed on the flexible substrate with highly specific bioaffinity recognition elements for chronic multisite brain recordings. Overall, this talk will depict a general approach to access real-time chemical information for a better understanding of the brain functions.

Engineering Redox Mediating Systems to Study Photoinhibition Effects of Exogenous Mediators in Purple Bacteria

Matteo Grattieri, Jeffrey Copeland, and Shelley D. Minteer
Departments of Chemistry and Materials Science & Engineering, University of Utah
315 S 1400 E Room 2020, Salt Lake City, (UT) 84112 USA
matteo.grattieri@utah.edu

Microbial (photo)electrochemical systems offer outstanding possibilities, spanning from sustainable (micro/low) power generation, biosensing of toxic compounds, bioelectrosynthesis of valuable chemicals, and bioremediation of contaminated environments. However, they also provide a unique platform for the study of the electrochemical processes at play between abiotic and biotic components. To date, achieving a detailed understanding of the electron transfer process between intact bacteria cells and an exogenous electron acceptor remains one of the biggest challenges in microbial electrochemistry.[1, 2] For the specific case of photosynthetic microorganisms, an additional challenge for studying the electron transfer process is posed by the confinement of their photosynthetic apparatus in membranes located inside their cells, thus physically separated from the electrode surface. In recent years, multidisciplinary approaches have proven effective in gaining insights into these complex systems. Specifically, electrochemical studies have been coupled to computational methods (i.e., modeling, bioinformatics, and quantum mechanic calculations),[3, 4] fluorescence techniques,[5] as well as the engineering of both the biotic and/or the abiotic components,[6] expanding our understanding of bio-photoelectrochemical systems.

Herein, purple bacteria are utilized as model photosynthetic organisms based on their extremely versatile metabolism and capability to adapt to environmental stresses,[7] which would enable their application for semi-artificial photosynthesis in the field. Various reports on the harvesting of photoexcited electrons from the photosynthetic apparatus of purple bacteria indicated that exogenous redox mediators are required to successfully establish a photocurrent, where both Os-based and quinone-based mediators were employed.[8, 9] However, over long term experiments, the use of exogenous mediators can lead to photoinhibition, resulting in decreasing photocurrent generation. With the aim to study photoinhibition effects of exogenous quinone mediators, we explored the use of an artificial, bio-inspired redox polymer and its corresponding monomeric diffusible redox moieties. The approach allowed unveiling different mediator-photosystem interactions, and the effects of diffusion and electron transfer limitations on the resulting photoinhibition,[10] providing directions for the rational design of artificial redox mediating systems for enhancing both photoexcited electron harvesting and the stability of the system.

The importance of autonomous energy is currently growing due to the rapid development of portable electronic devices, electric vehicles and power supplies for distributed energy systems. Combinations of various energy storage devices such as a battery, a fuel cell and a supercapacitor can be used to expand the range of operating modes of energy sources in terms of power and energy intensity. Among the electrochemical systems used in batteries, a lithium-ion system (lithium-ion battery, LIB) stands out, which is significantly ahead of other systems both in terms of characteristics and degree of development. At the same time, this system has significant potential for further development. The most numerous and diverse electrode materials are LIB's cathode materials. Having achieved notable success with oxide compounds of lithium and transition metals, the researchers turned their attention to a much wider class of polyanionic compounds, promising comparable energy intensity and significantly higher chemical stability and safety at operation. The electrode potential of intercalation compounds increases in the series of polyanions: SiO_4^{4-}, BO_3^{3-}, PO_4^{3-}, SO_4^{2-}. At the same time, intercalation compounds with various polyanions have a significant scatter in the values of theoretical capacity and practical characteristics depending on the composition as well as structural and morphological properties. For the targeted improvement of the electrochemical characteristics of electrode materials, the accumulation and analysis of information on the relationship between the preparation features, structural, morphological and electrochemical properties is necessary (Fig. 1) [1].

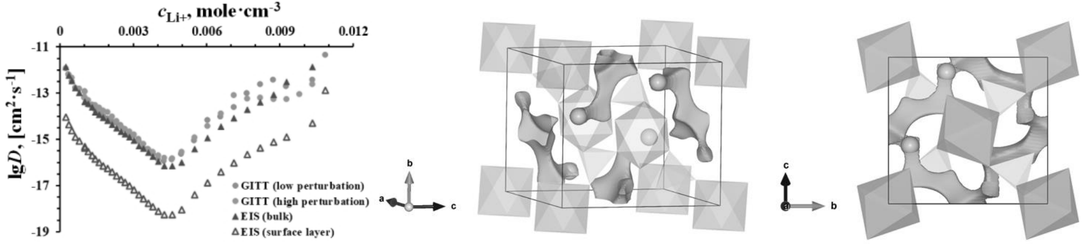

Fig. 1. Concentration dependences of the diffusion coefficient and the calculated diffusion map of lithium ions in the compound $Li_2Fe(SO_4)_2$.

Vadim.F.Lvovich@nasa.gov

All-electric vertical take-off and landing vehicles (eVTOL) for urban air mobility (UAM) concepts face numerous challenging technical barriers before their introduction into the consumer marketplace. The most challenging of these technical barriers to overcome is developing an energy storage system capable of meeting the rigorous aerospace safety and performance criteria. The performance metrics for eVTOL craft, such as specific energy and cycle life, are at least 2 times greater than those of electric automobiles. Furthermore, safety is essential for operation of commercial electric aerovehicles. Preliminary systems level analysis studies have indicated that there are five key properties which must be optimized for successful implementation of battery systems. Those five key criteria are safety, energy density, power, packaging design and scalability. Current state-of-the-art (SOA) lithium-ion batteries meet or exceed the requirements for electric aviation in the areas of power and scalability, yet are insufficient in the key performance criteria of energy, safety and packaging design.

The SABERS concept proposes a battery that meets all five key performance criteria through the development of a solid-state architecture cell design utilizing high energy density and power density sulfur-selenium cathode with a lithium metal anode. Data will be presented demonstrating high performing sulfur - selenium cathode that offers a balanced energy to power density ratio, which can be tailored to the specific application by altering the stoichiometric ratios of sulfur to selenium. This cathode is being developed by implementing NASA patented holey graphene technology as a highly conductive, ultra-lightweight electrode scaffold. Novel processing methods allow developing solid-state electrolyte that is a safe, non-flammable replacement to the highly flammable liquid organic electrolytes currently used in SOA lithium-ion batteries. The all solid-state lithium-sulfur-selenium cell design enables the implementation of a bipolar stack configuration, which has the advantages of reducing overall cell weight, reducing the amount of interfaced connections for the cell, and minimizing cooling requirements for the battery. In particular, the solid-state design allows for a serial stacking configuration to enable dense packaging of the cells within the bipolar stack. Lastly, optimization of battery components occurs through a robust and rigorous combination of various computational modeling techniques covering multiple length scales. The expected result will be a solid-state battery with operational temperatures from 0 °C to 150 °C which provides the required energy density, discharge rate, and inherent safety to meet strict aerospace performance criteria.

Electrolyte and Interface for Calcium Battery

Alexandre Ponrouch
Institut de Ciència de Materials de Barcelona (ICMAB-CSIC)
Campus UAB, 08193 Bellaterra, Catalonia (Spain)
aponrouch@icmab.es

Various metals have been used as battery anodes in electrochemical cells ever since the birth of the batteries with Volta's pile and in the first commercialized primary (Zn/MnO2, Leclanché 1866) and secondary (Pb/acid, Planté 1859) batteries. Li-MoS2 cells, employing Li metal anodes, with specific energies two to three times higher than both Ni/Cd and Pb/acid cells, were withdrawn from the market due to safety issues related to dendrites growth. Instead, Ca are currently being considered as safer metal anode alternative. [1] Pioneering work by Aurbach et al. in the early 1990's showed a surface-film controlled electrochemical behavior of Ca metal anodes in electrolytes with conventional organic solvents. [2,3] The lack of metal plating was attributed to the poor divalent cation migration through the passivation layer.

Nevertheless, recent demonstration of Ca plating and stripping in the presence of a passivation layer [4,5] has paved the way for assessment of new electrolyte formulations with high resilience towards oxidation. However, several challenges remain to be tackled for the development of Ca based batteries.[1,6] Among these, the need for reliable electrochemical test protocols, mass transport limitations and high desolvation energies (due to strong cation-solvent and cation–anion interactions) are implied.[8,9] Here, a systematic investigation of the electrolyte formulation impact on the cation solvation structure and transport is presented.[10] Finally, characterization of the passivation layer formed onto the Ca metal anode in various electrolyte formulations using complementary techniques will be presented allowing for the identification of the most suitable passivation layer components in terms of divalent cation mobility.

Understanding and Designing of Materials and Interface for High Energy Batteries

Yi Cui

Department of Materials Science and Engineering, Stanford University.

Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory.

Email: yicui@stanford.edu

Abstract: The fast growth of portable power sources for transportation and grid-scale stationary storage presents great opportunities for battery development. How to increase energy density, reduce cost, speed up charging, extend life, enhance safety and recycle are critical challenges. Here I will present 15 year research in my lab to address some of challenges by understanding the materials and interfaces and providing guiding principles for design. The topics to be discussed include: 1) A breakthrough tool of cryogenic electron microscopy, leading to atomic scale resolution of fragile battery materials and interfaces. 2) Materials design to enable high capacity materials: Si and Li metal anodes and S cathodes. 3) Interfacial design with polymer and inorganic coating to enhance cycling efficiency of battery electrodes.

Proton-Coupled Electron Transfer in Electrochemistry

Sharon Hammes-Schiffer

Department of Chemistry, Yale University, New Haven, CT 06520
e-mail: sharon.hammes-schiffer@yale.edu

Proton-coupled electron transfer (PCET) reactions play a vital role in a wide range of electrochemical processes. This talk will focus on theoretical studies of molecular and heterogeneous electrocatalysis, highlighting the interplay between theory and experiment. A general theory of PCET that includes the quantum mechanical effects of the electrons and transferring protons, as well as the motions of the proton donor-acceptor mode and solvent environment, has been developed. This formulation enables the calculation of rate constants, current densities, Tafel slopes, and kinetic isotope effects for comparison to experiment. The application of this PCET theory to molecular electrocatalysts designed for water splitting illustrates the use of multi-proton relays to transport protons over hydrogen-bonded networks, as well as the ability to tune the redox potentials through substituents and other molecular design strategies. The application of this PCET theory to proton discharge on a gold electrode in acetonitrile explains the experimentally observed potential-dependent kinetic isotope effect in terms of contributions from excited electron-proton vibronic states that depend on both isotope and applied potential. This theory also provides insight into the fundamental principles underlying proton discharge to a gold electrode in acidic and alkaline aqueous solution. These applications highlight the importance of using a vibronically nonadiabatic theory that quantizes the transferring proton and includes the effects of hydrogen tunneling and excited electron-proton vibronic states. Recent periodic density functional theory calculations of electric fields at electrochemical interfaces and PCET at graphite-conjugated acids elucidate the impact of the applied potential on the electronic structure and interfacial fields. The insights from these theoretical studies are useful for the design of both molecular and heterogeneous electrocatalysts to control the movement and coupling of electrons and protons for energy conversion processes.

Per- and polyfluoroalkyl substances (PFAS) are a category of persistent environmental contaminants that have been linked to health issues in humans. In this work, we investigate the detection of perfluorooctanesulfonate ($PFOS^-$), one such PFAS, by ion-transfer voltammetry at an array of microinterfaces between two immiscible electrolyte solutions (μITIES).[1] Cyclic voltammetry, differential pulse voltammetry and differential pulse stripping voltammetry (DPSV) indicated the ion-transfer behaviour and detection of $PFOS^-$, with the latter enabling detection at picomolar concentrations. Using a 5 min preconcentration time, during which $PFOS^-$ was preconcentrated into the organic phase of the μITIES array, a limit of detection (LOD) of 46 pM in aqueous electrolyte was achieved. This performance is attributed to the enhanced mass transport (radial diffusion) to the μITIES that occurs during preconcentration. To investigate the potentiality for applications of this analytical approach to environmental samples, measurements in a range of water matrices were investigated. Drinking water, laboratory tap water and seawater matrices were assessed by spiking with $PFOS^-$ over the 0.1-1 nM range. A matrix effect was observed, with changes in sensitivity and LOD relative to those in pure aqueous electrolyte solutions. Such matrix effects need to be considered in designing applications of these $PFOS^-$ measurements to environmental samples. The results presented here indicate that DPSV at a μITIES array can form the basis for a fast and sensitive screening method for $PFOS^-$ contamination that is suited to portable and on-site applications.

Catalytically Synthesized Prussian Blue Based Nanozymes Defeating Peroxidase: New Horizons for Electroanalysis

Komkova M.A., Zarochintsev A.A., Galushin A.A., Shavokshina V.A., Karyakin A.A.
Chemistry faculty of M.V. Lomonosov Moscow State University, 119991, Moscow, Russia
e-mail: mkomkova@analyt.chem.msu.ru

The term 'nanozyme' is attributed to nanoparticles with enzyme-like activity. Despite the attractive title, the enzymatic specificity, particularly in complex organic reactions, is hardly expectable for nanozymes. Nevertheless, the nanocatalysts with broad specificity can act as the labels or transducers in biosensors. Undoubtedly higher stability of artificial enzymes compared to natural ones, as well as low cost of nanoparticles, explain vivid interest towards nanozymes elaboration. Since peroxidase is probably the most widely used label, a variety of nanoparticles mimicking peroxidase-like activity have been studied.

Among the reported nanozymes, catalytically synthesized Prussian Blue (PB) based nanoparticles are, probably, the only nanozymes suitable for analysis due to their genuine enzymatic properties, including ultrahigh catalytic constant, an absence of oxidase-like activity and an ability to operate in physiological solutions [1]. Synthesis in course of $Fe^{III}[Fe^{III}(CN)_6]$ reduction by hydrogen peroxide, or by conducting polymer forming organic molecules occurs, upon the same reaction as in electrocatalysis. It results in PB structures with the highest catalytic activity, on the one hand, and allows to functionalized nanoparticle surface at deposition step, on the other hand. Such nanoparticles display the size-dependent catalytic rate constants in H_2O_2 reduction, which are significantly improved compared to natural enzyme peroxidase. So, for PB nanoparticles 200 nm in diameter, the turnover number is 300 times higher.

Simple drop-casting of the PB nanozymes suspension with subsequent drying provides improved analytical performance characteristics of the resulting electrochemical (bio)sensors. So, sensitivity of nanoparticles-based H_2O_2 sensors is 30% higher (up to $0.85\ A{\cdot}M^{-1}{\cdot}cm^{-2}$) compared to it for the sensors based on PB films [2]. Optimal sensitivity of the sensors is achieved in case of continuative nanoparticles monolayer (estimated by means of electrochemical impedance spectroscopy [3]) on the electrode surface. Similarly, the use of PB nanoparticles for elaboration of nanozyme-enzyme biosensors provides almost twice higher sensitivity ($> 0.2\ A{\cdot}M^{-1}{\cdot}cm^{-2}$) [4]. The improved analytical performance characteristics of the PB nanoparticles-based (bio)sensors are most probably due to their increased roughness providing more efficient mass transfer compared to conventional PB films.

Further improvement of the signal-to-background ratio peculiar to Prussian Blue is possible using the electrode supports characterized by ultra-low background current, such as boron-doped diamond (BDD). In contrast to PB films deposition using fully oxidized precursors, PB nanozymes immobilization is not detriment for the BDD surface and retains its termination. Compared to conventional graphite electrodes modified with Prussian Blue nanoparticles, the use of BDD provided up to 20 times decreased oxygen reduction currents resulting in 4 times increased signal-to-background ratio [5].

To validate PB based nanozymes as a novel electrochemical label for RNA detection, azido-groups functionalized nanoparticles were successfully conjugated with HULC (Highly Up-Regulated in Liver Cancer) gene sequences. The possibility of nanozymes detection at subnanomolar concentrations in chronoamperometric mode was shown. PB nanozymes conjugated probes are universal and can be used for diverse sensors elaboration.

Financial support through Russian Science Foundation grant #19-73-00166 is acknowledged.

Coulometric Transduction for Solid-Contact Ion-Selective Electrodes

Johan Bobacka, Tingting han, Zekra Mousavi, Ulriika Mattinen

A coulometric transduction method for solid-contact ion-selective electrodes (SCISEs) was introduced by our group in 2015 [1]. Since then, the coulometric method has been explored and optimized further by us [2-5] and others [5, 6]. A key feature of this method is that the potential of the SCISE *vs* the reference electrode is kept constant. Therefore, any potential change at the ion-selective membrane (ISM)|sample interface, due to a change in ion activity in the solution, causes oxidation/reduction of the solid contact. The result is a transient current that is measured and integrated to obtain the charge that is proportional to the change in the logarithm of the ion activity in solution. A unique feature of this coulometric method is that the analytical signal, *i.e.* charge (for a given change in ion activity) is proportional to the redox capacitance of the solid contact, meaning that the signal can be amplified by increasing the thickness (loading) of the solid-contact layer. This is an advantage of the coulometric method compared to classical potentiometry.

The coulometric method has been investigated using poly(3,4-ethylenedioxythiophene) (PEDOT) as solid contact in SCISEs for the detection of K^+ [2-4, 6], H^+ (pH) [4] and Cl^- [5]. The response time of the coulometric method was shortened by lowering the bulk resistance of the ion-selective membrane, either by increasing the geometrical surface area of the electrode [3] or by using spin-coated thin-layer ISMs [4, 5]. A theoretical capacitive model based on a series *RC* circuit gave an excellent explanation of the coulometric response of a Cl^--SCISE [5]. However, impedance measurements showed that the coulometric response for K^+-SCISEs was limited by diffusion even for thin-layer ISMs [4]. An extended theoretical model for the amperometric and coulometric response of K^+-SCISEs, which accounts for concentration polarization in the ISM was recently proposed [6]. Furthermore, coulometric SCISEs were evaluated for measurement of pH in seawater [4] and K^+ in serum [4, 6].

A further electrochemical study of the coulometric response and the corresponding charge transfer processes of Pb^{2+}-SCISEs and Ca^{2+}-SCISEs strengthened our understanding of the coulometric transduction mechanism. Electrochemical characterization of Pb^{2+}-SCISEs with different thicknesses of PEDOT, as well different thicknesses of ISMs, showed that the coulometric response of the Pb^{2+}-SCISE was limited by charge (ion) transport in the PEDOT solid-contact layer. This was explained by interactions between Pb^{2+} and PEDOT doped with poly(styrene sulfonate).

Enhancement of microbial fuel cell performance by introducing a nano-composite cathode catalyst

Mounika Kodali

Chemical and Biomolecular Engineering, University of California- Irvine
Samueli School of Engineering

mounikak@uci.edu

Microbial fuel cell (MFC) is a promising bioelectrochemical device that converts chemical energy into electrical energy through the catalytic reaction of microorganisms in (circum)neutral media at room temperature. Inside the MFC, the electroactive bacteria at the anode oxides the organics generating electrons and protons. Thus, generated protons transfer directly to cathode through the electrolyte while the electrons get transferred through the external circuit generating electricity. Electrons and protons get consumed at the cathode for reducing the oxygen. Unfortunately, the performance of MFCs are limited by several factors that hinder its large-scale applications such as high materials costs, the poor red-ox electrochemical performances and the relatively low durability of the electrodes. For the large part of the scientific community, one of the greater bottlenecks is related to the oxygen reduction reaction (ORR) at the cathode. Despite several oxidant options investigated in MFCs, oxygen is the most preferred solution due to its natural availability in the atmosphere at no additional cost and its high electrochemical potential. However, ORR suffers from its sluggish kinetics mainly due to the low operational temperature and the neutral pH. In order to maintain the biological activity at the anode neither the temperature nor the pH can be varied.

To improve the sluggish kinetics of ORR and the electrochemical performance, catalysts need to be used. ORR catalysts can be mainly classified into 3 categories i) platinum-based materials (PGM), ii) carbonaceous materials, and iii) platinum group metal-free (PGM-free) materials. Platinum-based ORR catalysts (PGM) have been extensively in use in the past but their high cost and low durability have significantly lowered their utilization. Various carbonaceous materials have been in use in MFCs due to their characteristic properties such as low cost, high durability, high electrical conductivity and mechanical strength. However, their performance as catalysts is not high enough, and the ORR kinetics still remains low. PGM-free catalysts (M-N-C) based on transition metals (e.g. Fe, Co, Ni, and Mn) are atomically dispersed on a carbon/nitrogen matrix. It was shown that PGM-free have superior performance compared to AC and Fe-based material is the most performing catalyst [1].

In this work, we investigated the electrocatalytic activity of Fe-AAPyr (Fe-Aminoantipyrine) and 3D-graphene nanosheet (3D-GNS) separately and physically combined for ORR along with AC control. 3D-GNSs were synthesized using a modified Hummers method technique and Sacrificial Support Method (SSM) while Fe-AAPyr was prepared using sacrificial support method with silica template and aminoantipyrine as an organic precursor (C-N matrix). The ORR activity of these catalysts at different loadings was investigated by using rotating ring disk (RRDE) electrode setup in the neutral electrolyte and then the catalysts were investigated in MFC by integrating them into air-breathing cathode. The co-presence of GNS (2 $\mathrm{mgcm^{-2}}$) and Fe-AAPyr (2 $\mathrm{mgcm^{-2}}$) catalyst within the air-breathing cathode resulted in the higher power generation in MFC of 235 ± 1 $\mu\mathrm{Wcm^{-2}}$ while Fe-AAPyr catalyst itself showed high performance (217 ± 1 $\mathrm{mWcm^{-2}}$), higher compared to GNS (150 ± 5 $\mu\mathrm{Wcm^{-2}}$) while AC generated power of roughly 104 $\mu\mathrm{Wcm^{-2}}$ [2].

Long-term durability of electrochemical energy conversion devices such as fuel cells and water electrolysers can only be achieved through utilization of stable components. In particular, durable electrocatalysts are required. It is a common practice that on the way to their potential application in real devices, electrocatalysts are typically evaluated in various accelerated stress tests. Unfortunately, even positive results do not guarantee durable performance of the devices, as many degradation processes go unnoticed in such tests. Coupled mass spectrometry techniques were designed to address this issue [1]. Tiny amounts of gasses or dissolved ionic/atomic species formed as a result of a degradation process can be detected using electrochemical gas mass spectrometry (gas MS) and on-line inductively coupled plasma mass spectrometry (on-line ICP-MS), respectively.

Since such techniques are still relatively rare in the electrocatalysis research, this talk will be started with a short introduction on basic operational principles of electrochemical MS in stability research. It will be shown that gas MS and on-line ICP-MS can be used in fundamental mechanistic studies. Moving to examples, dissolution processes in the state-of-the-art Pt/C and IrO_x catalysts and how they have assisted in understanding of catalysts degradation will be described [2, 3]. In order to demonstrate the versatility of the coupled mass spectrometry techniques in fundamental stability research, other representative examples will include: (a) light induced dissolution of Ir photoelectrocatalyst covered WO_3 photoabsorbers [4]; oxidative leaching of sulfur from Pt single atom catalysts; Cu leaching at pHs of interest for carbon dioxide reduction; degradation of non-noble metal fuel cell catalyst, etc. Moreover, novel approaches on application of on-line ICP-MS in more applied gas-diffusion-electrode (GDE) systems will be shown [5].

Simultaneous Electrochemical Detection of Important Advanced Glycation End Products Involved in Oral Pathology From Raw Saliva

Mihaela Tertiş,[a] Ana Teodora Ilea,[a] Aranka Ilea[b] and Cecilia Cristea [a]
[a]*Analytical Chemistry Department, Faculty of Pharmacy, Iuliu Haţieganu University of Medicine and Pharmacy; 4 Louis Pasteur Street, 400349 Cluj-Napoca, Romania*
[b] *Department of Oral Rehabilitation, Oral Health and Dental Office Management, Faculty of Dentistry, Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania*
mihaela.tertis@umfcluj.ro

The pathology of oral cavity is closely correlated with dietary intake. Advanced glycation end products (AGEs) are associated with the processed food and thus, can be ingested by consuming these types of food items. The majority of AGEs, such as methylglyoxal (MGL) and N-(carboxymethyl)lysine (CML) are considered markers involved in oxidative stress by producing long-term damage to proteins in ageing, atherosclerotic plaques and diabetes. AGEs are usually detected using ELISA, immunohistochemistry or HPLC, methods that require long time for analysis and implicit delayed diagnostic results 1,2. A novel approach for the sensitive electrochemical detection of MGL has been elaborated based on a lab-made printed platform using a flexible plastic foil as support, an Ag/AgCl conductive ink for the design of the reference electrode and the contacts, and a carbon ink for the working and counter electrodes. After drying, the surface of working electrode was decorated with a nanostructured platinum film that was generated electrochemicaly using cyclic voltammetry (CV) in the presence of hexachloroplatinic acid in hydrochloric acid. All the steps involved in the elaboration of the sensor were optimized based on the differential pulse voltammetry (DPV) signal of the target analyte. The optimized nanocomposite platform was then characterized using microscopic and electrochemical techniques. The selectivity tests performed for MGL have proved that the presence of CML in the same solution does not hinder the detection. Furthermore, the oxidation signal of CML was not influenced by the presence of MGL. The disposable sensor was successfully tested for direct electrochemical detection of MGL and CML using DPV. The employment of composite electrodes exhibits electron-mediating effect, which leads to a well-defined reduction peak associated to the MGL and a well-defined oxidation peak associated to the CML. The developed assay was shown to be selective and sensitive for the simultaneous analysis of salivary MGL and CML in healthy volunteers even when tested in vivo, being promising for the elaboration of point-of-care devices for salivary analysis.

Scanning Gel Electrochemical Microscopy (SGECM) for Corrosion: Methodology, Instrumentation and Prospects

Liang Liu, Mariela Brites-Helú, Ning Dang
Université de Lorraine, CNRS, Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l'Environnement (LCPME), F-54000 Nancy, France
liang.liu@univ-lorraine.fr

Scanning electrochemical probe techniques, such as scanning electrochemical microscopy and scanning droplet cell techniques (including scanning electrochemical cell microscopy) have been widely applied for studying localized corrosion processes. Recently, we reported the Scanning Gel Electrochemical Microscopy (SGECM) for measuring the topography and corrosion activity of metallic samples placed in air[1,2]. The concept is based on a gel probe that scans over the sample surface in tapping mode. The gel probe is fabricated by electrodeposition of chitosan on micro-disk electrodes or sharpened metal wires (**Figure 1**). It is approached to be in contact with the sample surface by either shear force or current feedback, which confines the electrochemical reactions in the contact area. So far, local amperometry, potentiometry, cyclic voltammetry as well as patterning have been achieved on a home-built SGECM setup with software written in VB.net (**Figure 2**)[1-3].

SGECM offers the following advantages for corrosion applications: (1) The sample is placed in air, making it suitable for studying atmospheric corrosion; (2) The electrolyte is immobilized so that it is applicable to samples of any complex shape; (3) The non-destructive soft contact between the gel and the sample protects the sample to a maximum extent; (4) The instrumentation is automated and foreseen to be miniaturized for field tests. With the recent development, the lateral physical resolution of SGECM reaches *ca.* 1-2 µm, which is already close to the crystalline phases of alloys. Moreover, by pressing or pulling the gel probe after touching the sample surface, the resolution is tuneable in the range of a few to tens of microns. These advantages make SGECM a promising tool for characterizing localized corrosion, as well as fixing coatings or pits at microscale. In this presentation, we will introduce the methodology and instrumentation of SGECM, as well as discuss about prospects and seek collaborations in the corrosion electrochemistry community.

Prussian Blue based nanozymes “artificial peroxidase” in (bio)sensors

Arkady A. Karyakin, Maria A. Komkova
Chemistry faculty of M.V. Lomonosov Moscow State University
119991, Lenin Hills, 1/3, Moscow, Russia
e-mail: aak@analyt.chem.msu.ru

In modern biotechnology and analytical chemistry peroxidase is apparently the most widely used enzyme. On one hand, it is used as a label in immuno- and DNA-sensors. On the other hand, it is the key enzyme to detect hydrogen peroxide including biosensing purposes.

More than 25 years ago we discovered ferric hexacyanoferrate, as the most advantageous electrocatalyst for hydrogen peroxide reduction. In neutral aqueous media favorable for bioanalytical applications, the advantages of Prussian Blue modified electrodes over the conventionally used platinum are: (i) 3 orders of magnitude higher activity in H_2O_2 reduction and oxidation in terms of the 1000 times higher electrochemical rate constants, obviously providing the similarly improved sensitivity, and (ii) 3 orders of magnitude higher selectivity in hydrogen peroxide reduction allowing low-potential H_2O_2 detection even in the presence of oxygen.

We’ve synthesized Prussian Blue nanoparticles through catalytic reaction involving hydrogen peroxide activation. Prussian Blue is known to be similarly a highly active electrocatalyst in H_2O_2 reduction and in its oxidation. Hence, synthesis of the highly active catalyst for one reaction (H_2O_2 oxidation) would provide its improved catalytic activity also in H_2O_2 reduction. From this point of view, the best reductant for ferricianide−ferric ion mixture would be hydrogen peroxide. Indeed, since precipitation of Prussian Blue in this case requires oxidation of H_2O_2, the most catalytically active structures would have the highest growth rate and, thus, would grow predominantly. As a result, the most catalytically active structures, also in H_2O_2 reduction, would be synthesized [1].

The resulting nanoparticles display the size-dependent catalytic rate constants in H_2O_2 reduction, which are significantly improved compared to natural enzyme peroxidase: for PB nanoparticles 200 nm in diameter, the turnover number is 300 times higher; for 570 nm diameter nanoparticles, it is 4 orders of magnitude higher. Comparing to the known peroxidase-like nanozymes, the advantages of the reported PB nanoparticles are their true enzymatic properties: (i) the ultrahigh activity, which is up to 4 orders of magnitude higher as compared to the enzyme peroxidase, (ii) enzymatic specificity (an absence of oxidase-like activity) and (iii) an ability to operate in physiological solutions. These unique properties allow to denote the catalytically synthesized PB nanoparticles as nanozymes ‘artificial peroxidase’. Together with high stability and low cost, obviously peculiar to noble metal free inorganic materials, the mentioned properties would allow the substitution of natural and recombinant peroxidases in biotechnology and analytical sciences [1].

Simple drop-casting of the catalytically synthesized Prussian Blue nanoparticles with subsequent annealing results in modified electrodes with high electrochemical and electrocatalytic activity. The electroactive fraction of the deposited Prussian Blue being independent of the surface concentration, is decreased with an increase of the nanoparticles size reaching its lower saturation at approximately 25%. Sensitivity of the corresonding hydrogen peroxide sensor is increased linearly with the amount of Prussian Blue reaching its upper saturation together with formation of continuative film, indicating most probably, a nanoparticles monolayer [2].

In contrast to bienzyme biosensors, we propose the nanozyme-enzyme based ones substituting the enzyme peroxidase with the more active and stable nanoparticles “artificial peroxidase”. The resulting nanozyme-enzyme lactate biosensor displays twice higher sensitivity (> 0.2 AM^{-1} cm^{-2}) compared to the Prussian Blue film based one [3].

Marcus-Hush Theory for Ultramicroelectrodes Revealed by Electron Tunnelling through Hexagonal Boron Nitride

Matěj Velický,[a,b,c]* Kostya S. Novoselov,[b] Héctor D. Abruña,[c] Robert A. W. Dryfe[a]

Although several experimental confirmations of the Marcus-Hush theory of electron transfer have emerged since its introduction in the 1950s, some interesting predictions remain unverified. This includes implications of this theory for ultramicroelectrodes, put forward by Feldberg in 2010, who predicted that significant deviations from the commonly invoked but less generic Butler-Volmer behaviour are to be observed under certain conditions [1]. However, a suitable experimental system, which would meet all of these conditions, including small electrode size, large overpotentials, slow electrode kinetics, and large reorganization energy, simultaneously, has not been found until a decade later.

We discuss electron tunneling through insulating hexagonal boron nitride (hBN), placed between a graphite electrode and an electrolyte solution of a redox mediator (Fig. 1a) [2]. This system favorably meets all of the conditions posed by Feldberg's analysis. The steady-state voltammograms of $[\mathrm{IrCl}_6]^{3-}$ oxidation and $[\mathrm{Ru(NH}_3)_6]^{3+}$ reduction, their rate constants (Fig. 1b), limiting currents, and transfer coefficients all significantly deviate from the expected Butler-Volmer behavior, in an excellent qualitative agreement with Feldberg's theoretical predictions.

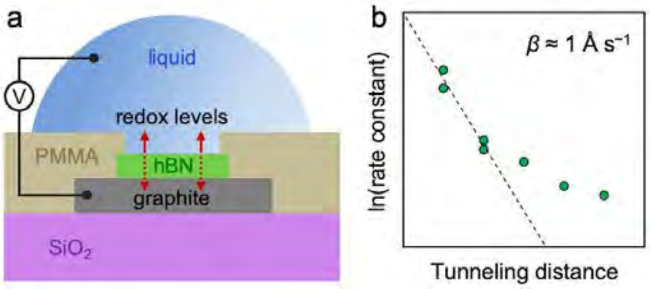

Figure 1: ***a,*** *Schematic of electron tunneling through hBN, between a graphite electrode and redox levels in a liquid.* ***b,*** *Deviation of the heterogeneous electron rate transfer rate constant from the exponential dependence on tunneling distance.*

Beyond another independent confirmation of a fundamental chemical theory, our findings also show that the electrochemical response of a conductive electrode can be effectively tuned by an insulating two-dimensional material of varied thickness. Such tuneability could be exploited in future research on electrode modification, electrochemical switching, or surface passivation [3].

Electrochemical Hydrogenation of Carbonyl Compounds: The Interaction Between Secondary Functional Group and Electrode and Its Influence on Catalytic Activity

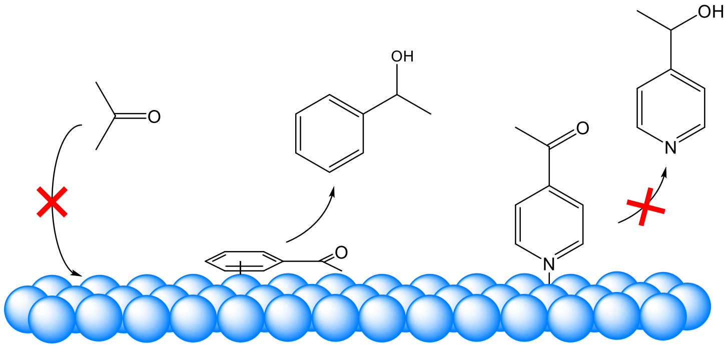

Graphical Abstract: Pt(111) is inactive for the hydrogenation of acetone as the letter will not adsorb. The phenyl ring of acetophenone forces the carbonyl function into a side-on geometry and activates it for the Pt(111)-catalyzed hydrogenation to the corresponding alcohol. 4-Acetylpyridine adsorbs to Pt(111) in an upright position. This makes the carbonyl function inaccessible to the catalyst surface and no hydrogenation can commence.

The heterogeneous hydrogenation of carbonyl compounds in chemical industry is highly relevant for the production of pharmaceuticals as well as fine chemicals. Its electrochemical counterpart has attracted interest, in view of efforts to electrify chemical industry, but also as a means to upgrade biomass derived bio-oils to fuels and platform chemicals. In this presentation we are going to discuss how the interactions between carbonyl compound and electrode surface affects the electrochemical reaction and how it depends on both the surface structure of the electrode and on the molecular structure of the substrate molecule.

Short chained aliphatic carbonyl compounds can only interact with the electrode surface via the carbonyl functional group. In this presentation we are going to show for platinum single crystal electrodes that the coordination number of an adsorption site determines the strength with which the carbonyl functional group adsorbs [1]. Both DFT calculations and experimental results show that acetone does not bind to surface sites featuring high coordination number such as Pt(111) and Pt(100) [1]. The absence of acetone adsorption results in the inactivity of these electrodes for acetone hydrogenation [1]. Adsorption and hydrogenation commences only at step and kink sites with low coordination numbers, whereas the adsorption strength determines whether the hydrogenation yields selectively 2-propanol (at Pt(110)) or in addition propane (at Pt(510)) [1].

Furthermore, we are going to show that adsorption through an inert secondary functional group present in the molecular structure of the carbonyl compound (phenyl ring in acetophenone, pyridine ring in 4-acetylpyridine) can have a strong influence on the reactivity as well. Adsorption through the phenyl ring forces the carbonyl functional group into a site-on geometry at Pt(111). Therefore, Pt(111) is able to catalyze the hydrogenation of acetophenone to the corresponding alcohol, which is not possible in the case of acetone [2]. Adsorption through the *N*-atom of the pyridine ring causes on all platinum surfaces a vertical adsorption mode of 4-acetylpyridine, which creates a physical distance between carbonyl functional group and electrode surfaces, thus inhibiting the hydrogenation reaction [2]. This is even true for Pt(110) which is the most active surface for acetone reduction.

A H^- Superionic Conductor $Ba_{1.8}LiH_{2.8}O_{0.9}$

Genki Kobayashi
Institute for Molecular Science, National Institutes of Natural Sciences
38 Nishigonaka, Myodaiji, Okazaki, Aichi 444-8585, Japan.
gkobayashi@ims.ac.jp

Hydride ions (H^-) can act as charge carrier as they exhibit several features suitable for fast ion conduction: monovalence, moderate ionic size comparable to O^{2-} and F^-, and high polarizability. Furthermore, hydride ions exhibit strong reducing properties through the standard H^-/H_2 redox potential (–2.3 V vs. SHE), which can be expected to be applied to novel electrochemical devices. Following some investigations on H^- conduction in alkaline earth metal hydrides[1-4], we reported H^- conduction in an oxide-based framework structure for the first time by finding a series of H^- conductive oxyhydrides, $La_{2-x-y}Sr_{x+y}LiH_{1-x+y}O_{3-y}$[5]. The discovery has triggered exploration of materials for H^- conductors such as K_2NiF_4-type Ln_2LiHO_3 (Ln = Pr, Nd)[6] and Ba_2ScHO_3[7] and fluorite-type $LaH_{3-2x}O_x$[8]. However, a H^- conductor exhibiting both high conductivity and low activation energy had not been developed yet. In the present study, we report a new H^- conductive oxyhydride, $Ba_{1.8}LiH_{2.8}O_{0.9}$, containing a high amount of barium and hydrogen vacancies and exhibiting long-range ordering at room temperature. Increasing the temperature above 315 ºC melts the ordered vacancies (Figure 1), triggering superionic conduction with a high H^- conductivity of over 0.01 $S\cdot cm^{-1}$ nearly independent of the temperature[8]. This is the first report of a H^- superionic conductor, which might open up possibilities for new electrochemical devices.

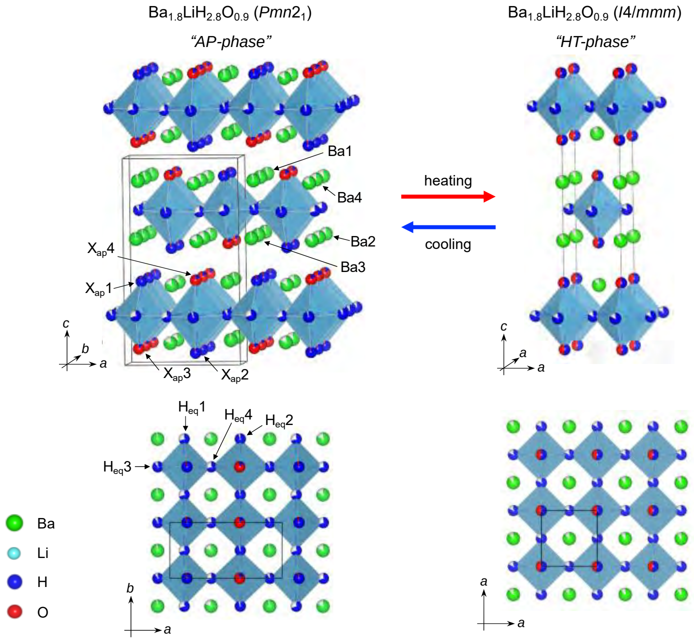

Figure 1. Crystal structures of K_2NiF_4-type $Ba_{1.8}LiH_{2.8}O_{0.9}$. Left: low temperature phase, Right: high temperature phase (high conductivity phase).

patrizia.mussini@unimi.it

To achieve enantioselectivity, electron transfer processes at the electrochemical interphase require the presence of a suitable enantiopure chiral selector, resulting in energetically different diastereoisomeric conditions for the two probe enantiomers.[1] A groundbreaking strategy is based on the use of molecular selectors endowed with "inherent chirality", *i.e.* with chirality and key functional properties originating from the same structural element, which in our case identifies with the main molecular backbone, featuring a tailored torsion with a racemization energy barrier too high to be overcome at room temperature. Large peak potential differences have been observed in voltammetry for the enantiomers of even very different chiral probes either (*i*) working in achiral media, on electrode surfaces modified with thin films of inherently chiral electroactive oligomers[1-4] or (*ii*) working on achiral electrodes, implementing inherent chirality in the medium, particularly in ionic liquids ILs, either chiral themselves, or modified by a chiral additive,[1,5,6] exploiting the peculiar IL high order at the interphase with a charged electrode.

Both strategies are being now extended and refined, particularly aiming to collect clues for the elucidation of the recognition mechanism, as well as to highlight attractive applications.

In the film case, we are studying in detail morphology, growth, chemical composition as well as functional properties of inherently chiral electroactive oligomer films, both as electrode surfaces and as self-standing membranes.

In the media case, chiral or inherently chiral molecules are being studied as advanced media and/or media additives/components, with impressive results.

Overall a wide palette of selectors (film or media) and/or probes are being compared, representing four classes of stereogenic elements*, i.e.* stereogenic centres, axes, planes and helixes.

The outstanding enantiodicrimination ability of the new selectors is also being considered beyond molecular chiral probes, *i.e.* towards polarized light components (in terms of circular dichroism and circularly polarized luminescence) and electron spins (in magnetoelectrochemistry experiments). Not only impressive effects have been observed, but fascinating correlations and connections are emerging among the three areas, worthy to be explored in detail, possibly providing further interpretative clues, as well as for possible exploitation in photonics and spintronics..

Technological advances in CO_2 Electrobiorefinery: Linking Bioelectrochemical CO_2 reduction with Renewable Energy

Deepak Pant*
Separation and Conversion Technology, Flemish Institute for Technological Research (VITO),Boeretang 200, Mol 2400, Belgium
*deepak.pant@vito.be

Carbon dioxide (CO_2) is considered to be the major cause of climate change by its accumulation in the atmosphere and its greenhouse properties. To counteract climate change, most research focused in the past on Carbon Capture and Storage (CCS). Nowadays it is recognized that rather than just storing it, emitted CO_2 can be a valuable source of carbon for the production of commercially valuable products. This Carbon Capture and Utilization (CCU) approach provides much needed additional capacity in the move towards a low carbon economy.

This presentation focuses on the use of CO_2 as feedstock for the synthesis of chemicals using biotechnology as core process. The main approach to be discussed is microbial electrosynthesis (MES) being used for the production of chemicals using bacteria as electrocatalyst. Already the bioelectrochemical reduction of carbon dioxide to acetate has been achieved as well as the reduction of CO_2 to methane and multi-carbon compounds. The key advantage foreseen here is the use of excess electricity that is often generated renewably such as from solar cells and wind mills, all of which cannot be utilized immediately and can be fed into a MES to produce chemical compounds. Results with specific bacteria towards bioelectrochemical conversion of CO_2 to organic compounds will be reported. Establishment of stable and robust biocathode for the bioelectrochemical CO_2 reduction at the graphite felt cathode succeeded repeatedly under long-term operation which led to the accumulation of higher titer to extractable amount (up to 8-10 g L^{-1} of acetate). When higher titers are obtainable from the CO_2 reduction based MES, product downstream process would be feasible. This requires continuous availability of CO_2 and sufficiently low cathode potential to ensure the supply of reducing equivalents/hydrogen. The dissolution of CO_2 and mass-transfer of reducing equivalents/hydrogen are the main limitations. Improvement on the dissolution and mass transfer rate of CO_2 was explored using gas diffusion electrodes (GDEs). GDE at least doubled the CO_2 mass transfer and MES was able to utilize CO_2 from the diluted gas mixture (20% CO_2) to produce acetate at the rate of 240 mg L^{-1} d^{-1} when the cathode was polarized at -1.1 V/Ag/AgCl.

Microbial electrosynthesis (MES) allow CO_2 capture and utilization for the electricity-driven bioproduction of organics such as acetic acid. Such systems can be coupled to any renewable electricity supply, especially those derived from solar and wind energy. However, fluctuations or even absence of electricity may cause damages or changes in the microbial community, and/or affect the performance and robustness of MES. Therefore, the effect of electric supply interruptions on MES performance was evaluated for the first time initially using bicarbonate as the substrate and later the transformation of gaseous CO_2 into organic products was assessed continuously during 120 days of operation. Time-increasing power outages, from 4 h to 64 h, were applied in order to evaluate the effects of electric energy (current) absence on microbial community, organics formation, production rates and product accumulation. Acetic acid was the main product observed before and after the power outages. In case of bicarbonate as substrate, interruptions affected the acetate production rate, causing a decrease of until 77% after 64 h off. With CO_2 as substrate, a maximum titer and production rate of 6965 mg L^{-1} and 516.2 mg L^{-1} d^{-1} (35.8 g m^{-2} d^{-1}) of acetic acid were observed, respectively.

Pathways Towards Next Generation Energy Storage Technologies Based on Redox Flow Batteries: Solid Boosters and Aqueous Organics

Redox flow batteries offer interesting options for electrochemical energy storage and even for heat-to-power conversion. In the first part of the talk, we will discuss the possibilities offered by organic redox couples in aqueous solutions,[1] report some recent examples from our lab, and describe our collaborative efforts for computational screening of organic redox couples within CompBat H2020-project.

In the second part of the talk, we shall introduce the concept of solid boosters for flow batteries. The advantage of such systems is that it allows relaxing the requirement for high solubility of the redox couple, significantly increasing the number of redox couples available for flow batteries. Wang et al. first suggested this concept, where the electrolyte tank is filled with solid redox active mm-sized beads forming a backed-bed type system, in 2013.[2] Firstly, the redox mediator is charged in the electrochemical cell and pumped back into the storage tank. The charge is then transferred into the solid material in a chemical reaction with the mediator, similarly to "*molecular wiring*" used, for example, in electrochemical enzymatic glucose sensors exploiting redox mediators to shuttle the electrons between the electrode and the enzyme.[3] The redox mediator can then be further charged in the electrochemical cell. We and others have shown that significant amount of the charge storage capacity of the solid materials can be used with a single mediator, if the redox potentials of the solid and soluble materials match well enough.[4-7] Since charge storage density is much higher in solids, lower concentration of the mediators can be utilized as the capacity of the flow battery boosted with solids is mostly due to the solid only.

The development of high-performing sensing materials, able to detect ppb-trace concentrations of volatile organic compounds (VOCs) at low temperatures, is required for the development of next-generation miniaturized wireless sensors [1-3]. Herein, we present the engineering of highly sensitive chemical sensors, comprising of different Metal Oxide Semiconductors (MOS as ZnO, SnO_2 and WO_3) layouts [4,5]. The chemical properties of these highly porous (> 90%) materials were systematically investigated in terms of composition and morphologies. Then, all the synthesized materials were tested towards different VOC species, namely ethanol (EtOH), acetone and toluene/ethylbenzene (EtBz), in order to eventually highlight the materials diverse selectivity. Optimized layouts demonstrate significant potential as chemoresistors operating at high temperatures (around 300-350 °C) especially in terms of sensitivity, reaching ppb concentrations as the low detection limits (Figure 1a). Furthermore, in order to elucidate the sensing mechanism, experimental *in situ* Modulated Excitation-XANES analyses (at the European Synchrotron Radiation Facilities in Grenoble) along with theoretical studies were carried out (Figures 1b and 1c). Theoretical outcomes reveal the pivotal role played by oxygen species adsorbed on the MOS surface. Hence, the matching of experimental and theoretical results gave us the possibility to hypothesize the possible phenomena at the basis of the sensing behavior.

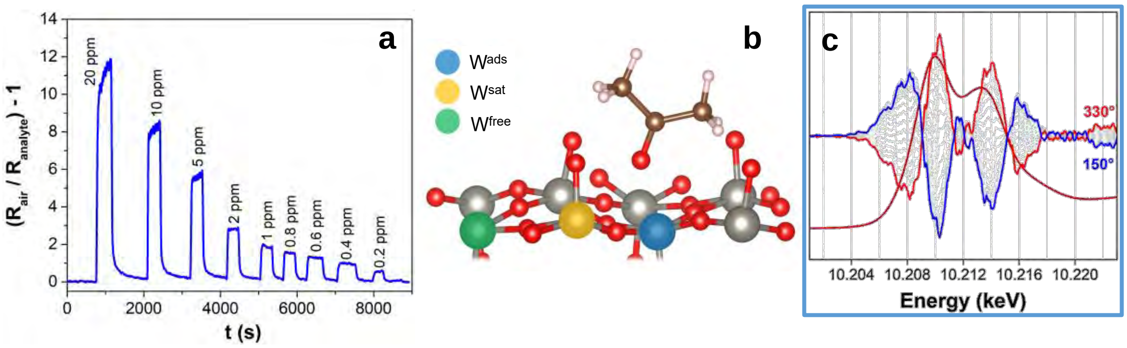

Figure 1. (a) WO_3 sensor response towards acetone; acetone adsorption onto WO_3 nanomaterials on (b) theoretical and (c) experimental (XANES measurements) points of view.

1-pentyl-3-(1-naphtoyl)indole (hereinafter referred to as "JWH-018") is a compound belonging to a heterogenous group of synthetic cannabinoids, which has recently appeared in the drug market. This substance is abused for its psychoactive effect and serves as alternative to classical drugs (heroin, cocaine, ecstasy) due to its legal status. In human organism, JWH-018 is rapidly and completely metabolized and thus parent compounds are often undetectable. It is necessary to know its metabolism pathway to enable detection of this compound.

In this research, the electrochemical methods were used to study drug oxidation and reduction. Since the electron transfer participates in metabolic pathways, electrochemical behaviour of JWH-018 was studied with purpose to identify short living intermediates of redox reactions. Simultaneously, above mentioned compound was incubated with human liver subcellular fractions (microsomes) and cytochrome. The products obtained by electrochemical and biochemical methods were identified by advanced chromatographic techniques UPLC-MS/MS and serve to identify the potential metabolism of synthetic cannabinoid.

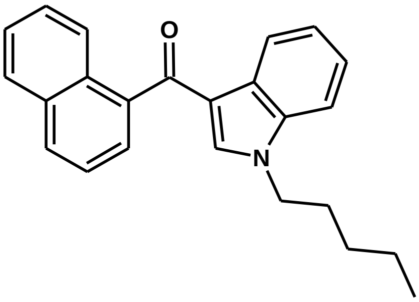

Figure 1: Chemical structure of JWH-018

The concept of Deep Eutectic Solvents (DES) was introduced by Abbott in 2001. DES are considered as an interesting alternative to molecular organic solvents and ionic liquids. They are constituted by at least two components that interact strongly to form an eutectic mixture. Deep eutectic solvents can be described by the general formula Cat+-X− with Cat+ being ammonium, sulfonium, or phosphonium and X− a Lewis base, in general a halide. DES are usually divided into four types: type I (quaternary salt and metal halide), type II (quaternary salt and hydrated metal halide), type III (quaternary salt and hydrogen bond donor) and type IV (metal halide and hydrogen bond donor). They have different advantages with respect to the other media like: easy, scalable, low cost synthesis; low vapor pressure; non flammability and biodegradability. There are very few works in literature concerning the electrochemistry or electroanalysis of and in DES media regarding the preparation of MIPs (Molecularly Imprinted Polymers), synthesis of nanomaterials, functionalization of carbon nanotubes and film electrodeposition [1]. From 2011 a new class of DES called NADES (NAtural Deep Eutectic Solvents) based on natural molecules was synthetized. In the class of NADES, Chiral Deep Eutectic Solvents (CDES) can be included. CDES were recently synthetized and there are no detailed studies in literature on their physicochemical properties, especially regarding the ones where chirality originates from the cation. The applications on CDES span from the field of catalysis to the one of enantioselective synthesis. They differ from ionic liquids for the possible use on large scale (low cost, low impact on the environment), for the easy synthesis (mixtures of at least two components) and for their composition (adduct between a hydrogen bond donator and a hydrogen bond acceptor). In this work we would like to present a new class of CDES in which the cation is both of natural origin and chiral. The hydrogen bond acceptor is a chiral organic salt of NOPOL-MIM/mesylate, because solid at room temperature and already studied by our group as chiral additive in achiral commercial ionic liquid for the enantiorecognition of chiral probes; the hydrogen bond donators used are the common ones largely employed in literature: glycerol, levulinic acid and urea. Firstly, these CDES were characterized by differential scan calorimetry (DSC) in order to study their physicochemical properties and to determine correctly the eutectic points. Then, we have performed enantioselectivity tests using these additives dissolved in a commercial achiral ionic liquid on plastic and paper screen printed electrodes with different working electrodes (carbon black, graphite and gold), by means of differential pulse voltammetry (DPV) and electrochemical impedance spectroscopy (EIS). Recorded DPV signals shown a really huge separation between the enantiomers of the chiral analyte in term of peak potential values. For these reason we have decided to test the chiral probes both in enantiopure and in racemic form. We have prepared different mixtures of the enantiomers of the analytes and determined the enantiomeric excesses. Results are really promising, recalling signals obtained as output of a chiral HPLC.

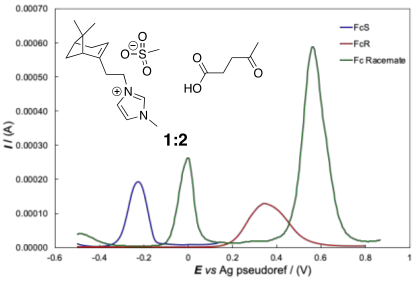

Fig. 1. Enantioselectivity tests on screen printed electrode using as additive the CDES with levulinic acid

and as chiral probe a ferrocenylic one, as pure enantiomer or as racemate

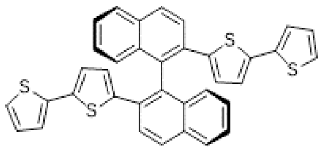
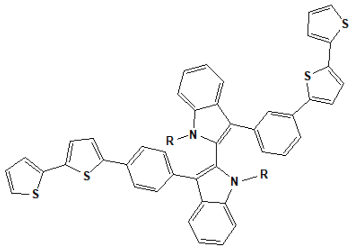
sara.grecchi@unimi.it

Enantioselective electroanalysis is a very attractive target, potentially enabling to discriminate between the enantiomers of electroactive chiral probes without preliminary separation steps. Inherently chiral electroactive monomers based on atropisomeric biheteroaromatic cores and oligothiophene wings have recently proved excellent starting materials for the electrodeposition of electrode surfaces consisting of inherently chiral oligomers, of outstanding enantiodiscrimination ability for chiral electroactive probes, in terms of large potential differences in voltammetry experiments [1-2]. In this context, we would like to present new inherently chiral monomers that have different atropisomeric properties and cores:

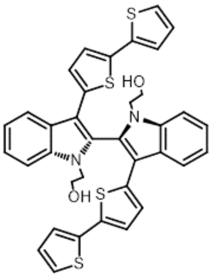
i) the new inherently chiral monomer **$Naph_2T_4$**, based on a biaromatic atropisomeric core, and advantageously obtainable in enantiopure form without HPLC separation steps, by a synthetic route hinging on enantiopure 2,2'-dibromo-1,1'-binaphthalenes;
ii) an inherently chiral monomer based on a 2,2′-biindole core **(N-R)-$Ind_2Ph_2T_4$**, as the prototype of a new inherently chiral monomer family, whose properties could be modulable through functionalization of the pyrrolic N atoms (with alkyl chains of different lengths);
iii) an inherently chiral monomer based on a 2,2′-biindole core with the N atom functionalized with an alcoholic residue **(N-OH)-$Ind_2Ph_2T_4$**



(*R*)-$Naph_2T_4$



Compound	R
(N-Me)-$Ind_2Ph_2T_4$	Me
(N-Pr)-$Ind_2Ph_2T_4$	n-Pr
(N-Hex)-$Ind_2Ph_2T_4$	n-Hex



(*R*)-(N-OH)-$Ind_2Ph_2T_4$

The monomers were electrochemically characterized by cyclic voltammety experiments, the electrooligomerization conditions were then optimized to convert the monomers into oligomeric films. The films show good stability upon subsequent potential cycling in monomer-free solution, as required for use as an enantioselective electrode surface and subsequently their enantioselection capabilities were tested using the model chiral probe *N,N*-dimethyl-1-ferrocenylethylamine, which can be regarded as a benchmark given that it displays an electrochemically and chemically reversible oxidation, but also probes of pharmaceutical interest (such as L- and D- DOPA and L- and D-Tryptophan). We have verified the general validity of the inherently chiral concept, which does not depend on the chemical nature of the atropisomeric scaffold, by testing the electro-oligomerized chiral surfaces starting from monomers with different molecular design. In order to fully clarify the enantioselection capacity of all these heteroaromatic systems, we also propose a comparison of these new inherently chiral surfaces with the benchmark monomer BT_2T_4.

Redox enzymes, which catalyze electron transfer reactions involved in several metabolisms, are key biomolecules in biotechnological and especially bioelectrochemical devices. Thanks to unique properties, such as huge specificity and affinity towards their substrate, high catalytic turnover, and low overvoltages with respect to their substrate, they are attractive receptors in biosensors or catalysts in biofuel cells. Electrochemistry provides key information about the thermodynamic and kinetic properties of the enzymes, as well as their physicochemical behavior upon immobilization at the electrode interface. It also enables characterizing the whole biodevices. However, several information are still missing in pure electrochemical studies. Among them, spatially-resolved information are lacking since the signal is collected and integrated over the whole electroactive surface where electron transfer reactions occur. No data about heterogeneities, or local enzyme environment during turnover, are provided. In this context, the interest in coupling electrochemical methods to microscopy techniques is increasing [1]. Indeed, it enables collecting simultaneously data at the global and local scales. Among these techniques, fluorescence confocal microscopy (FCM) is a method of choice for the study of bio-objects. Moreover, it enables rebuilding three dimensional images thanks to a non-invasive optical sectioning of volumes. FCM was already implemented *in situ* during electrochemical experiments in the abiotic context. It allowed notably elucidating reaction mechanisms through the determination of concentration profiles in the diffusion layer [2]. We show here that it also permits to characterize electro-enzymatic catalysis. We chose as a model enzymatic reaction the four electron-four proton O_2 reduction in water by the multi-copper enzyme bilirubin oxidase from *Myrothecium verrucaria* (*Mv*BOD). We demonstrate that the enzymatically generated local pH changes can be visualized using a pH-sensitive fluorophore, when *Mv*BOD is immobilized at a macro- or a micro-electrode. Reactivity at the electrode surface and in the electrolyte volume can thus be explored in a new way. We observe unexpected features, especially the pH evolution of the enzyme environment, which is also indicated by a characteristic concentration profile within the diffusion layer. Finally, we obtain a cartography of the reactivity at the enzymatic electrode, which could not be determined by pure electrochemical techniques [3].

Illustration of the experimental strategy. *Mv*BOD is immobilized at an electrode which provides the electrons for the enzymatic O_2-reduction. Simultaneously, protons consumption changes the pH locally, thus modulating the fluorescence of fluorescein whose quantum yield (Φ) is pH-dependent. The evolution of fluorescence intensity is recorded through the objective by FCM. Reproduced from [3].

stdenhar@vub.be

In the search for clean energy conversion systems, PEM fuel cells have attracted a lot of attention over the last decades. Nanostructured electrocatalysts such as porous platinum nanoparticles (NPs) are considered one of the most promising advances to lower the cost of these fuel cells and make them more commercially attractive. The efficiency of these catalysts is limited by their activity towards the oxygen reduction reaction (ORR), and most research is thus focused on understanding reaction mechanisms and improving the activity. It has been shown indirectly[1,2] that radical intermediates formed during the reaction can desorb from the catalyst surface. More importantly, these free radicals are suspected to be responsible for the degradation of the carbon support, leading to the deactivation of the electrocatalyst NPs[3].

We propose a combined electrochemical and electron paramagnetic resonance (EPR) procedure for the study of ORR intermediates generated at Pt NPs. Using spin-trap EPR spectroscopy complemented by electrochemical analysis, we show that we can detect and identify the free radicals that are produced during the ORR and are otherwise difficult to detect. Custom-made glassy carbon RDE's with a large geometrical surface area have been designed and were loaded with Pt nanoparticles via double pulse electrodeposition. The large surface area is necessary in order to produce sufficiently large amounts of free radicals to be detectable in the EPR spectrometer.

Our experiments show that only free •OH radicals are trapped by DMPO. Experiments with DEPMPO as spin trap confirm that no free •OOH radicals are present in solution. This is of great interest for on-going research to elucidate the ORR mechanism and to prevent degradation of the support and Pt electrocatalyst. We propose that our procedure can be used for a more rigorous quantification of free radicals involved in electrochemical reactions.

The electric double layer capacitor (EDLC) is an electricity storage device that charges and discharges by electrostatically adsorbing and desorbing ions in an electrolytic solution. Since it has a long cycle life of 10^5 times or more and high output power, it has been attracting attention in recent years for memory backup of mobile devices, compensation of instantaneous voltage drop in an emergency, energy regeneration of hybrid vehicles, etc. A typical problem, however, is that the energy density is lower than that of lithium-ion secondary batteries. Since the energy density of EDLC is proportional to the square of capacitance C and the operating voltage V, expanding V is the most effective method for increasing energy density. On the other hand, C is proportional to the electrode surface area S, and the reciprocal of the thickness of the electric double layer, and so C can be enhanced mainly by increasing surface area of active material, that is, activated carbon. It is thought that pore structure optimization may have reached a limit because of difficulty in how finely the pores enhancing C can be created; hence the number of studies aiming at the expansion of C is decreasing.

Therefore, in this study, we tried to enhance C from the viewpoint of reducing the double layer thickness d. Currently, ionic species with relatively large size and low charge density are generally used as charge carriers in non-aqueous EDLCs. This is because ions with small size and high charge density interact strongly with solvents and behave as giant solvated ions, increasing d. However, in our previous research, lithium bis(fluorosulfonyl)imide (LiFSI) was sufficiently dissociated even in a low dielectric constant solvent due to small interaction with ions, and lithium ion was easily de-solvated despite its high charge density.[1,2] In this study, we succeeded in utilizing weakly solvated alkali metal cations as charge carriers for EDLC by using a mixed solvent mainly composed of low dielectric constant solvent. In addition, we will report the detailed electrochemical results of the behavior of the electrode / electrolyte interface, and also report various studies conducted to improve the usability as a device.

A composite electrode using activated carbon as the active material, acetylene black (AB) as the conductive additive, carboxymethylcellulose (CMC) as the dispersant, and styrene-butadiene rubber (SBR) as the binder was prepared and used for evaluation. LiFSI or NaFSI were dissolved at a concentration of 1.0 mol dm^{-3} in an electrolytic solution in which a high dielectric constant solvent PC and a low dielectric constant solvent DMC were mixed at a volume ratio of 1: 9 or 1: 1. A three-electrode cell was constructed using the above-mentioned activated carbon electrode for both the negative electrode and the positive electrode and metallic lithium for the reference electrode. In this study, we designed the cell so that the Li^+ adsorption / desorption behavior at the negative electrode side would be the dominant cell property. That is, the cell design was performed so that the weight of the activated carbon at the positive electrode was largely increased to reduce the influence of the positive electrode.

CV measurements carried out for 1: 9 and 1: 1 systems using LiFSI (or KFSI afterwards). In a typical electric double layer behavior, the CV curve shows a clean rectangle, but our studies showed that the rectangle collapsed during Li^+ desorption in the 1: 1 system, but hardly collapsed in the 1: 9 system. On the other hand, when the same CV was performed using KFSI, the response current for cation adsorption / desorption increased regardless of the solvent composition, Furthermore, no significant distortion was observed on the desorption side observed in the 1: 1 system when LiFSI was used. Raman spectroscopy showed that when LiFSI is used, the solvation number of PC to Li^+ in 1: 1 is much higher than in the 1: 9 system. On the other hand, as for KFSI, the solvation number of PC was about the same as that of the 1: 9 system even in the 1: 1 system. Therefore, it is considered that the difference in CV behavior is due to the difference in the solvation state between Li^+ and K^+ even in the electrolyte solutions with the same solvent composition. These results demonstrate that the use of K^+, which has a relatively low charge density, reduces the adverse effects of solvation as compared to the Li^+ system.

Electrochemical Impedance Spectroscopy for the Characterization of Conductive Polymer Films – The Non-stationary Case

Győző G. Láng, Krisztina J. Szekeres, Mária Ujvári, Soma Vesztergom
Eötvös Loránd University, Institute of Chemistry
Pázmány Péter sétány 1/A, H-1117 Budapest, Hungary
langgyg@chem.elte.hu

According to the usual interpretation of the concept of impedance, impedance is not defined as time-dependent and, therefore, there should not exist an impedance out of stationary conditions. This means that if the requirement of stationarity in impedance spectroscopy is in conflict with the essential properties of the object, the measured data points are not "impedances", the obtained sets of experimental data are not "impedance spectra" and they cannot be used in any analysis based on traditional impedance models. When data recording occurs at low frequencies a complete measurement sequence can take considerable time (at least several minutes).

Many electrochemical systems, including polymer modified electrodes are intrinsically nonstationary and are affected by time-dependent phenomena. On the other hand, it is possible to show that under some suitable conditions time dependence can be conciliated into the concept of impedance [1,2]. The four-dimensional analysis (FDA) method is based on the assumption of the continuum of the object's state and parameters space. Every measured data at a given frequency should additionally contain the time of measurement (Fig. 1, a). By taking advantage of the continuity of the evolution, interpolation is performed resulting in instantaneous projections of the full impedance-time space (Fig. 1, b,c) and "reconstructed" impedances related to a selected instant of the time (Fig. 1,d). Each of these diagrams can be regarded as a stationary one, free of non-steady-state errors.

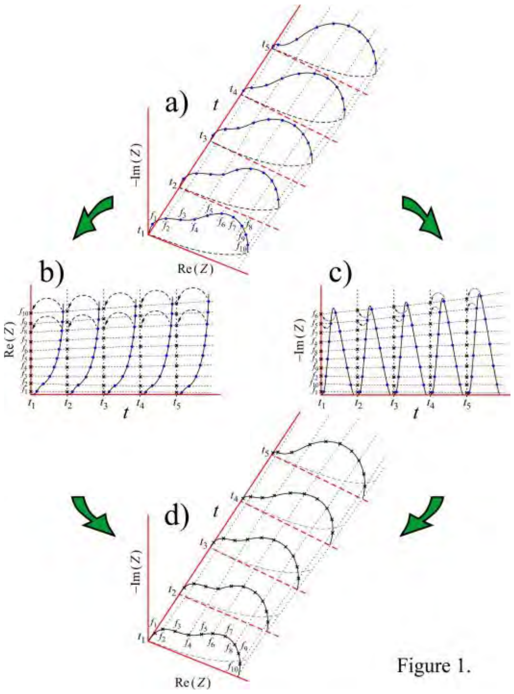

Figure 1.

Overoxidized poly (3,4-ethylenedioxytiophene (PEDOT) film on gold or glassy carbon in aqueous sulfuric acid is a good example of a nonstationary conductive polymer system for which the 4-dimensional analysis method can be effectively applied. After overoxidation, at both high and medium frequencies the complex-plane plot of the measured data is characterized by a "capacitive" arc (or depressed semicircle), while the low frequency part indicates "capacitive" behavior. However, the complex plane plots clearly indicate that the system is nonstationary [2]. E.g. it can be inferred from the shapes of the sequentially recorded impedance spectra that the charge transfer resistance at the substrate/polymer film interface decreases continuously over several hours. The impedance analysis results show that the FDA method can not only be used for the correction of the existing (experimentally measured) impedance data, but it opens up the possibility of the estimation of the impedance spectra outside the time interval of the impedance measurements.

In this study, the advantages and limitations/drawbacks of the method and its relation to CNLS-fitting are discussed.

Structural Dependence of Capacitive Performances of Multi-Metal Oxides Composites of Ordered Support–Layer Microstructure

Vladimir Panić
National Institute of Chemistry, Technology and Metallurgy, Department of Electrochemistry, University of Belgrade
Njegoševa 12, Belgrade, Serbia
panic@ihtm.bg.ac.rs

An important aspect of the contemporary investigation of powdered metal oxides as electrochemical supecapacitors relates to fully precise tailoring of their synthesis to reach ordered structures of complete availability of capacitive performances. Ordered structure aims to minimize the amount of noble metal oxides, *e.g.*, RuO_2, or to improve their activity in multicomponent composites of developed interactivity between layered noble metal oxide and poorly active or inert support. The ordering is to be gained at micro- and nano-level, with structural uniformity of supporting matrices and a layer of active component(s), and consequently of composite support–layer ordered microstructural fragments. This requires intrinsic synthesis routes of an *ex-situ* or semi-*ex-situ* approach – separate synthesis of the components and subsequent impregnation, or alternatively *in-situ*, by time-programmed hydrolysis or hydrolysis within emulsified micro-reactors.

Simple *in-situ* and *ex-situ* approaches for the synthesis of powdered RuO_2-based supercapacitive composites, with TiO_2 ($RuO_2|TiO_2$) [1] and perovskite-type $LaSrCo_3$ ($RuO_2/LaSrCo_3$) [2], respectively, as supports are presented and discussed. A synthesis procedure of ultrasonically induced combined hydrothermal/aerosol pyrolysis was found suitable to produce almost ideal microspheres with surface layer of uniformly dispersed active component. Capacitive performances, investigated by cyclic voltammetry, electrochemical impedance spectroscopy and galvanostatic charge/discharge experiments, are found sensitive to structure/composition of $RuO_2|TiO_2$, and indicated mutual improvement of the capacitive characteristics of Co_3O_4 and RuO_2 in $RuO_2/LaSrCo_3$.

The paper relates the electrochemical characterization by cyclic voltammetry, pulse-differential voltammetry and rotating disk electrode voltammetry of new azulene azotetrazole monomers (Fig. 1). These monomers have been synthesized [1] and used to obtain modified electrodes by electrochemical polymerization. The study led to the finding conditions for the application of these complexing modified electrodes in recognition of heavy metal ions.

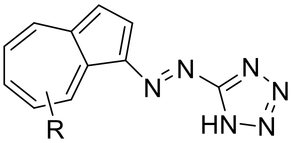

Fig.1. Investigated azulene azotetrazole derivatives; R: H; 4,6,8-Me3; 3,8-Me2-5-iPr

The modified electrodes were characterized by cyclic voltammetry in ferrocene solutions, EIS, SEM, AFM. The complexing properties of this polyfunctional material were used for the recognition of heavy metal ions (Pb, Cd, Hg, Cu) by anodic pre-concentration technique [2]. The best results have been obtained for Pb detection.

Diacylgermanes such as Ivocerin® are used for dental applications as serving as non-toxic photoinitiators for radical polymerization. The corresponding photo-induced reaction mechanisms are well established [1].

Irradiation with light in the visible region leads to a homolytic C-Ge bond cleavage resulting in radical formation. The absorption spectra of the photoinitiators depend on the electron donating/withdrawing character of substituents at the aromatic moieties [2-3].

Push-pull effects, however, also indicate a substantial effect on the redox properties of the acylgermanes monitored by means of electrochemical methods. The first electron reduction of the parent compounds yields an anion radical.

In this context, we present our results obtained by DC-polarography and cyclic voltammetry across a series of mono-, di-, tri- and tetraacylgermanes, di- and tri-nuclear polyacylgermanes as well as analogical silanes and stannanes, respectively [4]. The observed trends in their first reduction potentials will be discussed connected with the substitution pattern at the central atom.

Rifampicin (RIF) is an essential antibiotic for the short-course anti-tuberculosis treatment [1]. The intensive use of antibiotics including RIF results in the continuous release of the drugs into the environment, which leads to the development of antibiotic resistance genes (ARGs) and antibiotic resistant bacteria (ARB) making the treatment of some infections impossible [2]. One of the main anthropogenic sources for ARGs and ARB are suspected to be the effluents from urban wastewater treatment plants.

Therefore, there is a necessity to estimate RIF levels in biological, pharmaceutical and environmental samples. Accordingly, several analytical techniques based on chromatographic methods (liquid chromatography, thin-layer chromatography), electrochemical methods and spectrophotometry have been reported for RIF detection [1].

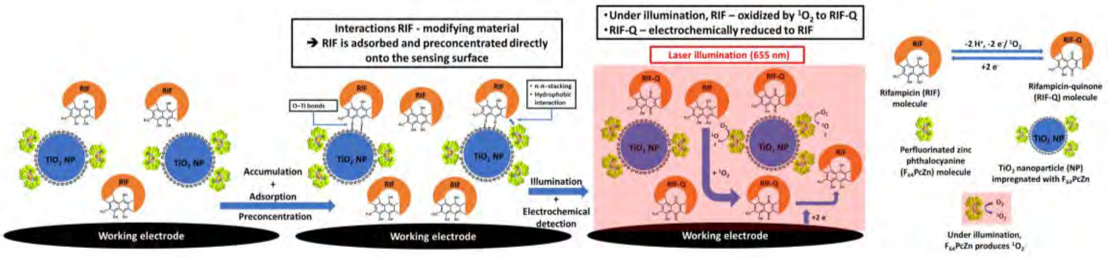

Figure 1. Schematic representation of the analytical method.

Here, we propose a new robust and sensitive photoelectrochemical method for RIF detection based on a concept developed earlier [3] using a perfluorinated zinc phthalocyanine ($F_{64}PcZn$) as a type II photosensitizer. Deposited on an electrode, $F_{64}PcZn$ generates reactive singlet oxygen ($^1O_2$) under visible light illumination resulting in oxidation of phenolic analytes. This is followed by electrochemical reduction of the product and corresponding current rise [3] in the electrocatalytic cycle similar to enzymatic sensors.

$F_{64}PcZn$ is deposited on the electrode together with a supporting element – TiO_2. The later can bring an analytical advantage due to enhanced interaction between TiO_2 surface and vicinal phenols (1,2-dihydroxybenzene, 1,8-dihydroxynaphthalene) like in the structure of RIF [3, 4]. The photosensitizer itself can also interact with RIF, both being highly hydrophobic molecules, further increasing the possibility for enhancing the overall sensitivity by pre-concentrating RIF on the sensing surface.

Using this concept and employing an incubation step, a low limit of detection of 10 nM was obtained. Also, based on the characteristics of the interaction between RIF and the sensing material, the capability of the method to distinguish from RIF and certain other phenolic compounds was also demonstrated, by testing other phenols and real samples, represented by effluents from urban wastewater treatment plants.

This approach could be even further extended for other polyphenolic compounds, based on the promising results showed.

High-speed spectroelectrochemistry with quantum cascade laser frequency comb spectroscopy

Markus Mangold, Andreas Hugi, Urszula Szczepaniak, Raphael Horvath, Markus Geiser
IRsweep AG
Laubisruetistrasse 44, 8712 Staefa, Switzerland
markus.mangold@irsweep.com

Frequency comb spectroscopy is a promising development, allowing for higher resolutions, faster acquisitions, and higher throughput, especially when compared with non-laser based spectroscopic techniques.[1] We have developed a spectrometer based on quantum cascade lasers, combining many advantages of dual comb spectroscopy with the relative affordability and ease of use of semiconductor lasers.

The method of dual-comb spectroscopy employs broadband lasers emitting hundreds of wavelengths simultaneously, enabling studies of the time evolution of multiple molecular absorption features. The recent advent of quantum cascade laser based mid-infrared frequency combs and the demonstration of their suitability for dual-comb spectroscopy led to the integration of the technique into a spectrometer.[2,3] This spectrometer is based on two quantum cascade laser frequency comb sources that are overlaid to produce a heterodyne beating signal.

As the spectrometer contains no moving parts, a careful selection of the mode spacings allows for spectra to be acquired on a sub-microsecond timescale, and this can be done continuously for hundreds of milliseconds. The bright laser sources allow a combination of low noise (1 mOD at 100 µs) with high spectral resolution (< 0.0001 cm^{-1}) to be achieved. Additionally, optically dense samples can be probed, for example affording measurements through highly absorbing water backgrounds. Validation of the method was done by comparing time-resolved dual comb spectroscopy measurements of a protein photocycle to an equivalent step-scan FTIR experiment.[4] Closely matching spectral and kinetic behavior was found. Furthermore, the Stark tuning rate of fluorobenzene was measured in a vibrational Stark spectroscopy experiment using the frequency comb spectrometer.[5] Most recently, the measurement of the potential dependent desorption of a monolayer of a pyridine derivative with time resolution as high as 4 µs was achieved.[6] In this presentation, we will detail the route towards in-situ spectroelectrochemical analysis with frequency comb sources and we will lay out the potential of studying microsecond dynamics in electrochemical systems.

In conclusion, the development of a solid-state mid-infrared dual-comb spectrometer based on quantum cascade lasers is detailed. Reference experiments show good signal to noise ratios at short integration times and in single-shot measurements, allowing for new applications to be explored.

To protect metal constructions from corrosion, organic coatings are widely applied. However, these coatings can be prone to breakdown when exposed to aqueous environments during prolonged periods of time. The initial step of failure of a coating when it comes into contact with water is water uptake. This water uptake has been studied extensively in literature [1, 2] by Electrochemical Impedance Spectroscopy (EIS) and/or gravimetry. With EIS, the coating capacitance is followed as a function of time, and the dielectric constant of the coating over time is extracted. The water uptake can then be estimated by either using the Brasher-Kingsbury equation [2] or the linear relationship [3]. This method to determine water uptake from EIS results, takes as an assumption that water only diffuses perpendicular to the surface, while lateral diffusion could also occur from a theoretical standpoint.

In this work, the validity of this assumption is investigated, by not only measuring the capacitance change of the coating surface exposed to electrolyte, but also at surfaces that are not directly exposed. The capacitance will be monitored through odd random phase electrochemical impedance spectroscopy (ORP-EIS). The test will be performed on model coatings, which are based on acrylic and/or methacrylic backbones. From initial research, it is found that the water uptake in these coatings has to be measured immediately after the immersion of the coating as it is a very fast process. This rapid water uptake in the coatings is monitored using the time-resolved instantaneous impedance calculation [4] from ORP-EIS measurements. To identify the lateral diffusion, the impedance is measured simultaneously at the immersed surface and at a surface that is not in direct contact with the solution. This measurement is performed using a custom-made dual potentiostat that shares the working electrode, which is the metal substrate underneath the coating. Results show that there is indeed a measurable capacitance increase in the measured surface outside of the immersed surface, indicating the lateral diffusion of water. The lateral diffusion coefficient can be calculated and compared to the perpendicular diffusion coefficient.

In this lecture I report recent research progress achieved in our ERC-funded ARTISTIC project,[1] which aims at developing a digital twin of the manufacturing process of Lithium Ion Batteries (LIBs) to accelerate their optimization.[2] Such digital twin is supported on a hybrid approach encompassing a physics-based multiscale modeling workflow, Artificial Intelligence (A.I.) informatic algorithms and systematic experimental characterizations. Different steps along the battery cells manufacturing process are simulated, such as the electrode slurry, coating, drying,[3-6] calendering[7] and electrolyte filling. The multiscale modeling workflow couples Coarse Grained Molecular Dynamics, Discrete Element Method and Lattice Boltzmann simulations and it allows predicting the impact of the process parameters on the final electrode mesostructure. The predicted electrode mesostructures are injected in a 4D-resolved performance simulator capturing the influence of the pores networks and spatial location of carbon-binder within the electrodes on the electrochemical response.[3,5-8] Systematic experiments allow models validation. A.I. is used as a complementary tool to discover manufacturing parameters interdependencies directly from the experimental data,[9] to support the physical models' parameterization[4] and as a guideline for reverse engineering. The predictive capabilities of this digital twin are illustrated with results for different NMC-based and graphite-based formulations. Finally, practical implications of ARTISTIC towards the acceleration of the manufacturing process optimization of advanced batteries are discussed.

It is well known that amorphous iridium oxide materials (electrochemically synthesized or thermally obtained at low temperature) are more active than their well-crystalline counterparts, but usually it is at the expense of their stability. The presence of Ir hydroxo groups at the surface of highly active catalysts has been established.[1, 2] However, despite extensive studies, the reason of the higher activity of amorphous materials is also still the matter of a strong debate. We have recently extended the aerosol synthesis route to the preparation of highly porous noble-metals and noble-metal alloys[3] and noble-metal pure and mixed oxides.[4] In the case of pure iridium oxide, we have shown that the surface state, the crystallization and crystallite size and therefore the electrochemical properties can easily be tuned by changing the post-synthesis thermal treatment.[4] In this work, we are taking the advantage of the versatility of this green, cheap and scalable synthesis technique to prepare a large panel of iridium-non-noble metal mixed oxides. By introducing molybdenum along with iridium into the structure, we are able to delay the crystallization of the materials while the chemical transformation occurs in the same temperature range as for pure iridium. Measurements of the electrochemical activity towards the OER also show that, if the calcination temperature of the material is optimized, the activity of the catalyst is independent of the Mo content (Fig. 1).
This uniqueness allows us to decouple the influence of the oxidation state from the structure of the material and provide unambiguous proof of the impact of the interatomic ordering onto the electrochemical activity of iridium based materials towards the OER. These findings are supported by a large set of techniques including SEM, XRD, XRF and STEM-EDX (Fig. 1) as well as surface (XPS) and bulk (XAS) characterizations. Besides, to the best of our knowledge, we report for the first time the synthesis of true iridium-molybdenum mixed-oxides. Indeed, the preparation of the material by the aerosol technique permit the quenching of the initial precursor solution and therefore an intimate mixing of the two metals during the drying-step; after calcination mixed oxide $Ir_xMo_{1-x}O_2$ with $1 \leq x \leq 0.5$ can be obtained.

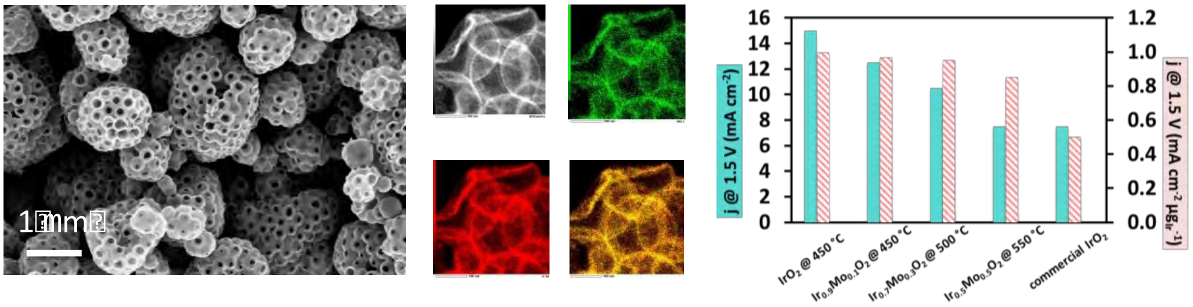

Figure 1: from left to right, SEM images of $Ir_{0.7}Mo_{0.3}O_2$ calcined at 550 °C, STEM-EDX analysis of $Ir_{0.7}Mo_{0.3}O_2$ calcined at 550 °C and histogram of activity at 1.5 V for different composition of mixed oxide refer to IrO_2

Electrochemical Zinc Deposition onto Au(111) and Au(100) from [MPPI][TFSI]

Fabian M. Schuett, Jerome Mayer, Maren-Kathrin Heubach, Maximilian Ceblin, Ludwig A. Kibler, Timo Jacob

Institute of Electrochemistry, Ulm University
Albert-Einstein-Allee 47, D-89081 Ulm, Germany
fabian.schuett@uni-ulm.de

Zinc deposition and dissolution was thoroughly investigated in recent years for the improvement of rechargeable zinc/air batteries.[1,2] Mainly the influence of water, air and other additives on the structure of the Zn deposit and possible dendrite formation was studied.[3,4] However, the influence of the crystallographic orientation of the underlying substrate on the initial stages of Zn deposition and the structure of the Zn deposit was not focused on in detail, yet.

In this work, the differences between the electrochemical deposition and dissolution of zinc on Au(111) and Au(100) model electrodes from the ionic liquid (IL) *N*-methyl-*N*-propyl-piperidinium (MPPI) bis(trifluoromethanesulfonyl)imide (TFSI) was investigated. The aim of our study was to evaluate the role of the electrode surface structure on a possible dendrite formation

To better understand the fundamental processes which take place during the deposition and dissolution of zinc from this ionic liquid, a first characterization of the system was conducted using cyclic voltammetry (CV) and *in-situ* scanning tunneling microscopy (STM). The clearly different structures of deposits during the initial stages of zinc electro-crystallization on both gold electrodes reveal the strong influence of the crystallographic orientation on the metal deposition of zinc (Figure 1). The deposition of Zn leads to a positive shift in the cathodic decomposition potential of [MPPI][TFSI], which limits the potential window for Zn electro-crystallization.

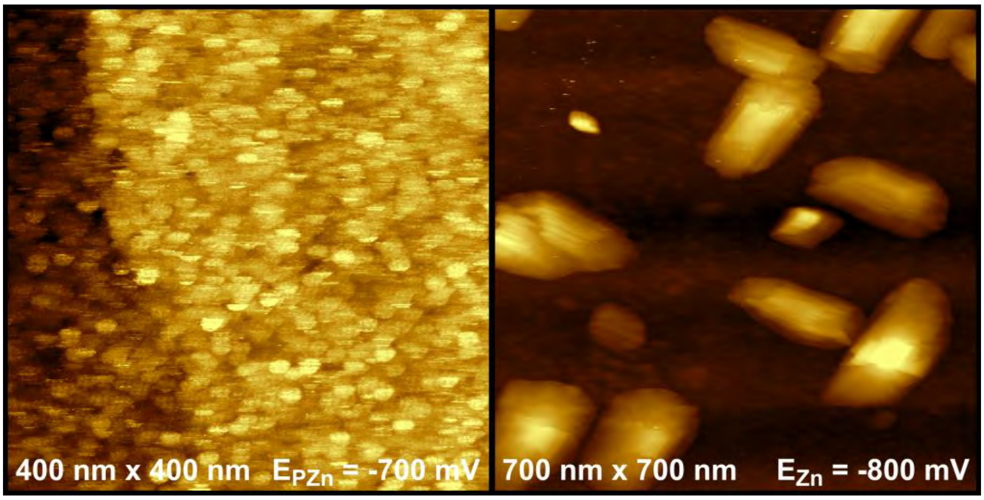

Figure 1: *In-situ* STM images of the early stages of the zinc bulk deposition on Au(111) (left) and Au(100) (right).

Zn deposits fabricated by several potential cycles were examined by Auger electron spectroscopy (AES) and scanning electron microscopy (SEM). While *in-situ* STM as well as AES sputter experiments indicate an alloy formation that takes place during the zinc deposition a complete plating of the Au electrodes upon continued potential cycling was found. Furthermore, under the studied conditions there were no signs of dendrite formation during Zn deposition on both Au single crystal electrodes.

Electrochemically Activated Stereoselective Functionalization of Amino Acids in Ni(II) Coordination Environment

Tatiana V. Magdesieva
Lomonosov Moscow State University, Chemistry Dept.,
Leninskie Gory 1/3, Moscow 119991, Russia
tvm@org.chem.msu.ru

Elaboration of new stereoselective synthetic approaches is a topical problem nowadays since a configuration of stereocenters is often determinant in practically important properties of a compound. Novel approach based on a combination of electrochemical activation with a stereoselective synthesis in a redox active metal coordination environment opens new horizons in stereoselective functionalization of amino acids in the form of the Ni-Schiff base complexes. The approach is compatible with the modern sustainable science requirements and allows reactivity and selectivity control on the substrates at the molecular level (due to cathodic or anodic activation) thus broadening a scope of available reaction routes (including processes which were not possible in common reaction conditions).

Various types of electrochemical activation will be discussed in the presentation, including electrochemical *in situ* generation of the active species; deprotonation of the substrates using electrogenerated base, targeted regioselective activation of the different sites of the molecule, etc.
Electrochemical formation of chiral nucleophilic equivalent of glycine which is *in situ* involved in various reactions, including multistep one-pot transformations (oxy- and thioalkylation, nucleophilic addition to activated C=C and C=O double bonds, radical reactions, etc.) allowed developing practical and highly efficient electrochemical routes to various types of enantiomerically pure α-amino acid derivatives.

Mechanistic insight into electrochemical processes helpful for understanding the manner of the stereocontrol of the reactions will be provided.

Using the electrochemical approach, a number of unique amino acids in the form of Schiff bases were synthesized. Among them, novel fulleroamino acid derivatives with “double” chirality, in which amino acid is directly linked to the cage via the chiral α-amino acid carbon center providing noninherently chiral functionalization pattern; novel types of the α,α-cyclopropanated amino acids and other interesting structures will be considered.

Electrochemical functionalization made available the wide range of diastereomeric couples; each diasteromer was isolated in the individual form. This allowed performing a comparative voltammetric research on the redox properties of a series new diastereomeric Ni-Schiff-base complexes. It revealed an interesting phenomenon of the stereodependent redox activity inherent to the derivatives of various types of amino acids. The difference in the redox potential values for the diastereomeric complexes is rather significant, opening the route for the electrochemical discrimination of the stereoisomers. The origin of the phenomenon, clarified using voltammetry data and DFT calculations, will be also discussed in the presentation.

Corrosion testing and electrochemical measurement under variable pH: experimental setup and examples of applications

Michele Curioni, Meng Lyu, Fabio Scenini

Department of Materials, School of Natural Sciences, University of Manchester, Oxford Road, M13 9PL, Manchester, UK.

Michele.curioni@manchester.ac.uk

A novel experimental setup to control the pH of a sodium chloride solution during corrosion testing and electrochemical measurements is presented. The setup comprises a purpose built electrochemical cell that is separated in two compartments by a porous material which allows ions exchange. In each of the two compartments a graphite electrode is placed and connected to a computer controlled, variable voltage, power supply. A pH electrode is immersed into one of the two compartment (the test compartment) and connected to a controller which sends the pH value to the computer. In the same compartment where the pH electrode is placed, an independent counter electrode, an Ag/AgCl reference electrode and a working electrode (i.e. the material under study) are placed. An automatic controller connect the two graphite electrodes placed into the two half cells and applies a sufficient potential to develop hydrogen from one electrode and oxygen from the other. As a result, the pH in the half cell where hydrogen is developed increases, whereas the pH in the half cell where oxygen develops decreases. By alternatively measuring the pH in the test cell and applying adequate potential to the graphite electrodes, it is possible to vary the test cell pH precisely and to perform pH sweep experiments. Further, the same controller enables to perform electrochemical measurements on the working electrode placed in the test cell. As a result, it is possible to obtain information on the variation of electrochemical behavior as a function of pH with a single experiment. This paper presents the experimental setup and provides some example of applications, such as that illustrated in Figure 1 below.

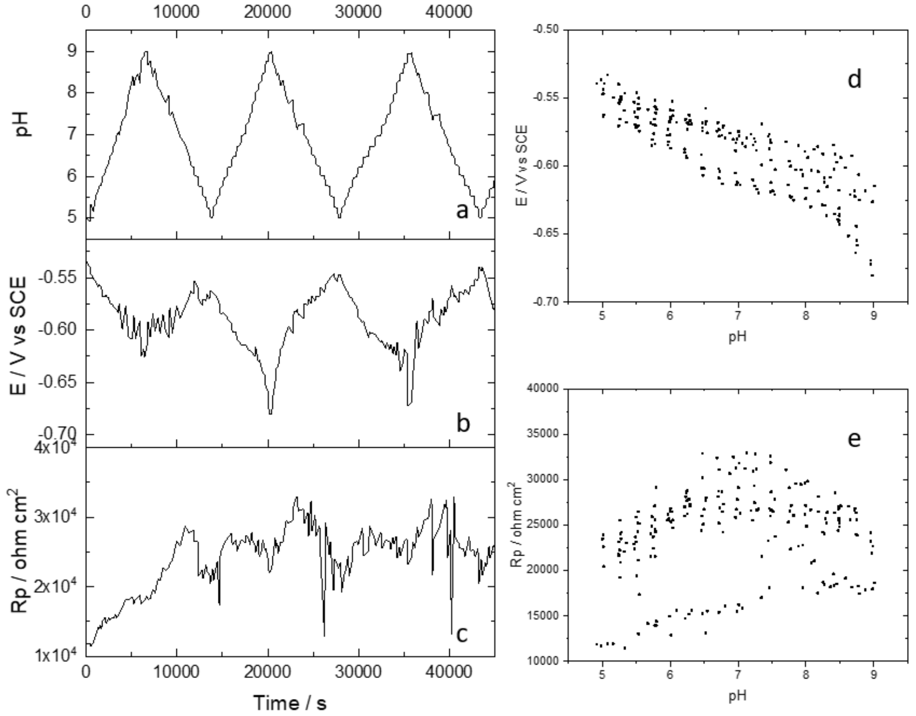

Figure 1: pH (a), corrosion potential (b) and polarization resistance (c) as a function of time for an AA2024T3 specimen immersed in 3.5 wt.% NaCl solution. For the same experiment, the corrosion potential (d) and the polarization resistance (e) as a function of the solution pH.

Influence of Micrometric Inter-electrode Distances and Water Hardness on Mineral Scaling at the Electrode Surface during Electrochemical Advanced Oxidation Process

Faidzul Hakim ADNAN, Emmanuel MOUSSET, Marie-Noëlle PONS
Laboratoire Réactions et Génie des Procédés, Université de Lorraine, CNRS, LRGP, F-54000 Nancy, France
emmanuel.mousset@univ-lorraine.fr

In electrolytic water treatment, scaling or deposit is an inevitable challenge and it normally ends up in capital loss due to technical issues. When the electrode is polarized at a sufficiently negative potential, dissolved oxygen and water are reduced to hydroxyl ions [1, 2]. These two phenomena result in an increase of local pH at the vicinity of electrode. In presence of Mg^{2+} and Ca^{2+}, hydroxide scales can potentially be produced. On another side, this pH increment also shifts the thermodynamic ratio of carbonates/bicarbonates favoring the production of carbonate scales [3-5]. Several authors have reported the formation of scaling in an electrochemical setup while working with different hard water coming from multiple sources: cooling water used in industries [9, 10], artificial underground water [11], artificial [4] and real seawater [12]. Due to abundant resources capable of restricting the application of electrolysis, meticulous study to comprehend and to avoid the formation of deposits seems primordial.

The influence of reactor design on mineral scaling was investigated in this study by considering a microfluidic thin-layer cell in micrometric range compared to electrolyzer with inter-electrodes distance in centimeter range [6, 7]. Short distances have shown to enhance mass transfer within the cell and it overcomes the barrier of working with low ionic conductivity electrolyte [8]. $Mg(OH)_2$ and $CaCO_3$ deposits were selected in this work, as they are the main scales encountered in the field. The objective was to establish optimal operating conditions of microfluidic electrochemical cell in-which the scaling does not occur for all-type of hard waters. The results present here-in are the first to report on the scaling in microfluidic thin-layer cell. Its configuration is distinct as compared to that found in the literature where rotating disk electrode was used as working electrode. In particular, its electrode surface area is 25 to 250 times bigger relatively to the rotating disk electrodes (0.2 to 2 cm^2). The electrochemical cell is hence more representative to reactors used on a larger scale.

The applicable current density range was larger with thin films in comparison to centimetric inter-electrode distances to prevent scaling formation, which could enlarge the applications of micro-reactors. Coupling the experimental results with voltammetry and impedance spectroscopy allowed depicting the mechanism of nucleation and scaling. Mathematical models were fitted to the experimental results to validate scientific approach notably on the effect of applied current density, inter-electrode distances and matrix of electrolyte.

Recent Advances on Wearable Platforms for On-body Analysis Using Membrane-Based Sensors

Gaston A. Crespo
KTH Royal Institute of Technology, Department of Chemistry, Teknikringen 30, 100 44, Stockholm, Sweden
gacp@kth.se

Recent investigations of wearable electrochemical sensing have largely focused on development of flexible materials and electronics using traditional electrochemical sensing principles (i.e., potentiometry and amperometry) without genuine innovation of the chemical design, interrogation and readout parts. This has limited the true digital transformation of this fascinating concept because those devices do not meet the minimum requirements for healthcare purposes, such as being calibration-free, having strict validation and correlation, robustness during on-body measurements, cytotoxicity assessment and analytical reliability, among others.[1] In this talk, recent advances that include the analytical development and evaluation of the sensing part of wearable electrochemical sensors for on-body monitoring of certain physiological parameters will be discussed. Importantly, the selected wearable devices exclusively contain membrane-based sensors and are classified in two types of platforms: (i) epidermal patches for the analysis of ions and biomolecules in sweat encompassing perspiration during sport practice; and (ii) (micro)needle-based platforms for the intradermal determination of ions and biomolecules with clinical purposes.

The engineering of epidermal patches for real time characterization of sweat has required special attention in the design and fabrication of appropriate microfluidic system allowing for the creation of a safe path or the sweat coming from the eccrine glands towards the electrodes' surfaces, with no contamination or evaporation risk while providing a passive sweat pump encompassed to the sweat rate in the individual.[2] Having achieved that, the most crucial issue is to demonstrate the analytical reliability of on-body measurements through a meticulous and reliable validation strategy. This implies the accomplishment of a protocol based on sweat sampling and its analysis using a standard analytical technique that has been recently suggested by our research group, for example ion chromatography for ions but also for glucose and lactate. Specifically, it has been demonstrated that on-body measurements in sweat involving enzyme-based sensors require for pH and T correction towards more accurate outcomes. On the other hand, of special interest is the case of lactate detection, since particular efforts are needed in the electrode design to reach the required levels expected in sweat (ca. from 1 to 25 mM). Several strategies will be inspected in the talk.

Intradermal analysis using membrane-based sensors has additional handicaps related to the biocompatibility of the tailored electrodes as well as physicochemical resistance to skin penetration. The platform used per excellence to reach the desired level of penetration is (micro)needles that are adequately modified to sense different targets. Different sizes and designs would in principle allow for the availability of interstitial fluid, blood and intramuscular measurements. However, up to date, only in vitro tests have been presented in the literature.[3, 4] In our research group, we are working in one step further in terms of validation strategy, in vitro simulation of skin penetration and field experiments in mice based on *post mortem* measurements. In particular, recent advances on the monitoring of scaffolds degradation my measuring pH and lactate by means of new (micro)needle-based devices will be presented.

The Role of Poly(3-octylthiophene) as Redox Mediator of Ion Fluxes Across Voltammetric Thin Membranes

María Cuartero, Yujie Liu and Gaston Crespo
KTH Royal Institute of Technology, Department of Chemistry, Teknikringen 30, 100 44, Stockholm, Sweden
mariacb@kth.se

Previous publications have demonstrated the effective tuning of ion-transfer processes across ion-selective membranes formulated with a thickness in the nanometer order by modulating the oxidation state of a film of poly (3-octylthiophene) –POT– that is in backside contact.[1, 2] The beauty of the concept is based on the connection of the charge transfer (CT) process occurring in the POT lattice with any ion-transfer (IT) process at the sample–membrane interface, being framed by the application of a linear sweep potential rather than the typical measurements with ion-selective membranes at zero current (i.e., traditional potentiometry). Several attempts on the theoretical description of this CT-IT system considered the Nernst equation for the description of the POT oxidation process, providing a sigmoid-shaped curve for the CT.[3, 4] Besides some theoretical assumptions, to the best of our knowledge, there is no experimental evidences confirming this behavior of the CT whether this process comes coupled to IT process(es) of different nature. In this talk, a new strategy for the experimental characterization of the CT process in POT films involved in different CT-IT systems is presented. For this purpose, we take advantage of the absorbance change in the POT film while being oxidized to monitor the CT process linked to non-assisted and assisted IT at the sample–membrane interface. Thus, spectroelectrochemistry is used as the readout of ITO-based electrodes modified with a double layer design comprising POT and the ion-selective membrane. In particular, the concept is demonstrated for membranes containing one (potassium), two (lithium and potassium), and three (lithium, sodium and potassium) ionophores, thus promoting a change in the nature and number of the IT processes.

The CT visualizes as independent sigmoid appearing at different potential ranges according to the assigned IT process. Advantageously, it is here proposed an easy calculation of both CT (dynamic absorbance versus applied potential) and IT (coulovoltagram) based on the Sigmoidal–Boltzmann model. Both experimental and theoretical definition of the role of POT as redox mediator of ion fluxes across voltammetric thin membranes open up new possibilities for the further design of sensors with superior analytical features, mainly in terms of improved selectivity because of the independency of CT according to different IT occurring in the electrode. In addition, the Sigmoidal–Boltzmann model may allow for the calculation of ion-ionophore binding constants in the membrane using an easy relationship between the peak potentials corresponding to non-assisted and assisted ITs.

In addition, the linear correlation found with the concentration of the cation(s) analyte(s) in the sample solution on the basis of the newly proposed spectroelectrochemical experiments deserves special attention towards further analytical purposes. A deep optimization of membrane thickness, scan rate in the applied linear sweep potential as well as frequency acquisition (and resolution) of the optical measurements will contribute to a fine tuning of the obtained linearity. The tandem light-electrochemistry has demonstrated a series of unique fundamental but also analytical applications that are inaccessible with other techniques: mechanistic studies, analytical electrochromic devices, protein-related investigations and analytical sensors among others. In particular, the electrodes herein developed based on nanometer-sized membranes in backside contact with POT present a high potential towards real-time extracellular measurements of different ions used to stimulate the cells in conjunction to light, undoubtedly offering new horizons in this field.

Due to the continuous combustion of fossil fuels into the atmosphere, an historical high point was reached in 2015 when CO_2 emissions exceeded the threshold of 400ppm. It is broadly known that the excessive emission of CO_2 has a negative impact on the environment. It is therefore of utmost importance that the CO_2 concentration is inhibited by reducing the combustion of CO_2 into the atmosphere in order to mitigate the effect on global warming. In this context, CO_2, as a feedstock, represents a great alternative for the synthesis of fuels and valuable chemicals. Utilizing renewable energy sources as the required energy supply to convert this CO_2 into value added products has the additional advantage that the process is CO_2 neutral. Since renewable energy displays the fastest growth of all this implies new challenges concerning production-consumption profile matching for which the electrochemical conversion of CO_2 offers a solution [1]. Electrochemical conversion of CO_2 is one of the most promising routes because of the ability to tune the product selectivity by adapting the operating potential and catalyst material [2].

In this research, CuAg core-shell nanoparticles are used as electrocatalysts to convert CO_2 in CO. As broadly known, by combining metals with certain arrangements, energetic effects lead to the ability to tune the product selectivity. In case of CuAg core-shells nanoparticles, the product selectivity is tuned towards CO because of the change in adsorption of CO_2 on the catalyst surface. By reducing the size of the CuAg core-shells, more electrochemical active surface area (EASA) is obtained using significantly less material, making the total process less expensive.

The gap in current research is the knowledge on ideal shell thickness to convert CO_2 into CO. Here, we gained novel insights into the influence of the shell thickness on the electrochemical reduction of CO_2. The CuAg core-shell nanoparticles where synthesized through a colloidal method succeeded by galvanic displacement of Ag with Cu [3]. The shell thickness was varied by using different Ag concentrations and displacement times. The activity of these electrocatalysts was firstly studied in an in-house designed H-type cell with an aqueous solution of $KHCO_3$ saturated with CO_2. The activity was screened with cyclic voltammetry to compare the onset potential of the different core-shells. Further information on the selectivity was gained by analyzing the materials in an in-house designed electrolyzer. Chrono-amperometry experiments were performed, gaseous products were analyzed with an in-line gas chromatograph (GC) and the liquid products with a HPCL. Finally the core-shell structures were investigated by TEM, to understand the link between the structure, the activity and the selectivity.

Hydrogen Generation Derived from Water Dissociation (24)

Kenji SAKAMAKI and Ryusei OOTOMO

Chemistry Course, Department of Applied Chemistry and Biochemistry, Fukushima College,
National Institute of Technology, Fukushima 980-8034, Japan
sakenji@fukushima-nct.ac.jp

We created a two-compartment cell (2CC) separated by a bipolar membrane (BPM[1]) sandwiched between a through-holed (TH) electrode assembly (BPMTHEA-2CC) with the distinguishing feature of integrated functionality of dualities based on the Golden Rule for sustainable water splitting derived from water dissociation (WD) with a dual chemical bias (CB).[2,3] A decisive advantage of this system is that all electrolytes used are sustainable because the reaction starts from WD. The opposite bidirectional charge separation of H^+ and OH^- ions derived from WD generates inner CB within BPM. Many anolyte–catholyte combinations are possible in BPMTHEA-2CC, which induces outer CB (OCB). Therefore, dual CB reduces overall water electrolysis voltage. We present here supporting proof of our concept.

We have achieved hydrogen generation derived from WD with BPMTHEA-2CC using an oxygen evolving reaction active TH dimensionally stable anode (De Nora Permelec Ltd) prepared on Pt gauze. Liberated gas was analyzed using a gas chromatograph (GC-390B, GL Sciences) equipped with a stainless-1/8”x3m MS-5A 30/60 column and a thermal conductive detector (TCD). We succeeded in detecting appropriate amounts of molecular hydrogen generated in the cathodic compartment of BPMTHEA-2CC, anolyte (water)|TH anode|BPM|TH cathode|catholyte (water), by imposing a voltage with less than the theoretical 1.23 V for water splitting at room temperature.

jean-marc.noel@univ-paris-diderot.fr

Oxidations are an important class of reactions in the chemical industry for the production of huge quantities of intermediate and final products. In the current economic and environmental context the ideal oxidant is O_2 as it is abundant and benign. The use of Fe porphyrins (Figure 1A) is an interesting biomimetic approach for O_2 activation as Fe^{II} can reproduce the metabolic transformation catalyzed by Fe enzymes such as CytP450 [1]. The optimization and control of the O_2 activation process requires a complete understanding of the mechanism and the identification of intermediates involved. Some of these intermediates being very reactive, their lifetime are very short making them difficult to detect experimentally. Thus there is a need to develop *operando* methodologies to probe them at the earlier stage of their formation directly in reaction layers.

The scanning electrochemical microscope (SECM) is a perfect tool to capture, quantify and characterize short-lived intermediates, including in complex molecular homogeneous catalytic systems [2,3].

Herein we propose to use the SECM in generation-collection mode to quantitatively analyze O_2 reductive activation in organic media catalyzed by three different Fe porphyrins as illustrated in Figure 1. We particularly focus on the first intermediate produced in non-acidic medium, the (peroxo) intermediate $Fe^{III}(OO^{2-})$ adduct issued from the reduction of a (superoxo) $Fe^{III}(OO^{\bullet -})$ formed from the binding between O_2 and Fe^{II}).

In one single SECM experiment new thermodynamic and kinetic parameters such as the redox potential of the intermediate, the association constant of Fe^{II} with O_2 and the pKa of the $Fe^{III}(OOH^-)$/ $Fe^{III}(OO^{2-})$ couple can be obtained and related to earlier DFT calculations [4]. Such information, obtained in the absence of H^+, are then related to the efficiency of these catalysts for O_2 reduction in the presence of H^+. The results obtained can contribute to a further understanding of the parameters controlling the catalytic efficiency of the Fe porphyrin towards O_2 activation and reduction.

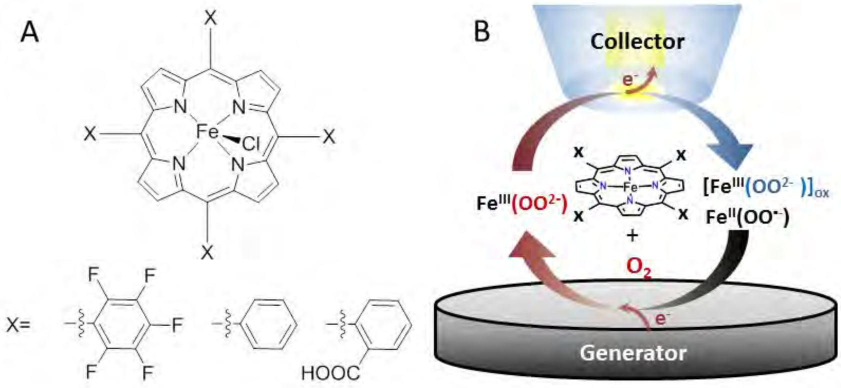

Figure 1: A) structure of the porphyrins complexes used. B) Principle of the SECM experiments

In Situ Raman Study of Interfacial Water Structure at Pd Single-Crystal Surface

Yao-Hui Wang,[1] Shi-Sheng Zheng,[2] Feng Pan,[2] Jian-Feng Li[1],*
[1] *College of Chemistry and Chemical Engineering, Xiamen University, China*
[2] *School of Advanced Materials, Peking University, Shenzhen Graduate School, China*
Li@xmu.edu.cn

Water molecules are essential component of the electrochemical double layer (EDL) during electrochemical reaction process. The discharge processes of water molecules or hydrated proton are the initiation of the classical hydrogen evolution reaction (HER). Thus, the structure and composition of interfacial water molecules directly affect the HER process. Pd has excellent HER performance. The study of interfacial water molecules of Pd single-crystal surface is of great significance for understanding the HER process. However, the perception of water molecules during the HER process at Pd single-crystal surface has been still elusive due to the complex interfacial environment, such as various water orientations, hydrated ions, and hydrogen bonds network in water molecules [1].

Herein, using electrochemical in situ shell-isolated nanoparticle-enhance Raman spectroscopy (SHINERS) [2] and ab initio molecular dynamics (AIMD), we systemically investigated the structure and composition of water molecules from interfacial solution phase and electrode phase during the HER process. It was found that the interfacial water is mainly composed of water of trihedrally and tetrahedrally coordinated water and Na^+ hydrated water ($Na.H_2O$) at Pd surface. The structure and composition of interfacial water dynamically changes and forms an ordered structure as HER progress. Meanwhile, we studied interfacial solution phase (ion concentration and types) for the influence of interfacial water and HER. We found that the population of $Na.H_2O$ in high concentration electrolyte is the highest in interfacial water molecules, while the HER also shows a better performance in the same condition. Thus, according to the increased population of $Na.H_2O$ in high concentration electrolyte, the ordered $Na.H_2O$ plays a key role during HER process.

To understand the role of ordered $Na.H_2O$ during HER, we further investigated the electrode phase (crystallographic orientation and electronic structure) for the influence of interfacial water and HER, Pd (111) shows the best HER performance and the highest population of $Na.H_2O$ in three low-index Pd (hkl) single-crystals. Therefore, we believe that $Na.H_2O$ is more conducive to water dissociation during HER process. The ordered interfacial water structure could accelerate the efficiency of electron transfer. Theoretical calculations also show that $Na.H_2O$ is more susceptible to dissociate HO-H bond than trihedrally and tetrahedrally coordinated water at electrode surface during HER process. We propose a new structure-relationship between the interfacial water and HER, which could help to understand the nature of electrocatalysis.

Bipolar electrochemistry has gained remarkable interest in recent years as a powerful technology for the modification of conductive objects and for the electrochemical synthesis of novel functional materials in a wireless mode[1],[2]. In fact, differently to conventional electrochemistry, bipolar electrochemistry offers the extraordinary advantage to perform electrochemical reactions at both extremities of a wireless electrode, or bipolar electrode (BPE), through the application of an external electric field generated in a low concentration of a supporting electrolyte.

Bipolar systems, which are generally composed of an electrochemical cell and a pair of driving electrodes, can be designed with different geometries and configurations, in order to achieve the electrosynthesis of functional materials with desired morphologies and characteristics. For example, bipolar electrolysis using a cylindrical insulator enabled the perpendicular growth of a uniform conducting polymer array[3], or the electrochemical fluorination of triphenylmethane was performed in a U-shaped electrochemical cell employing a split BPE system[4]. Nevertheless, the distribution of potential gradient in these bipolar systems is dynamic and gradually changing and its direct monitoring is hampered due to the wireless nature of the BPE. The possibility to obtain a direct indication of the potential distribution would have tremendous impact on the application and further development of original bipolar systems.

In the present contribution, we explore the use of Electrogenerated Chemiluminescence (ECL) to visualize the distribution of potential gradient at the level of a BPE in such bipolar systems. The ECL technology represents the ideal approach due to the electrochemical nature of light emission. In fact, ECL involves the generation of photons at the electrode surface triggered by an electrochemical stimulus and, nowadays, it is widely employed as a highly sensitive imaging technique[5]. Our method exploits the use of a mixture of different chromophores in solution that, in presence of a coreactant species and upon application of anodic potentials at the BPE, can be simultaneously electro-oxidized generating mixed ECL emissions at different wavelengths. Since every luminophore is characterized by a specific oxidation potential and a typical wavelength for ECL generation, the mixed ECL emission can be resolved and associated to the correspondent single emitting species and, hence, to the correspondent oxidation potential. This approach permits to map the distribution of potential gradient in a specific bipolar cell, and can be applied to any other bipolar system in general.

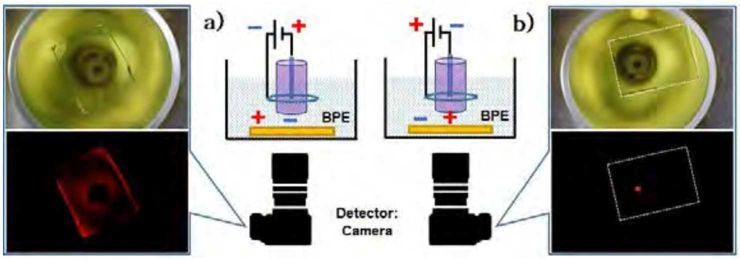

Figure 1: ECL emission of $Ru(bpy)_3(PF_6)_2$ 0.05 mM / TPrA 10 mM system in acetonitrile solution at BPE in cylinder configuration with different polarities: a) cathodic area under the cylinder and b) anodic area under the cylinder.

Alloying Ni with another highly corrosion-resistant component leading to strengthening is a field of interest in plating industry. Alloying Ni with oxoanion-forming metals such as Mo, W and Re is possible from citrate-type baths with the so-called induced codeposition mechanism. In this work, electrodeposition was performed from a solution of small citrate content (citrate/Ni^{2+} ratio: 0.5) with no volatile component (like NH_3). The concentration of Na_2MoO_4 in the bath was the varying parameter. The highest deposition efficiency, $\eta \approx 0.94$, was found for pH = 6.1, regardless of the current density applied. Both the increase in the molibdate concentration and the decrease in current density resulted in the increase of the Mo mole fraction in the deposit. Saccharine as stress reliever was found to be beneficial for the deposition of crack-free samples.

X-ray diffraction full line profile analysis was carried out to study the microstructural parameters such as the crystallite size, the dislocation density and the stacking fault probability. The increase in the Mo content up to 5.3 at.% led to one order of magnitude enhancement of the dislocation density while the crystallite size reduction was less significant. In addition, the twin boundary formation activity during deposition increased with increasing Mo concentration. The results obtained were compared with bulk nanocrystalline Ni-Mo materials with similar compositions but processed by severe plastic deformation. It was found that the microstructure in electrodeposited Ni layers is more sensitive to the Mo concentration than bulk ultrafine-grained Ni-Mo materials processed by severe plastic deformation.

Differential scanning calorimetry (DSC) experiments were performed on the Ni films deposited with and without Mo to study the thermal stability of the deposits. It was revealed that the increase of the Mo mole fraction in the deposit significantly improved the thermal stability of the nanocrystalline microstructure in Ni layers, despite the much higher defect density and smaller grain size which act as thermodynamic driving force for recovery and recrystallization. The better thermal stability can be attributed to the pinning effect of Mo solute atoms on the lattice defects (e.g., dislocations and grain boundaries) during annealing. The comparison of thermal relaxation processes of the electrodeposited samples and those obtained with severe plastic deformation (SPD) revealed that the annihilation of the structural faults takes place at the same rate as referred to the original defect density of the specific samples, although the defect densities were distinctively different for samples obtained with the two procedures.

The energy stored in the crystallographic defects in the nanocrystalline Ni-Mo alloy films was also determined from the DSC experiments. It was revealed that the majority of the heat released during DSC (~77%) was related to the grain boundaries. It was also found that the increase of Mo content from 0.4 to 5.3 at.% yielded an enhancement of the stored energy with a factor of about two. In the SPD-processed samples, there was a considerable contribution of vacancies to stored energy while their effect in the electrodeposited layers was lower.

The structural changes as a result to the increase in the Mo mole fraction to 5.3 at.% caused a fourfold increase in the yield strength for the latter sample. The Ni film with low (0.4 at.%) Mo concentration showed a normal strain hardening while the sample having high Mo content exhibited a continuous softening after a short hardening period. The strain softening was attributed to detwinning during deformation.

Studying Water Reactivity at Electrochemical Interfaces by Nanoconfinement Strategies

Alexis Grimaud
Chimie du Solide et de l'Energie, Collège de France, UMR8260
75213 Paris Cedex 05, France
alexis.grimaud@college-de-france.fr

Understanding and controlling water reactivity at electrochemical interfaces is pivotal for the development of electrochemical energy storage and conversion devices such as water electrolyzers or aqueous batteries, among other systems. However, it is a rather challenging task owing to the ambivalent role played by water as both solvent and reactant, which often masks reactive water molecules at interfaces in their surroundings. Unfortunately, only few techniques can be used to determine the water structure (density, orientation etc.) in the first molecular layers at electrochemical interfaces. Among them, operando spectroscopies were employed. While powerful, they are often limited by their spatial resolution and generally require the use of model electrodes. Similarly, computational chemistry approaches prove very powerful but suffer from the large computing cost of including explicit solvent molecules as well as taking into account charge transfer.

Unlike for electrochemical systems, assessing the ability for water to interact with itself or its environment has always been pivotal to understand nature phenomena such as the folding of proteins, the winding of DNA or the complex organization of lipids into sheets. Strategies were thus developed to isolate water molecules in specific environments and study their behavior/reactivity. In this work, we demonstrate a strategy consisting in confining water molecules inside an organic liquid matrix in order to form aqueous nano-domains. Varying the concentration of water and/or supporting salt, we further demonstrate that the size of the aqueous domains can be tuned and found that the reactivity of these domains at electrified interfaces depends on their size and chemical composition. In definitive, we show that complementary to the develop of spectroscopic tools capable of probing at the nanoscale active sites and their environment, another promising complementary approach relying on the control at nanoscale of the reactant itself, e.g. water, can be taken. Doing so, strength of short- and long-range interactions can be selectively studied, which can then be used to develop more efficient and selective electrocatalysts for water, CO_2, O_2 or N_2 reduction.

Molecular-level Analysis of Catalytic Activities of Electrode Surface for Electrochemical Deposition Reactions using Theoretical Calculations and Surface Enhanced Raman Microscopy with Plasmonic Sensors

Takayuki Homma[1,2], Masahiro Kunimoto[1], Morten Bertz[2], Masahiro Yanagisawa[2]
[1] Department of Applied Chemistry, Waseda Univ., Shinjuku, Tokyo 169-8555, Japan
[2] Nano Technology Research Center, Waseda Univ., Shinjuku, Tokyo 162-0041, Japan
t.homma@waseda.jp

Electrochemical deposition reactions have been widely utilized to prepare functional surfaces with controlled micro/nano structures featuring their precise controllability. In order to establish the methodology to achieve further higher performance and precise control, molecular-level understanding of the reaction mechanisms is required. For this, we attempted to apply theoretical calculation such as density functional theory (DFT) as well as surface enhanced Raman microscopy equipped with plasmonic sensors. In this work, we will describe these approaches with some of resent results. By using DFT calculations, we investigated the catalytic activity of the electrode surfaces for the reaction of reductants for electroless deposition processes, including the behavior of their intermediate species, the interaction with additive species, as well as solvation effects. While the DFT analysis provides quantitative insights for the origin of the catalytic activity of the electrode surfaces and the reaction mechanisms, obtaining these data from experimental approach is challenging. In order to overcome this, we applied surface enhanced Raman scattering (SERS) equipped with confocal microscopy and developed plasmonic sensors with controlled nanostructures to achieve very high signal enhancement. For the plasmonic sensors, we developed “reflection” type and “transmission” type sensors, which could achieve very high sensitivity analysis[1]. Furthermore multi-confocal type SERS microscopy was employed for mapping and imaging analyses of the electrode surface as well as local pH distributions. By using these techniques, various systems have been investigated and modelling of their reaction processes has been carried out.

This work was financially supported in part by “Development of Systems and Technology for Advanced Measurement and Analysis,” Japan Science and Technology Agency, and Grant-in-Aid for Scientific Research, MEXT, Japan.

Recently, redox-active Prussian blue analogs (PB) have gained attention to be promising water-oxidation electrocatalysts integrated with semiconductor absorbers for photoelectrochemical (PEC) water splitting, due to high catalytic activity, low cost and facile fabrication.[1-3] Especially, CoFe-Prussian blue analog (CoFePB) performs exceptional stability in acid media.[4] In previous work from our group, Si photoanodes based on the metal-insulator-semiconductor (MIS) junction were modified with NiFe-Prussian blue analog (NiFePB) by electrodissoluting homogeneous Si/SiO_x/Ni photoanode. This modification transformed homogeneous to inhomogeneous Si/SiO_x/Ni MIS junctions, and led to considerable photovoltage (V_{oc}) enhancement.[5] Furthermore, these modified Si photoanodes exhibited a pronounced electroactivity for oxygen evolution reaction (OER) and urea oxidation reaction (UOR).
In this presentation, with the aim of extending the knowledge on the photoelectrochemical properties of these inorganic systems, we introduce the modification of CoFePB and NiRu-Prussian blue analog (NiRuPB) on homogeneous Si/SiO_x/Co and Si/SiO_x/Ni MIS electrodes, respectively. CoFePB was deposited by chemically etching Co layer, meanwhile NiRuPB was introduced by electrodissolution of the Ni layer in the presence of the metal cyanide salts. The electrochemical properties of two systems were studied, which unveiled clearly-defined and distinct electrochemical responses. Interestingly, the V_{oc} of *n*-Si/SiO_x/Ni/NiRuPB were significantly improved from ~200 to >350 mV with an increasing modification time. Conversely, *n*-Si/SiO_x/Co/CoFePB ones were found to be independent on modification (~230 mV). We do think that these surprising distinct behaviors are indicative of a different morphology of the MIS junction, that was investigated by atomic force microscopy and scanning electron microscopy. Additionally, the NiRuPB-modified Si photoanode with the optimal V_{oc} was employed for solar-driven OER and UOR, exhibiting a remarked photocurrent density of 8.3 and 17.5 mA cm^{-2} at 1.23 V vs RHE, respectively. This finding demonstrates that our surface modification could bring a new strategy to develop low-cost solar hydrogen technology.

Boron Nitride Nanosheet as Novel Electrocatalysts for Oxygen Reduction Reaction and Hydrogen Evolution Reaction
- Combination with Inert Substrates and Metal Nanoparticles -

Kohei Uosaki
National Institute for Materials Science
Tsukuba, Japan
Uosaki.kohei@nims.go.jp

Electrochemical energy conversion plays central roles in the future sustainable society based on renewable energy. For example, hydrogen, one of the most important carriers, is produced by electrolysis of water and is converted back to electricity by hydrogen - oxygen fuel cell. Electrochemical hydrogen evolution reaction (HER)/oxygen evolution reaction (OER) and hydrogen oxidation reaction (HOR)/oxygen reduction reaction (ORR) are elemental processes in water electrolysis and hydrogen - oxygen fuel cell, respectively. The rates of these reactions are strongly dependent on electrode materials, i.e., electrocatalyst [1], which are the key to improve the efficiencies of electrochemical energy conversion processes.

Large overpotential for ORR is one of the most serious problems in the development of fuel cells. Although Pt group metals are the most efficient electrocatalysts, world-wide efforts have been made to find alternative catalysts because of their high cost, less abundance, poor stability, and still sluggish kinetics.

We proposed theoretically [2-5] that boron nitride, which has similar geometric structure to that of graphite but is an insulator with a wide band gap (˜5.8eV) and, therefore, is not considered as an electrocatalytic material, may act as an efficient electrocatalyst for ORR when it has defects or is placed on inert metal gold substrate such as Ni. Electrocatalytic activity for ORR of BN placed on gold substrate, which is inert for ORR with 2-electron process and high overpotential, is experimentally proved, although ORR still proceeds by 2-electron process [5, 6]. Among various types of BN, BN nanosheet (BNNS) shows highest activity. By decorating BNNS by gold nanoparticles (AuNPs: 5 ~ 30 nm), 4-electron ORR route to water is open, although only ca. 50% of oxygen is reduced to water [7]. Theoretical free energy analysis shows that 4-electron reduction becomes possible because small Au clusters drastically stabilize adsorbed O by 1.6 eV, making the dissociation of adsorbed OOH, which is an uphill process at BNNS/Au electrode, downhill. Considering the importance of BN/Au interface, one would expect further improvement of electrocatalytic activity for ORR by using smaller AuNPs for decoration. It is found that not only the overpotential is reduced further by 100-120 mV and is only 100 mV more than that at a Pt electrode but also more than 80% of oxygen is reduced to water at the Au electrode modified by BNNS decorated with AuNPs of small size (ca. 5 nm) with narrow size distribution [8].

We also found that BNNS/Au is a good electrocatalyst for HER [9]. DFT calculation suggests that the origin of small overpotential is the existence of energetically favored sites at BN edge for adsorbed hydrogen, i.e., intermediate state, and further improvement of electrocatalytic activity for HER by increasing the fraction of atoms at the edges of BNNS on Au substrate, which can be achieved by decreasing the size of each BNNS at a given amount of BNNS on the surface. Actually, it is proved that the smaller the BNNS size, the lower the HER overpotential [9]. AuNPs modification is effective for the reduction of HER overpotential [10]. Amounts of Au can be reduced by using nanoparticles of Au alloys by other metals such as Ni, Cu, and Co [10].

Novel Non-Liquid Electrolytes for EIS Characterization of Surface Layers on Heritage and Art Objects

Ivana Šoić, Sanja Martinez
University of Zagreb, Faculty of Chemical Engineering and Technology
Marulićev trg 19, HR-10000 Zagreb
smartin@fkit.hr

Electrochemical Impedance Spectroscopy (EIS) is being successfully applied by the conservation scientists [1] to rate the efficiency of protection offered by thermoplastic resins, clear lacquers or thin layers of wax, to the surface of heritage and art objects. Passive layers on stainless steel, rust layers on Corten steel and iron as well as patinas on copper and bronze are being probed by EIS. For such objects, application of non-liquid electrolytes was proven to be of special interest as it enables direct measurements on flat or curved surfaces and easy transfer of EIS from the laboratory into the field. Damaging of the metallic surface is the primary concern of any intervention on valuable metallic pieces, including the corrosion related measurements. Although EIS is known to be a non-destructive method, it still needs to meet high standards that tolerate no alteration of surface appearance at the place of EIS cell contact [2]. Additionally, EIS cell electrolyte should have a low enough conductivity not to interfere with the surface layer impedance that may approach that of the bare metal. The non-liquid electrolyte should also retain constant surface area during the EIS measurement, should follow the object surface pores [3] and should be easily washed of leaving no traces. In the present study, we investigate EIS characteristics of various natural wax-based paste electrolytes and their performance in measuring impedances of protective layers on metallic substrates. Flexible conductive-polymer electrodes and the electrochemical setup that has been described in our recent paper [4], were used for performing EIS measurements. Impedance spectra were measured in a broad frequency range from 10^5 to 10^{-2} Hz. Additionally, measurements on samples were repeated five times at a single frequency of 0.1 Hz, and the arithmetic mean, that varied between $k\Omega\ cm^{-2}$ and $100\ G\Omega\ cm^{-2}$, was taken as indicative of the degree of protection [5]. Surface layers of high impedance have been successfully probed by all the investigated electrolytes. Interference of electrolyte spectra with the sample spectra was seen for some electrolyte formulations on low impedance samples. The interference was visible at low frequencies and manifested itself as an increase in impedance modulus and phase angle, due to the electrolyte. Some electrolytes, although being of low conductivity, were unable to follow the pores of the substrate yielding impedance overestimate of the few orders of magnitude. The results of the good electrolyte formulations were highly correlated to the measurements obtained in the solution, in a press-on cell. The investigation exemplifies the importance of the non-liquid electrolyte consistency and electrical characteristics on the success of the surface layer impedance measurements that uses flexible conductive-polymer electrodes and is easily applicable in the laboratory and the field.

Ion-selective sensor based on modified electrospun nanofibers – towards 2D sensing layers

Agata Michalska[1], Anna Baranowska-Korczyc[1], Ewa Jaworska[1], Marcin Strawski[1], Bohdan Paterczyk[2], Krzysztof Maksymiuk[1]
[1] Faculty of Chemistry, University of Warsaw, Pasteura 1, 02-093 Warsaw, Poland
[2] Laboratory of Electron and Confocal Microscopy, Faculty of Biology, University of Warsaw, Miecznikowa 1, 02-096 Warsaw, Poland
agatam@chem.uw.edu.pl

A challenge in ion-selective sensors is to reduce the ion-selective membrane thickness down to a few nanometers. Thus obtained ion-selective layers can in principle offer significant advantages both in respect to analytical parameters and applicability for current driven sensors.

We propose application of core-shell modified nanofibers mats as ultrathin ion-selective membranes for electrochemical and optical sensors[1]. Nanofibers mats are used as inert support for liquid ion-selective membrane. Thus obtained systems offer significant advantages compared to classical membranes. Due to application of nanofibers, keeping the overall macroscopic size of the recognition element as for classical plasticized poly(vinyl chloride) membranes, herein proposed systems resulted in ultrathin (< 10 nm) receptor layers with total area nearly 1000 times larger. The surface area to volume ratio of the proposed system is close to $7.5 \cdot 10^7$, making it first close to 2D potentiometric membrane. Formation of thin and continuous liquid film on nanofibers was confirmed by XPS studies. The nanofibers based ion-selective receptors used offer slope and detection limit well comparable with those for classical plasticized poly(vinyl chloride) based membranes sensors. Despite nanometric thickness of ion-selective layer, the reproducibility of recorded potentials, studied for more than 30 days, was high. Using confocal microscopy it was shown that electrolyte transport through porous nanofibers mat phase is the rate limiting step in conditioning. Estimated electrolyte diffusion coefficients for nanofibers phase are close to 10^{-10} cm^2/s, thus are orders of magnitude lower compared values characterizing ion transport through classical poly(vinyl chloride) bases membranes.

The truly nanostructural character of nanofibers based ion-selective receptors is visible in chronoamperometric experiments. It was shown that core-shell nanofibers mat behave as an array of nanoelectrodes – individual nanofibers. Thus, novel nanofibers based architecture of ion-selective receptor brings also new quality to current based electrochemistry of ion-selective sensors.

Teaching the Electrochemistry: Between Theory and Practice

Branimir N. Grgur
Faculty of Technology and Metallurgy, University of Belgrade
Karnegijeva 4, 11020 Belgrade Serbia
BNGrgur@tmf.bg.ac.rs

Electrochemistry is mainly experimental science with well-established theoretical background. Today many, usually younger, researchers presents and explained experimental results that are not theoretically correct. Some of the examples are mixing concentration and activity of the species in the solution, misunderstandings of the concept of the electrode potential and usage of different reference electrodes, reporting Tafel slope as high as 0.5 to 1 V dec^{-1}, determination of exchange or corrosion current densities by extrapolating slopes of the curve under mixed activation-diffusion to reversible or corrosion potentials, etc. To avoid such confusions strong connection of the electrochemical theory and experiments.

At the Faculty of Technology and Metallurgy, University of Belgrade electrochemistry has a long history. Through generations, program of the Electrochemistry course has been changed, and today is teaching with following main subjects: Equilibrium and non-equilibrium in the electrolyte solutions, Electrodics, Electrochemical kinetics and applied electrochemistry [1]. The concept of course is based on theoretical lectures followed by experimental work for each important subjects.

In this lecture will be presented the short theoretical background and corresponding laboratory exercises, under modest experimental conditions, of the main subject of the electrochemistry, like activity and activity coefficient, Faraday law, determination of the electrode potentials and their application, thermodynamics of the electrochemical cells, kinetics of some electrode reactions under activation, mixed and diffusion control, preparative electrochemistry and specific energy consumption, corrosion and electrochemical power sources.

"Electrodeposition + Pulling" Gel Probes for Local Electrodeposition by Scanning Gel Electrochemical Microscopy (SGECM)

Mariela Brites Helú, Liang Liu
Université de Lorraine, CNRS, Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l'Environnement (LCPME), F-54000 Nancy, France
mariela.brites-helu@univ-lorraine.fr

Electrochemistry is a powerful tool for locally modifying conductive surfaces by electrodeposition of etching. This is achieved through scanning electrochemical probe techniques, notably scanning electrochemical microscopy and scanning droplet cell. A recent development is to attach gel on the electrode probe and to do local electrochemistry at the interface between such gel probe and the sample (denoted as scanning gel electrochemical microscopy (SGECM)[1]). To achieve high spatial resolution, one need to sharpen the gel, which is inherently difficult due to its soft nature.

Inspired by cheese fondue, we take advantage of the thin meniscus formed while pulling a sharpened metal wire (for scanning tunneling microscopy) from a viscous chitosan precursor. At the same time, we apply cathodic potential on the metal wire to jellify chitosan based on well-known electrodeposition mechanism driven by pH modulation. This elegant "electrodeposition + pulling" approach, as illustrated in **Figure 1a**, combines electrodeposition with fluid mechanics offering sharp gel probes as shown in **Figure 1b**. The shape of the gel probes is rationally tuned by the electrodeposition and pulling parameters with good reproducibility, and the process is automated on a home-built setup as simple as pulling glass capillaries.

The sharp gel probes fabricated by "electrodeposition + pulling" are used for local electrodeposition and etching on a SGECM setup (**Figure 2a**). A model system is demonstrated, where Ag surface is oxidized to AgCl or etched by Cl^- or NO_3^- containing gel probes, respectively (**Figure 2b-c**). With the sharp gel, the lateral spatial resolution of local electrodeposition reaches *ca.* 1 µm. Moreover, due to the elasticity of the gel, one may also press or stretch the gel after contacting the sample, like writing or painting with an ink brush. That is to say, the resolution of each gel probe can be tuned in a range from a few to tens of microns. Since the gel probe immobilizes the electrolyte, it is also used for local electrochemical patterning on 3D-printed complex-shaped structures (**Figure 2d**), where the steps, steep planes and sharp edges are challenging for other techniques. Note that both the "electrodeposition + pulling" process and the local electrodeposition by SGECM are generic, with the possibility to play with the chemistry of the gel in future.

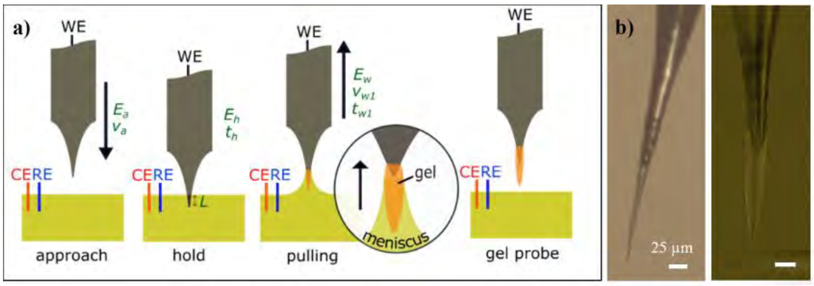

Figure 1. a) Scheme of "electrodeposition + pulling". **b)** Photos of gel probes.

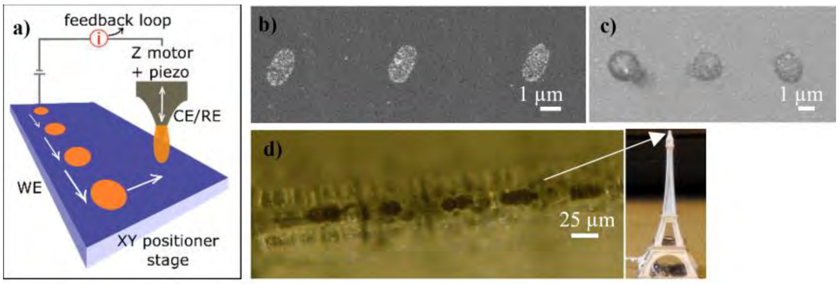

Figure 2. a) Scheme of SGECM for electrochemical patterning. **b)** Spots of AgCl on Ag plate. **c)** Etched holes on Ag-coated ITO. **d)** Dash line patterned at curved-side edge of 3D-printed Eiffel tower model.

Email: nicolas.plumere@rub.de

Widespread implementation of energy conversion devices cannot proceed without solutions that mitigate the cost of rare metal catalysts and the intrinsic O_2-instability of bio-inspired replacements. Recently, thick films of redox polymers were shown to prevent O_2 catalyst damage (1, 2), but also resulted in unnecessary catalyst load and mass transport limitations (3). Here, we apply novel methods for formation (4) and characterization (5) of homogeneous thin films that provide O_2-immunity while achieving highly efficient catalyst utilization (6). Resistance to O_2 inactivation can theoretically be obtained for non-limiting periods of time even when using highly fragile catalysts such as hydrogenases. Experimentally, the lifetimes of hydrogenases under constant aerobic turnover can reach up to one week at the condition that protection also targets reactive oxygen species (7). Different protection mechanisms operate depending on matrix dimensions and intrinsic catalyst properties, and can be integrated together synergistically to achieve large and stable H_2 oxidation currents in the presence of O_2, potentially enabling a plethora of practical applications for bio-inspired catalysts in harsh oxidative conditions.

Calcium, being the fifth most abundant metal on earth, combines high abundance with competitive volumetric capacity. As newer studies show promising results concerning electrochemical Ca plating/stripping (1-5), a combination with an oxygen cathode promises impressive theoretical energy densities. In literature some pioneering work on the Ca $-O_2$ system exists (6-8) but deeper fundamental research is necessary to get insights into the reaction mechanism of oxygen reduction reaction (ORR) and oxygen evolution reaction (OER).

In this study we are investigating the ORR and OER in Ca^{2+} containing system with various electrochemical and analytical methods. The product distribution of ORR products is investigated with differential electrochemical mass spectrometry (DEMS) and rotating ring disc electrode (RRDE) using Pt and Au as electrocatalysts. The main products are Ca-peroxide and Ca- superoxide. Both products are soluble in DMSO. A complete blocking of the electrode surface, as it is known from Li-O_2 literature, was not observed. Still the formation of superoxide in presence of the deposited film on the electrode is observed. Characterization of the ORR products was done via ex situ XPS measurements. There we could confirm calcium peroxide and calcium superoxide as ORR products. Another oxygen containing product seems to be calcium oxide, which is located close to the electrode (shown by Ar^+ etching and XPS). In the electrochemical experiments the electrocatalysts can fully be regenerated by applying higher electrode potentials as XPS studies showed. In addition the deposition of products on the electrode was investigated with EC-AFM.

On basis of the new findings the reaction mechanism of the ORR in Ca^{2+} containing DMSO will be discussed.

Does the most active nanocatalyst evolve the largest nanobubble?

Jean-François Lemineur, Paolo Ciocci, Jean-Marc Noël, Catherine Combellas, Frédéric Kanoufi
ITODYS, Université de Paris, CNRS UMR 7086
15 rue J.A. de Baïf, 75013 Paris, France
frederic.kanoufi@univ-paris-diderot.fr

The (photo)electrochemical generation/conversion of gases is drawing considerable interests as a sustainable solution for energy storage or conversion. Among them, the evolution of dihydrogen gas, HER, during water splitting is one of the most actively studied processes. While numerous efforts are produced towards the design of sustainable and efficient catalysts of HER, particularly employing nanoparticles, NPs, there is a need for the *operando* observation and quantification of the gas nanobubbles (NBs) formation involved in this reaction

Single-Entity Electrochemistry offers different toolboxes to reach the ultimate goal: a benchmarking study of the intrinsic electrocatalytic activity of NP materials. However it is often limited to the study of single nanoobjects without considering the whole process such as the near neighbors effect and is technically difficult to implement. To have a wide-field overview of the NBs formation process, we coupled electrochemistry and interferometric optical microscopy. Indeed optical microscopies can image various nano-objects *operando*, and under certain conditions, both individual catalytic NPs and gas NBs can be visualized. It allowed counting at high throughput the production of NBs and therefore addressing the nucleation rate of NBs on various supports and during HER [1-3]. However, very few examples have demonstrated a quantitative and dynamic sizing of these NBs [2]. We propose such quantification process for scattering-based, label free microscopy. It allows mapping at high throughput the local gas evolution rate (NB growth or dissolution) of an electrode.

The Figure below shows example images obtained by interferometric microscopy, correlated with SEM, of the growth of individual NB at individual 40nm Pt NPs. Besides analyzing the growth rate of individual NBs, the toolbox offered by super-localization and quantitative optical microscopy allows asking relevant questions for gas evolution catalysts: do the imaged Pt NPs where H_2 is evolving have the highest electrocatalytic activity? In other words, how to correlate a gas evolution rate map to a map of NP electrocatalytic activity?

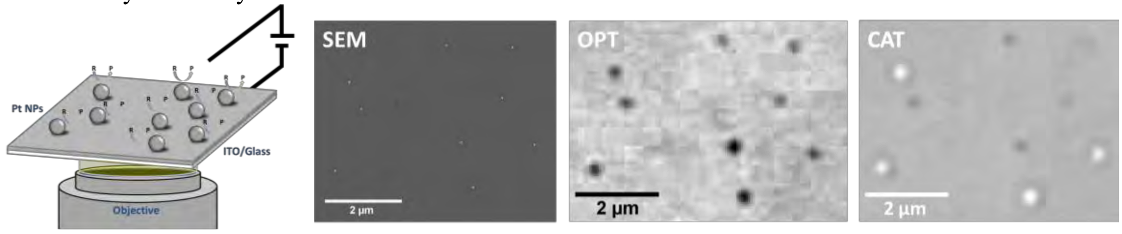

Figure: Optical monitoring of HER generation of NBs at Pt 40nm NPs. Nine single Pt NPs are imaged both by SEM and *operando* by interferometric optical microscopy before (OPT) or during (CAT) HER. The appearance of 4 bright features indicates that only 4 of the 9 NPs evolve single NBs.

Mining Nanopore Big Data to Reveal the Single Molecule Heterogeneity

Yi-Lun Ying, Xin-Yi Li, Hong-Yan Niu, Meng-Ying Li, Shao-Chuang Liu, Yi-Tao Long

The recent development of nanopore techniques pushes the envelope in precision and complexity to maximize the information content. Once a molecule is inside the nanopore, the signal due to the interaction of the molecule with the nanopore sensing interface is observed. Hence, the signals from individual analytes lead to an abundance of stochastic fluctuations in the shape, structure, conformation, position, and orientation of the molecule within the sensing interface.[1] These features permit single molecules to participate in unique noncovalent bonding interactions with the sensing interface of a nanopore, which in turn regulates the dynamic redistribution of ions along the sensing interface. Therefore, each ionic current response contains small ionic fluctuations, which offer continuous snapshots of the confined single molecule. After statistical time-domain analyses of duration, current amplitude, and occurrence of characteristic ionic current events as well as the frequency domain decomposition, differences in the features of single molecules, such as chemical properties, conformational changes, and charge distributions, could be detected.[2] The very beginning frequency analysis let us mine more information from the data, which could help to unravel different hierarchical pathways and enables to discovery the subpopulations and hidden kinetic during the dynamic motion of single molecules.[3-4] Together with the advanced data mining methods, we potentially show that nanopores are promising for identifying protein/peptide post-translational modification, and even decoding the sequential information.

Compositional Control of Electrodeposited Ag-Fe Films

Yunkai Sun, Giovanni Zangari,
Department of Materials Science and Engineering and CESE, University of Virginia
395 McCormick Rd, Charlottesville, VA, 22904, USA
gz3e@virginia.edu

Composition control in electrodeposited alloys is necessary to predict microstructure evolution, phase transformations and ultimately functionality. Some alloys however are intrinsically difficult to be electrodeposited, mainly due to the large difference in equilibrium potentials and/or widely differences in reduction kinetics of the alloy components; the Ag-Fe system is one of those. In this work, a novel alkaline citrate-dimethylhydantoin (DMH) Fe(II)-Ag(I) bath has been used to synthesize Ag-Fe alloy films with several predetermined composition.

Here we demonstrate the procedure for designing a novel metastable alkaline DMH-citrate Ag-Fe electrolyte, we compare the prediction of redox potentials from thermodynamic data with the observed CV profiles, and we rationalize the composition control by exploiting limiting current concepts. Stabilization of the deposition bath was achieved by utilizing the mixed potential theory through addition of 1% of Fe^{3+} to positively shift the redox potential of the redox couple Fe^{3+}/Fe^{2+}. Alloy compositions have been predicted by imposing limiting current ratios. Little deviations from these predictions were found, probably caused by the solution metastability.

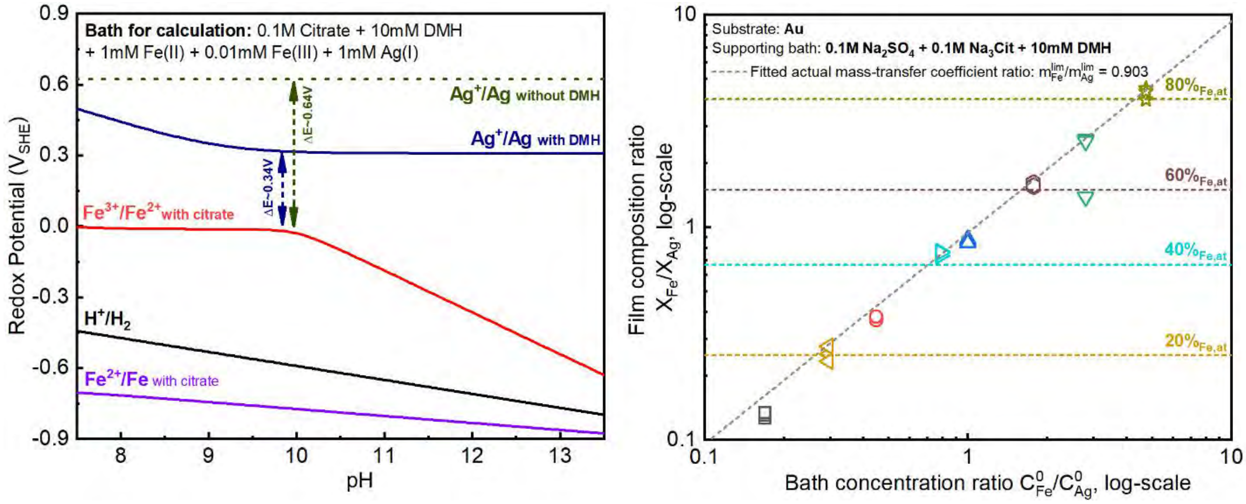

Figure 1: (a) Electrochemical equilibria calculations of the redox potentials related to the DMH-citrate complexed Ag-Fe electrolyte, based on the Nernst equation and thermodynamic data available, with the redox pair that influences the solution stability marked with arrows in the plot; (b) the stabilized bath exhibits a well-behaved linear trend between solution concentration ratio and film composition ratio.

Design of Effective Pulse Deposition Process for Functional Cr Coatings from Cr^{3+} Electrolyte

SRBrankovic@uh.edu

Our work investigates the pulse current deposition process for electrodeposition of functional Cr films from Cr3+ electrolytes. Results suggest that growth stress during direct current (DC) Cr deposition is compressive with steady state values in the range below -100 MPa. The negative stress is associated with blistering in Cr films and accumulation of different defects on the surface which indicate significant amount of dissolved hydrogen either as an interstitial impurity or as a part of chemically bonded H as Cr-hydride. Our TEM data, stress, impedance and optical results undoubtedly suggest that weakened structure of the Cr films by oxidation process has a true origin in Cr-hydride formation and subsequent oxidation of its degradation by-products (H and Cr). Therefore, the electrodeposition process that produces less Cr-hydride should be more desirable when the crack and defect free Cr films are the goal.

The pulse current function design is driven by the goal to achieve Cr-films with minimum amount of Cr-hydride phase. The off time of the pulse current cycle is designed to allow break up and decomposition of hydride phase which has been formed in preceding pulse current step of the pulse cycle. The details of the pulse current cycle designed are developed upon modeling our stress relaxation transients recorded during the pulse current stage. Our in situ stress data show that using such approach, it is possible to completely change the sing of the growth stress in Cr films from compressive to tensile. More importantly, we will show the first indications that pulse electrodeposited Cr films have similar micro-cracked structure as Cr films electrodeposited from Cr6+ solutions.

Atom transfer radical polymerization (ATRP) is one of the most important and widely used methods of reversible deactivator radical polymerization [1]. It is mainly catalyzed by Cu complexes with N-based ligands. In electrochemically-mediated ATRP (*e*ATRP), polymerization is triggered and sustained by fast electrochemical (re)generation of Cu^I from Cu^{II} (Fig. 1a). *e*ATRP allows modulation of reaction rate through easy control of the distribution of Cu^I and Cu^{II} species in solution and the possibility of switching the process from active to dormant state and vice versa, by varying the electrochemical parameters applied to the system [2].

ATRP in water is quite challenging due to high activation rate constants (k_{act}) and equilibrium constants (K_{ATRP}). It has been reported, however, that the presence of small amounts of H_2O (~10 vol%) in organic solvents has beneficial effects on ATRP, enhancing the overall rate of polymerization without compromising control over molecular weight distribution [3,4]. The origin of this effect is not well understood although some hypothesis has been formulated mainly on intuitive basis.

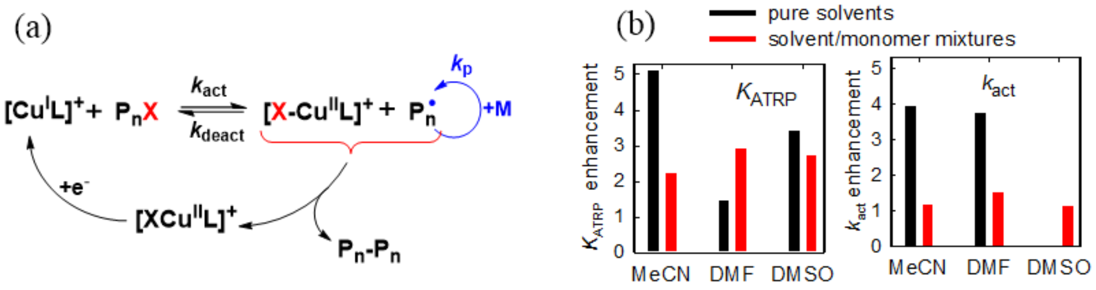

Fig. 1. (a) General mechanism of *e*ATRP and (b) effect of 10 vol% H_2O on k_{act} and K_{ATRP} in pure solvents and solvent/monomer mixtures (50/50, v/v).

We investigated the role of small amounts of water (up to 10 vol%) in *e*ATRP of methyl acrylate using $[Cu^{II}TPMA]^{2+}$ as catalyst. Experimentally, we observed an increase of the overall polymerization rate, R_p, when the reactions were performed in mixtures of MeCN, DMSO, DMF and [BMIm][OTf] with H_2O. The effect of H_2O on the redox potential of the catalyst, as well as on k_{act} and K_{ATRP} for the activation of methyl 2-bromopropionate by Cu^I was examined in pure solvents and in 50 vol% solvent/methyl acrylate mixtures. While $E^\ominus$ of the Cu^{II}/Cu^I couple was not much affected by H_2O addition, both k_{act} and K_{ATRP} were enhanced by the presence of H_2O in both pure solvents and solvent/monomer mixtures (Fig. 1b). Since R_p can be related to K_{ATRP}, the observed enhancement of K_{ATRP} may provide a plausible rationalization of the accelerating effect of H_2O in organic solvents.

Direct electron transfer (DET) between an electrode and redox/catalytic center(s) in oxidoreductases is a core "elementary" process in enzyme bioelectrochemistry.[1,2] Favourable orientation and high enzyme loading on electrodes are paramount in DET-type bioelectrocatalysis to ascertain high catalytic activity and ET rate.[3] Fructose dehydrogenase (FDH) from *Gluconbacter japonicas* is a membrane-bound oxidoreductase with three subunits, subunits I (67 kDa), II (51 kDa) and III (20 kDa).[4] Subunit I holds a flavin adenine dinucleotide (FAD) cofactor as the active center of two-electron fructose oxidation to 5-keto-D-fructose. Subunit II carries three heme *c* moieties, serving as ET relays between electron acceptors and FAD. Subunit III has no redox center and possibly contributes to structural integrity of enzyme.

We present here systematic investigation of the effects of both self-assembled molecular monolayers (SAMs) and nanoporous (Au-)electrode structure on DET-type bioelectrocatalysis of FDH absorbed on SAM-modified Au(111) electrodes. Two different SAMs with varying functional terminal-groups and alkyl chain lengths were studied. FDH on a 2-mercaptoethanol (BME) SAM showed the best DET performance with a maximum current density ($\Delta j_{\mathrm{max,det}}$: 54.88 ± 3.03 μA cm^{-2}) and DET-capable fraction derived from $\Delta j_{\mathrm{max,det}}$ over mediated $\Delta j_{\mathrm{max,met}}$ (χ_{det}: 13.33 %) due to the most favourable FDH orientation on the electrode surface. FDH on Au(111) functionalized with 3-mercaptopropanoic acid (MPA) SAM exhibited the best mediated ET with Δj_{max} of 640.76 ± 7.65 μA cm^{-2} using ferrocenemethanol as the mediator. This can be explained by the negatively charged SAM surface efficiently adsorbing FDH. Non-linear fitting to the electrocatalytic profiles was performed. The FDH catalytic properties strongly depend on the alkyl chain length, showing significant decrease with increasing SAM carbon chain length. Nanoporous gold supported FDH was also prepared. Porous gold structures not only improved the catalytic performance by increased enzyme loading and χ_{det}, but also increased notably the operational stability.

Acknowledgments

The PhD project is kindly supported by China Scholarship Council (CSC).

Transparent cathode material for photobioelectrochemical cell development

M. Riedel, S. Höfs, F. Lisdat
Biosystems Technology, Institute of Life Sciences and Biomedical Technologies,
Technical University Wildau,
15745 Wildau, Germany
flisdat@th-wildau.de

The combination of light-sensitive entities with electrodes has gained increasing interest in the last decade. Light can be used to switch electrochemical reactions which gives access to multiplexing by spatially resolved illumination of sensing surfaces, but it can also be used to modulate the electrochemical reactions [1]. This is interesting with respect to different aspects. One direction of research is devoted to systems which can improve the potential behavior for electrochemical signal chains. This is relevant particularly in bioenergetic applications.

Thus, we have already demonstrated the development of a photobioanode which allows the collection of electrons from the sugar oxidation at extremely low potentials under illumination. Here a combination of two semiconducting materials (TiO_2 and PbS) with a biocatalytic reaction (FAD-GDH or PSII) has been exploited [2,3].

The present study is devoted to the investigation of a material which can be prepared as a thin layer by a simple spin coating procedure on FTO slides (fluor doped tin oxide) as cathode material. The material used here is $BiFeO_3$. It is characterized by a rather high positive onset potential for cathodic photocurrents (~0.6V vs AgAgCl) and a high open circuit potential. This is based on a proper position of valence and conduction band of the material. When hydrogen peroxides is added to the solution the cathodic signals can be significantly enhanced - although there is no electrochemical H_2O_2 reduction in the dark at the electrode. The generated photocurrent provides sufficient stability with millimolar hydrogen peroxide concentrations and a defined dependence on the light intensity and H_2O_2 concentration.

This provides the basis for the construction of a photobiocathode with a rather high potential by coupling an enzymatic reaction to the photoactive electrode.

These investigations may illustrate the potential of coupling suitable semiconductor structures with biocatalytic conversions on electrode surfaces for application in bioenergetics but also in biosensing.

In the continuously growing field of post lithium-ion batteries (LIBs), sodium-ion batteries (SIBs) have emerged as a prominent candidate and valid alternative solution to the Li-ion technology, especially in systems dedicated to large-scale stationary energy storage. The abundance and availability of sodium reserves, combined with the low use of critical raw materials have sparked the investigation of high performance and efficient electrode materials for SIBs.

Currently, hard carbon (HC) represents the anode of choice for SIBs. Bio-waste derived HC, in particular, is very attractive in terms of sustainability, cost and electrochemical properties [1,2]. However, the processes governing the electrochemical performance of HC anodes are not completely understood, most likely stemming from the lack of a widely agreed-upon model of the HC structure, which hinders a comprehensive description of the processes occurring upon sodiation and its effects on the electronic and structural configuration of the materials. For example, the formation of the solid electrolyte interphase (SEI) layer and the sodium ions' uptake and release are two crucial processes affecting the battery lifetime and performance. Several mechanisms have been proposed so far, however, a universally accepted mechanism governing these reactions is still largely discussed [3,4].

This study aims at using powerful chemically sensitive synchrotron-based fluorescence and photoelectron spectroscopies to elucidate the composition and structure of complex materials. In order to gain insights into the SEI formation and the Na uptake in the underlying HC anode, a combined approach of X-ray spectroscopies with a tunable probing depth is used allowing differentiation of the spectral contributions of the bulk electrode from those related to the SEI layer. HC-based electrode samples have been investigated at different stages of (dis)charge using X-ray absorption (XAS), emission (XES), and photoelectron spectroscopy (XPS) in the soft and tender X-ray regimes, revealing the formation and evolution of the SEI during the initial sodiation process and subsequent cycles. The chemical species observed in the SEI mainly originate from the decomposition of the salt and the carbonate-based electrolyte, as also shown with *post mortem* Fourier-transform infrared spectroscopy (FT-IR) measurements. Additionally, resonant inelastic X-ray scattering (RIXS) measurements at the C K-edge provide supplementary information about the Na-insertion mechanism into the anode structure due to its excellent atom-specificity and mapping of the C band structure at different (dis)charge stages. The study has been complemented with an in-depth investigation of the structural changes of the HC electrode upon (de)sodiation by *in situ* Raman spectroscopy. This comprehensive spectroscopic study provides new insights into the complex mechanisms governing the sodium insertion and the SEI formation in hard carbon anodes.

Micro-scale capacitive-faradaic fuel cells for ions separation from water

Youri Gendel*, Gidon Amikam, Paz Nativ, Naama Manor-Korin

Technion-Israel Institute of Technology. Faculty of Civil and Environmental Engineering. Environmental Electrochemistry Laboratory. Yitzhak Rabin Bldg r625, Technion City, Haifa 32000, Israel. E-Mail: ygendel@tx.technion.ac.il

A novel method for separation of ions from water and wastewater using micro-scale (10µm – 5 mm) fuel cells has been recently proposed[1]. The fuel cells comprise activated carbon particles loaded with bifunctional catalyst for hydrogen oxidation and oxygen reduction reactions. Within the proposed process of ions removal, the particles act as *micro-scale capacitive-faradaic adsorbing fuel cells* (*MS-CF-AFC)* which require oxygen and hydrogen gases for adsorption of ions during the water treatment step and desorption of ions in brine production. The process was proved for removal of perchlorate ions from $NaClO_4$ solutions in deionized water and groundwater using batch and packed-bed reactors for two types of *MS-CF-AFCs* prepared from Lewatit AF5 microporous carbon and a powdered activated charcoal loaded with Pt (5wt%) catalyst. Within the O_2-induced adsorption of ClO_4^- ions, the reduction of oxygen on Pt (faradaic electrode of the *MS-CF-AFC*) results in depletion of electrons from the carbonaceous part (i.e. the capacitive electrode) of the micro-scale fuel cell, which leads to adsorption of anions in the electrical double layer. The hydrogen oxidation that occurs during the regeneration of the ClO_4^-- loaded *MS-CF-AFCs* results in accumulation of electrons in the capacitive electrode and in repulsion of perchlorate ions into the regenerant solution. This way the chemical energy of H_2 and O_2 is converted by the *MS-CF*-AFCs into the electrical energy which is utilized for separation of ions. The technique was proved for separation of cations as well in batch mode experiments of Cu^{2+} ions separation from $CuCl_2$ solutions. In this case the *MS-CF-AFCs* were powered by H_2 gas during the Cu^{2+} adsorption step and by O_2 gas in brine production.

Accelerated discovery of next-generation battery materials and interfaces

Tejs Vegge
Technical University of Denmark, DTU Energy, 2800 Kgs. Lyngby, Denmark
teve@dtu.dk

Secondary batteries play a crucial role in the transition to a clean energy infrastructure, but until now, the development of novel, low-cost, high capacity and/or high voltage electrode materials, has been too slow. Understanding and controlling the complex and dynamic processes taking place in the electrodes, electrolytes and in particular at the battery interfaces/interphases holds the key to develop more durable ultra-high performance batteries. Atomic-scale simulations have reached predictive accuracy in many critical areas of materials design and characterization, e.g., the identification of rate- and potential limiting reaction steps. Here, we provide recent examples of how density functional theory (DFT) simulations supported by AI, machine learning and cluster expansion techniques [1] can been used to identify the limiting thermodynamic, ionic and electronic charge transfer mechanisms in next-generation electrode materials and interfaces [2-3], and how interfacial dopants and additives can be used to improve their performance [4]. Finally, we will discuss the "Battery Interface Genome – Materials Acceleration Platform" (BIG-MAP) project in the large-scale European research initiative Battery 2030+, focusing on simultaneous utilization of data from multiple domains. BIG-MAP aims to accelerate the materials and interface discovery process for batteries, and here, we present our perspective on AI-orchestrated discovery of batteries using autonomous workflows [5] and generative deep learning models to control and ultimately (inverse) design better battery interfaces [6]. These models are trained on all sources of available data, i.e., large-scale multi-fidelity data sets, multi-scale computer simulations and databases, operando X-ray and neutron characterization from large-scale research facilities, high-throughput synthesis and laboratory testing.

$H_2V_3O_8$ as model system for ion insertion

Jürgen Schoiber, Daniela Reiff, Michael Karl, Simone Pokrant
University of Salzburg, Dept. of Chemistry and Physics of Materials
Jakob-Haringer-Straße 2a
juergen.schoiber@sbg.ac.at

Since the elucidation of the Lithium-Ion shuttle mechanism many developments and investigations in the battery field were enabled.[1-4] The mechanism consists of the idea of shuttling a specific ion (*e.g.* lithium ion) between two host materials with a sufficient electrochemical potential difference in order to electrochemically store energy.[5] This basic principle of energy storage was transferred to other cations, *e.g.* Na^+, K^+, Mg^{2+}, Ca^{2+}, Zn^{2+} or Al^{3+} aiming for novel/other metal-ion battery (MiB) systems.[3, 4, 6, 7] While very promising candidates for each MiB system are under investigation, only few materials have been discovered which can intercalate more than one specific ion with substantial capacities. This is due to the different chemical properties and the electrochemical behavior of the investigated ions. However, this is a very general statement and only little attention has been paid to the reasons why materials work exclusively for one specific insertion cation.

A promising material to address the question, which parameters dominate the electrochemical storage behavior is $H_2V_3O_8$ (HVO), since Li^+, Na^+, K^+, Mg^{2+} or Zn^{2+} can be inserted.[8-11] While each work proved exclusively that HVO is as promising host material for the investigated insertion ion, neither conclusions nor comparisons were made with respect to the different ion storage behaviors, such as which crystallographic position will be occupied or why and how the crystallographic structure changes during the insertion process. Answering these questions, however, has the potential to provide insight into the storage behavior. From there conclusions can be drawn why this material is so versatile in the uptake of various insertion ions and which parameters lead to this behavior.

In this contribution, we present new insight in the $H_2V_3O_8$ structure and why this material is a promising candidate to investigate the needs which must be addressed as a function of the insertion ion. In particular, we will discuss the influence of structural modifications and, for the first time for this material, of the operating temperature on the storage behavior of various cations (*i.e.* Li^+, Zn^{2+}). The obtained electrochemical and structural results will be discussed and compared with respect to the different insertion ions.

Background of this research

Epithelial-mesenchymal transition (EMT) is a process that epithelial cells lose epithelial features and acquire mesenchymal characteristics. This phenomenon progresses for a few days with changing adhesion structures at nanoscale until losing cell-cell adhesion. As a result, EMT brings about cancer invasion and transition with morphological variations, and it is also known that there are only two states (Epithelial state to Mesenchymal state) under EMT. Recently, some researchers reported that there was some intermediate states with differences of gene expression between two states[1]. However, continuous dynamics of cell surface is not comprehensively understood at nanoscale by conventional analytical techniques. Therefore, tracking nanoscale morphological changes are necessary throughout a few days to investigate the intermediate states. In this study, we visualized topographical changes on cell membranes at nanoscale by scanning probe technique.

Scanning Ion Conductance Microscope

Scanning ion conductance microscopy (SICM) is one of scanning probe microscopies for visualizing nanoscale topography of cell surface without invasion[2]. Figure 1 shows a schematic illustration of SICM. A glass nanopipette (tip diameter: 100 nm) filled with medium and Ag/AgCl wire is used as a probe. When a voltage is applied between the nanopipette and the medium, ionic current due to ionic flow through the probe is measured. The ionic current is used as a feedback signal to control the distance between the probe and a sample surface[2]. Nanoscale images can therefore visualize without physical contact and fluorescence labelling.

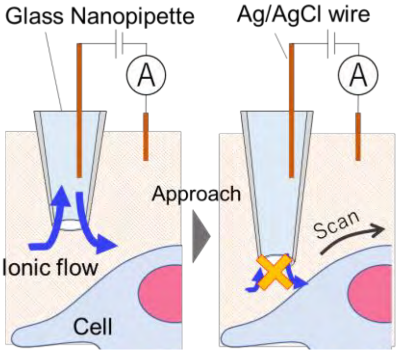

Figure 1: Schematic illustration of SICM

Experiments, results and future works

A549 cells (Human alveolar adenocarcinoma cell line) were used as a model of epithelial cells. Before EMT process, multiple microvilli were observed on A549 cell surface by SICM. After treatment with 10 ng/mL TGF-β in the culture medium, microvilli decreased within 6 days. From immunostaining results, A549 lost E-cadherin within 5 days. The process of losing cell-cell adhesion can be observed by SICM. These results indicated that the EMT was progressed by treatment of TGF-β, and the membrane remodeling was visualized at EMT transition states by SICM. Currently, we have developed a combined SICM system with an incubator that can achieve long-term measurement to understand intermediate states in EMT. We expect that this technique will be useful for understanding the mechanism of EMT.

Photosystem I (PSI) is one of the key protein complexes driving oxygenic photosynthesis, a highly developed process by Nature through billions of years of evolution for the efficient conversion of sunlight into chemical energy. Resembling a photodiode, PSI is able to perform charge-separation upon absorption of visible light, with a considerably high quantum efficiency for the photon-to-electron conversion process. After subsequent internal electron transfer, a final state is obtained at PSI, consisting of two redox centers of opposite charge with a potential difference of about 1.0 V. In addition, PSI is a robust and widely abundant biomolecule. As a result, PSI is considered an attractive building block for the fabrication of semi-artificial energy conversion devices. However, a consequence of the large voltage difference between the terminal redox sites at PSI is that it translates directly into a substantial driving force for recombination and short-circuiting processes, as a result canceling out at least part of the generated photocurrents in conventionally implemented devices [1,2]. Therefore, one of the major challenges in the development of PSI-based photobioelectrodes constitutes the fabrication of well-defined structures able to provide a unidirectional electron flow.

Taking advantage of the amphiphilic nature of PSI, the molecule can be used for the preparation of dense Langmuir monolayers. After spreading isolated PSI protein complexes onto a water-air interface, the hydrophilic ends adopt a specific orientation either being solubilized in water or facing air, while the hydrophobic regions stack together after compression of the movable barriers at a Langmuir trough. Since the terminal redox centers at PSI are located at opposite sides of the biomolecule within the hydrophilic ends, a densely packed and stable monolayer presenting a preferential orientation is obtained. This molecular structure can be transferred to the electrode surface for the fabrication of PSI-based biophotoelectrodes presenting an anisotropic electron flow [3]. On this basis, novel architectures for the fabrication of PSI-based photobioelectrodes are presented, enabling the development of more efficient solar-to-chemical energy conversion devices as a result of the decreased charge recombination and short circuiting processes.

Since its discovery, graphene attracts immense attention of the scientific community and it is frequently claimed to be the perfect material for numerous applications. It is not surprising that graphene quickly found its place in electrochemical laboratories. This is natural because electrochemists have been using carbon materials for decades, and graphene indeed possesses some properties which are attractive to electrochemists. High conductivity and large specific surface are some of them. However, perfect (pristine) graphene is chemically inert and reacts poorly with basically any atom in the Periodic Table of Elements [1]. Luckily, it turns out that for electrochemists pristine graphene is not so interesting. Much more can be obtained by the introduction of defects and functional groups on graphene basal plane and edge sites, pawing a way to new battery materials, materials for electrochemical capacitors or electrocatalysts. However, to fully exploit the potential of graphene-based materials an atomic level of understanding is a must, and theoretical methods can help us along this path. We shall present some of the recent results of our group on the modelling of graphene-based materials for energy conversion applications. First, we shall address some general features of functionalized graphene surfaces with heteroatoms and oxygen functional groups [2] and demonstrate such functionalization can be employed in metal-ion batteries [3]. Then we shall address the tailoring of graphene-oxide for the applications in electrochemical capacitors [4]. Finally, we shall describe how different levels of theory can be used to guide the development of novel graphene-based platinum-free electrocatalysts for hydrogen evolution [5]. We intend to present a realistic situation in the field, demonstrating possibilities, but also limitations of the use of graphene-based materials in electrochemistry.

reshma.rao@imperial.ac.uk

Efficient (photo)electrochemical oxidation of water is pivotal to the production of energy carriers such as hydrogen, ammonia, synthetic carbon-neutral fuels by CO_2 reduction and the production of metals from metal oxides[1]. Nickel-based oxides have been widely employed as water oxidation catalysts in alkaline electrolyte owing to their high intrinsic activity and stability[2,3]. In order to understand and further improve the activity of catalytically active centers, it is imperative to understand the reaction mechanism and atomic scale processes occurring during water oxidation. Specifically, nickel-based oxides form an oxyhydroxide structure under oxidizing conditions relevant to water oxidation[4], which have layered structures, with varying degrees of long-range order. Water and electrolyte ions can intercalate within the resultant three-dimensional structure to access redox states within the bulk, beyond the surface and sub-surface layers[5]. Thus, both, the intrinsic activity for water oxidation and the density of accessible active sites need to be increased in order to design the most active catalysts.

In this study, we use *operando* spectroelectrochemical methods[6] to assay the concentration of oxidized species for a series of metal-doped NiO films ($M_{0.1}Ni_{0.9}O$, M = Fe^{3+}, Co^{2+}, Mn^{2+} and Zn^{2+}) synthesized from the respective chloride salts. We first demonstrate how the dopant atoms can be used to rationally tune the binding energetics of the Ni site for water oxidation. The density of oxidized species accumulated under reaction conditions at potentials between 1.5 V_{RHE} and 1.8 V_{RHE} decreases in the order $Mn_{0.1}Ni_{0.9}O > Co_{0.1}Ni_{0.9}O > Fe_{0.1}Ni_{0.9}O > NiO > Zn_{0.1}Ni_{0.9}O$, which correlates with the onset of the Ni^{2+}/Ni^{3+} redox peak position, i.e. the accumulation of redox species is greatest for chemistries that are easiest to oxidize. On the other hand, we find that the kinetics of water oxidation, defined as the turn over frequency per active oxidized species, increases from $Mn_{0.1}Ni_{0.9}O$ to $Co_{0.1}Ni_{0.9}O$ and $Fe_{0.1}Ni_{0.9}O$ but decrease for NiO and $Zn_{0.1}Ni_{0.9}O$, demonstrating a volcano relation where the ideal Ni site binds oxygen neither too weakly nor too strongly. In the next part of this study, we use different precursor salts (chloride, nitrate, sulfate, triflate) to synthesize the metal oxides, which results in a change in the local structural environment around the active site. Differences in local structure are manifested as changes in the rates of generation of oxidized species as a function of potential, suggesting that the accessibility of active sites is influenced strongly by the local structure around the active site. Thus, based on the use of combined optical and electrochemical techniques, we highlight possible strategies to enhance the activity of Ni-based oxides by tuning both the intrinsic activity per active site by modifying the electronic structure as well as the accessibility and utilization of these sites.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement 732840-A-LEAF.

Cancer is associated with aberrant glycosylation and each type of malignant issue is characterized by a distinct change in the glycan structure. Therefore, analysis of tumor-linked glycan alterations is proposed as a valuable tool for diagnostic and prognostic purposes. The glycosylation profile of tumors is currently characterized by long and complicated protocols, based on final MS detection or with the use of lectins. However, these procedures cannot be applied for routine analysis in early detection of cancer. In consequence, to translate these biomarkers from discovery to clinical diagnostics there is a clear need for extremely selective methods, able to differentiate the glycan profile characteristic of disease conditions. Aptamers can be tailored to specifically detect aberrant glycosylation at each protein or even at each glycosylation site, and the use of aptamers as synthetic receptors appears to be a promising approach to replace the current methods [1]. In the case of the prostate cancer, it has been recently described that there is a variation in the fucose and the sialic acid in the glycan structure of the Prostate Specific Antigen (PSA), the only biomarker approved for clinical use in this type of cancer. This aberrant glycosylation is a better marker of the aggressiveness of prostate cancer. [2]

In this work we present a strategy to direct the selection of aptamers toward the glycosylation site of the protein PSA, both glycan and surrounding peptide moieties. The SELEX procedure is based on counter-selection steps against the recombinant PSA (unglycosylated) and two different strategies using lectins. The aptamers in the last cycle are cloned, sequenced and classified into families using bioinformatics tools. The most abundant aptamers are characterized by electrochemical binding assays. The best aptamer is able to recognize specifically the glycans of the protein PSA due to the interaction with aminoacids of the protein but does not recognize other glycoproteins.

We employed the as-selected aptamer or an aptamer previously described for PSA, which only recognizes the peptidic part [3], for the development of an impedimetric label-free aptamer-based sensor, onto home-made gold electrodes modified with gold nanoparticles as support of the sensing phase. With both aptamers we obtained two different calibration curves for the analysis of the total PSA and glycosylated PSA. The sensor responds to different levels of total PSA in human serum reaching levels well-below the 4 ng/mL cut-off. These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated.

Material Screening Revisited: Challenging the Paradigm of a Thermoneutral Electrocatalyst as Apex of a Volcano Plot

Kai S. Exner
University of Duisburg-Essen, Faculty of Chemistry, Department of Theoretical Chemistry
Universitätsstraße 5, 45141 Essen, Germany
kai.exner@alumni.uni-ulm.de

On the way toward a sustainable energy scenario, environmentally friendly and efficient electrocatalysts need to be developed. Material screening is a promising strategy to recognize potential electrode and electrolyte compositions. Most researchers apply the volcano approach, as introduced by Nørskov, Rossmeisl, and co-workers, which connects Sabatier's principle and the Brønsted-Evans-Polanyi relation to the analysis of simple binding energies, while neglecting the applied overpotential and kinetics in the analysis **[1]**. This methodology purports that an optimum electrocatalyst stabilizes all reaction intermediates thermoneutral at zero overpotential ($\Delta G_{\mathrm{RI}} = 0$ eV at $\eta = 0$ V).

Recently, the author derived material-screening approaches that pay proper attention to the applied overpotential and kinetics: while the concept of kinetic scaling relations enables resolving the rate-determining reaction step within a homologous series of materials at overpotentials corresponding to typical reaction conditions **[2,3]**, overpotential-dependent volcano curves enclose the applied overpotential into the determination of the volcano's apex **[4-6]**. These advanced methods have been connected to Nørskov's theory by establishing a unifying material-screening approach **[7,8]**, which has shown to excel the conventional volcano scheme with respect to thorough sorting of electrode materials into active and inactive catalysts **[9]**.

Most notably, the inclusion of the applied overpotential and kinetics into the volcano concept indicates that optimum electrocatalysis requires thermoneutral bonding of the crucial reaction intermediate at target overpotential ($\Delta G_{\mathrm{RI}} = 0$ eV at $\eta > 0$ V), that is, endergonic bonding at $\eta = 0$ V. This result was corroborated by microkinetic modeling **[10]**, giving rise to reappraise the traditional understanding of the volcano approach for electrocatalytic processes: electrocatalysts that bind the decisive reaction intermediate endergonically at $\eta = 0$ V are not necessarily catalytically inactive, whereas the opposite case holds true, that is, exergonic bonding of reaction intermediates at $\eta = 0$ V results in a poor catalytic activity. Consequently, electrocatalysts with $\Delta G_{\mathrm{RI}} > 0$ eV at $\eta = 0$ V should not be discarded when conducting volcano analyses (cf. **Figure 1**).

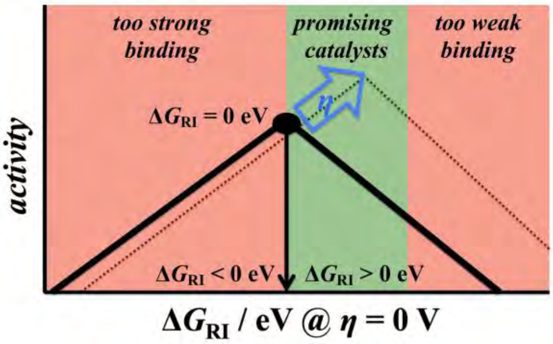

Figure 1: The apex of the volcano curve for a simple two-electron process shifts toward weak bonding when the applied overpotential and kinetics are included in the analysis.

Center for Energy and Environmental Chemistry Jena (CEEC Jena)
Philosophenweg 7a, 07743 Jena
patrick.gerlach@uni.jena.de

Organic radical polymers (ORPs) have received a growing interest over the last decades, as they combine fast kinetics with typical characteristics of organic redox active materials like flexibility, sustainability and versatility [1]. Today one of the most investigated ORPs is poly(2,2,6,6-tetramethylpiperidinyl-N-oxymethacrylate) (PTMA), which was first introduced by Nakahara et al. in 2002 [2]. PTMA bears a 2,2,6,6-tetramethylpiperidinyloxy-group (TEMPO) in the repeating unit and thus provides a theoretic capacity of 111 mAh g^{-1} and a high rate capability as well as high cycling stability [3]. Most of the work dedicated to PTMA-based electrodes has been done utilizing typical lithium-ion batteries (LIBs) electrolytes e.g. 1M lithium hexafluorophosphate in ethylene carbonate/ dimethyl carbonate (1M $LiPF_6$ in EC/DMC). Little effort has been directed towards the use of ionic liquids (ILs), although these electrolytes - which could be used neat, in mixtures with organic solvents or in gel polymer electrolytes - could be interesting for the development of advanced polymer-based energy storage devices. [4],[5]. In one of our previous studies, we were able to show that the use of neat 1-butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide ($Pyr_{14}TFSI$) has a positive effect on the cycling stability as well as the self-discharge behavior of PTMA in a metal-free setup [6].

In this work, we performed a systematic analysis of the electrochemical behavior of PTMA-based electrodes in combination with two aprotic and two protic ILs. Namely $Pyr_{14}TFSI$, 1-butyl-1-methylpyrrolidinium bis(fluorosulfonyl)imide ($Pyr_{14}FSI$) (aprotic), 1-butyl-pyrrolidinium bis(trifluoromethane-sulfonyl)imide ($Pyr_{H4}TFSI$) (protic) and 1-butyl-pyrrolidinium bis(fluorosulfonyl)imide ($Pyr_{H4}FSI$) (protic). By doing so, we were able to show that the nature of the cation and the anion of the ILs has a strong impact on the performance of PTMA. Furthermore, we demonstrate that when neat $Pyr_{14}FSI$ is used as electrolyte, PTMA-based electrodes display outstanding stability for 2.5 months during float experiments carried out at a potential of 1.1 V *vs. Ag* (corresponding to 4.1 V vs. Li/Li^+) (Figure 1).

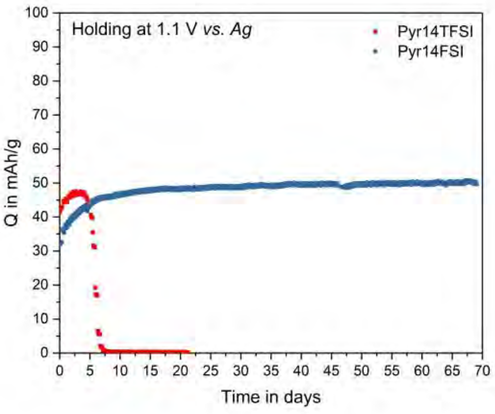

Figure 1: Capacity retention of PTMA based electrodes in $Pyr_{14}TFSI$ $Pyr_{14}FSI$ after 70 days of floating at 1.1V vs. Ag (corresponding to 4.1 V vs. Li/Li^+)

Nanostructured Pt_xM/C (M = Cu, Co, Ni, Ir, Y) Alloy Electrocatalysts Synthesized via a Novel Top-Down Route Towards the Enhancement of the ORR Activity

Theophilus Kobina Sarpey[a], Johannes Fichtner[a], Sebastian Watzele[a], Batyr Garleyyev[a], Jan M. Macak[b], Aliaksandr S. Bandarenka[a,*]
a. Physics of Energy Conversion and Storage, Technical University of Munich, James-Franck-Straße 1, 85748 Garching, Germany
b. Central European Institute of Technology, Brno University of Technology, Purkynova 123, 612 00, Brno Czech Republic

Addressing the sluggish kinetics of the oxygen reduction reaction (ORR) which occurs on the cathodic end of the fuel cell is of peculiar interest for future sustainable energy conversion and storage in the automotive industry to be specific. Continuous search for an optimum catalyst to address this challenge has led to the discovery of Pt-based nanostructured alloys as prominent candidates. As such, alloying nanostructured Pt with 3d transition metals and/or rare-earth elements is an auspicious approach to tune the electrocatalytic activity towards the ORR. Usually, bulk Pt-alloys are used in the synthesis of nanostructured Pt-alloys. With the exception of Pt_xIr nanoparticles (NPs) that were synthesized from their bulk metal alloys, all the other NPs investigated in this study were synthesized using a different strategy or method. For the first time herein, this study presents the direct dissolution and/or deposition of 3d transition metal/rare-earth element precursor salts into the 1.0 M KOH electrolyte to produce NPs from bulk Pt. By so doing, nanostructured Pt_xM/C (M = Cu, Co, Ni, Y) alloys were synthesized using a novel top-down nanostructuring technique which is the electrochemical erosion of bulk metal and/or metal alloys. The nanoparticles were characterized using transmission electron microscopy, energy-dispersive x-ray spectroscopy, x-ray diffraction and spectroscopy. The electrocatalytic oxygen reduction activity for the various nanocatalysts were also measured.

All the synthesized samples apart from the leached Pt_xY/C-15V exhibited specific activities (SAs) higher than the reference Pt/C TKK catalyst. In terms of mass activities (MAs), aside Pt_xNi/C-10V and Pt_xY/C-15V that displayed lower MA compared to the reference Pt/C TKK catalyst, all the other investigated nanostructured electrocatalysts outperformed the reference Pt/C TKK catalyst. In particular, Pt_xCu/C-15V showed a 4 fold enhancement (0.64 A/mg_{Pt} at 0.9V vs RHE) in terms of mass activity and ~ 5.5 fold higher specific activity (2.27 mA/cm^2 at 0.9V vs RHE) when compared to the reference Pt/C TKK catalyst.

andrea.balducci @uni-jena.de

Electrical double layer capacitors (EDLCs) display high power, high cycle life and high safety and, due these favorable features, they are nowadays considered one of the most interesting energy storage systems [1-2]. The properties displayed by EDLCs are originated by the storage mechanism taking place in these devices, which is relying on the formation of an electrical double layer at the interface between electrodes and electrolyte. The state-of-the-art EDLCs consist of composite electrodes containing highly porous activated carbons (AC) as active materials and electrolytes based on a salt dissolved, in most of the cases, in an organic solvent.

Nowadays, the AC utilized in EDLCs are typically realized through the chemical activation of carbonaceous precursors. This process is allowing the realization of designed AC, able to display high capacitance. However, the overall process is resource consuming and it requires several washing steps to separate carbon and activation reagents [3]. For this reason, its optimization would significantly improve the overall sustainability of EDLCs.

In this work we present a holistic concept, indicated as "in-situ electrolyte" in which by-product salts, which are formed during the synthesis of AC are not considered as waste products but rather upcycled to an organic electrolyte for EDLC application [3-4]. Thereby, the waste production during the EDLC preparation is minimized greatly (with an increase of the mass productivity of 15-fold) and only the use of a solvent is required for the realization of EDLCs. We showed that EDLCs realized utilizing the "in-situ electrolyte" approach display high capacitance at high current density (30 F g^{-1} at 10 A g^{-1}) and high cycling stability.

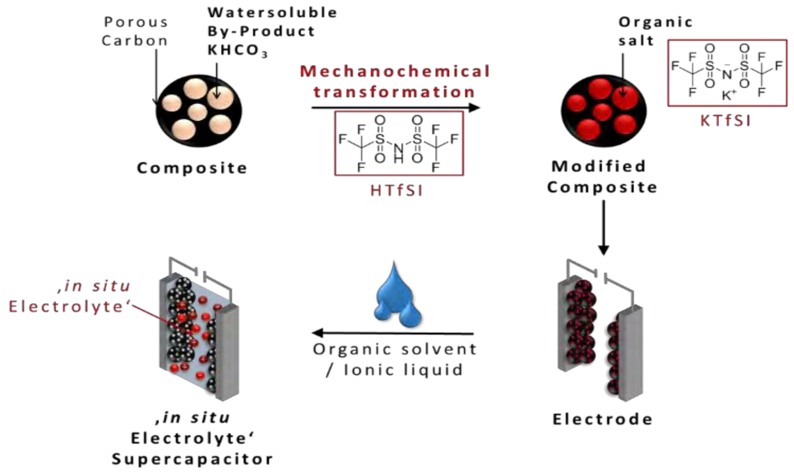

Figure 1. Schematic representation of the in-situ electrolyte approach

Metal oxides are important functional materials with a wide range of applications, especially in the field of electrocatalysis. However, quick and accurate assessment of their real electroactive surface area (ECSA), which is of paramount importance for the evaluation of their specific activity, remains a challenging task. In the presentation, I will present a relatively simple strategy for an accurate *in situ* determination of the ECSA of commonly used metal oxide catalysts, namely: Ni-, Co-, Fe-, Pt- and Ir-based oxides. Similar to the well-established practice in electrocatalysis, the method is based on the phenomenon of specific adsorption. It uses the fact that, at the electrode potentials close to the onset of the oxygen evolution reaction (OER), specifically adsorbed reaction intermediates manifest themselves through so-called adsorption capacitance, which is unambiguously detectable using electrochemical impedance spectroscopy.[1,2] With simple impedance measurements, experimentalists can acquire the adsorption capacitance values and accurately estimate the real electroactive surface area of the above-mentioned oxide materials, including nanostructured electrocatalysts. Additionally, as illustrative examples, I will demonstrate an application of the method for the determination of the ECSA of oxide catalyst nanoparticles.

Zinc is an important nutrient playing important role in metabolic processes (cell growth, DNA transcription etc.). At the same time, there is a mounting evidence of zinc being involved in potentiating learning and memory, although the mechanism of zinc action on the latter processes is not clearly identified and understood.

In this work, the effects of Zn^{2+} cations on the exocytosis in PC12 cells was studied. Zn^{2+} cations were shown to influence exocytotic release and storage in neurotransmitter-containing vesicles. In order to characterize and quantify different aspect of this complex process a combination of several techniques was used. Transmission electron microscopy (TEM) was employed for structural analysis and size measurements of the vesicular dense core and halo (less compacted zone), while single-cell amperometry allowed investigating the vesicle fusion pore size changes induced after zinc treatment. The amperometric traces before and after Zn^{2+} treatment were analyzed and compared to theoretical predictions based on the concept of partial release as opposed to full quantal release and incorporating structural information obtained from TEM.

This powerful combined analytical approach allowed establishing the existence of an unsuspected strong link between vesicle structure and exocytotic dynamics. These results allowed delineating possible mechanism of regulation of synaptic plasticity by Zn^{2+} through modulation of kinetics and amount of neurotransmitter release [1].

Electrochemical impedance spectroscopy with nanoporous structures composed of nonconductive polystyrene nanoparticles

Jakub Sopoušek[1,2], Karel Lacina[2]
[1] *Department of Biochemistry, Faculty of Science, Masaryk University, Kamenice 5, Brno, Czechia*
[2] *Central European Institute of Technology, Masaryk University, Kamenice 5, Brno, Czechia*
jakubsopousek@gmail.com

Electrochemical impedance spectroscopy (EIS) is a suitable method for in-depth studies of interfacial processes. As its output signal is a function of applied potential modulated in frequency domain (instead of time), lots of information can be gathered from a single measurement. Using EIS, we investigated solid-state nanoporous interfaces formed by assembling nonconductive polystyrene nanoparticles in densely packed layers on the electrode (Figure A). Due to the dense hexagonal packing, the interstitial space among three neighboring nanoparticles can be considered as a nanopore of specific diameter. Monolayers composed of carboxylated polystyrene nanoparticles different in size were tested. These monolayers were further modified with protein (human serum albumin) with the intention to reduce the dimensions of the nanopores and to monitor the corresponding electrochemical impedance behavior. Moreover, ordered multilayer structures of nanoparticles, built layer-by-layer, were investigated throughout the same experiments. Unexpected and interesting outcomes were acquired. The absolute impedance of the monolayers corresponded to the level of carboxylation of the particular nanoparticles apart from the influence of reduced nanopores (Figure B, C; Sopoušek et al., ACS Appl. Mater. Interfaces, 2020, in press). The impedance spectra of multi-layered structures exhibited additional resistance component (Figure D). All impedimetric data were fitted with theoretical equivalent circuits and the interfacial effects in such matrices were discussed.

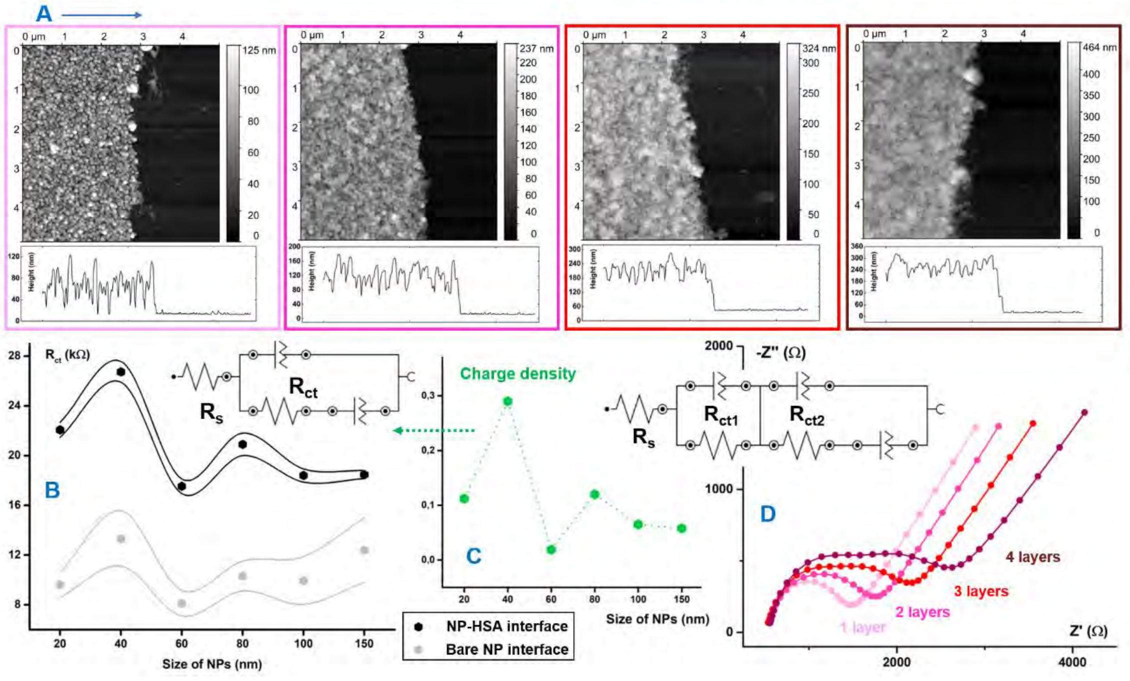

Figure: A: Visualization of the nanoporous structures composed of 80 nm nanoparticles using AFM (including heights in cross-section). B: Charge transfer resistance (R_{ct}) of un/modified monolayers of nanoparticles containing nanopores of different diameter. The strange behavior corresponds to the level of carboxylation of individual nanoparticles in C. D: Impedance spectra of multilayers indicate additional resistance component.

The importance of double layer charging and electrolyte composition in electrochemical CO_2 reduction

Karen Chan
Technical University of Denmark
Department of Physics, Fysikvej, Kongens Lyngby Denmark 2800
kchan@fysik.dtu.dk

Electrochemical CO_2 reduction is a particularly challenging process from both modelling and experimental perspectives. The challenge arises from the complexity of its reaction network and the sensitivity of its activity and selectivity to the electrolyte composition and the associated interfacial field effects. In this talk, I will first discuss developments in methods to model the electrochemical interface - the accuracy of widely applied continuum approximations of the electrolyte, as well as a new unified approach to obtain electrochemical barriers from both explicit and implicit solvent simulation approaches. In particular I emphasize that the surface charge gives the most appropriate proxy of the local potential (vs. the traditionally considered work function). Then, I will discuss the impact of the electrolyte composition - pH and ions - on electrochemical CO_2R activity of both transition metals as well as supported single atom catalysts. Finally, I discuss the implications of our findings for electrocatalyst design and electrolyte engineering.

Reaction Confinement Enables High-Capacity and Stable Anodes for Alkali-Ion Batteries

Laifa Shen, XiaogangZhang
Jiangsu Key Laboratory of Electrochemical Energy Storage Technologies,
Nanjing University of Aeronautics and Astronautics
Nanjing, 210016, P.R. China
Email: lfshen@nuaa.edu.cn

Current insertion anode chemistries are approaching their capacity limits; thus, battery technologies have to move toward the employment of electrode materials based on “multi-electron redox reactions”. Materials based on alloying reactions offer this characteristic, enabling the storage of a few alkali ions and electrons per host atom. In particular, silicon and germanium are considered as potential alternatives for the currently employed graphite because of their very high theoretical lithium storage capacity (3578 mAh g^{-1} for $Li_{15}Si_4$ and 1623 mAh g^{-1} for $Li_{4.4}Ge$). However, their performance is far from being satisfactory because of the large volume change and severe capacity decay that occurs upon lithium alloying and dealloying processes. To address these problems, we propose and demonstrate a versatile strategy that makes use of the electronic reaction confinement via the synthesis of ultrasmall Ge nanoparticles (10 nm) uniformly confined in a matrix of larger spherical carbon particles ($Ge\subset C$ spheres). This architecture provides free pathways for electron transport and Li^+ diffusion, allowing for the alloying reaction of the Ge nanoparticles. The thickness change of electrodes containing such a material, monitored byan in situ electrochemical dilatometer, is rather limited and reversible, confirming the excellent mechanical integrity of the confined electrode. As a result, these electrodes exhibit high reversible capacity (1310 mAh g^{-1}, 0.1C) and very impressive cycling ability (92% after 1000 cycles at 2C). A prototype device employing such an alloying electrode material in combination with $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ offers a high energy density of 250 Wh kg^{-1}.

The world is increasingly turning to the use of Li-ion batteries in electric vehicles; therefore, there is a growing need for lithium (Li). I propose new method for recovering Li from used Li-ion batteries by using Li separation method by ionic conductor; LiSMIC [1]. Li ionic conductor is functioned as a Li separation membrane. This innovative LiSMIC involves the use of an Li separation membrane whereby only Li ions in a solution of used Li-ion batteries permeate from the positive electrode side to the negative electrode side during electrodialysis; the other ions, including Co, Al, and F, do not permeate the membrane.

$Li_{0.29}La_{0.5}7TiO_3$ was selected as the Li separation membrane. The positive side of the dialysis cell was filled with used Li-ion battery solution, and then the negative side was filled with distilled water. In this study, the platinum (Pt) electrodes are bonded to the right and left faces (the two main faces) of the LISM, respectively. The applied dialysis voltage was 5 V, and the electrode area was 16 cm^2 and 4 cm^2 as new Li separation membrane. The Li recovery ratio increased with electrodialysis time. Furthermore, Li permeation speed was not depended on the electrode area, and I succeeded in the development of new Li separation membrane with small area electrode.

After electrodialysis, the Li recovery water was bubbled by CO_2 gas to produce lithium carbonate (Li_2CO_3) as a raw material for Li-ion batteries. The high purity Li_2CO_3 powder was easily generated under CO_2 gas bubbling method. Also, the Li recovery water was dried to produce lithium hydroxide (LiOH) as a raw material for Li-ion batteries. The high purity LiOH powder was easily generated under vacuum drying atmosphere.

Thus, LiSMIC is most suitable for the Li recycling of used Li-ion batteries (Fig.1).

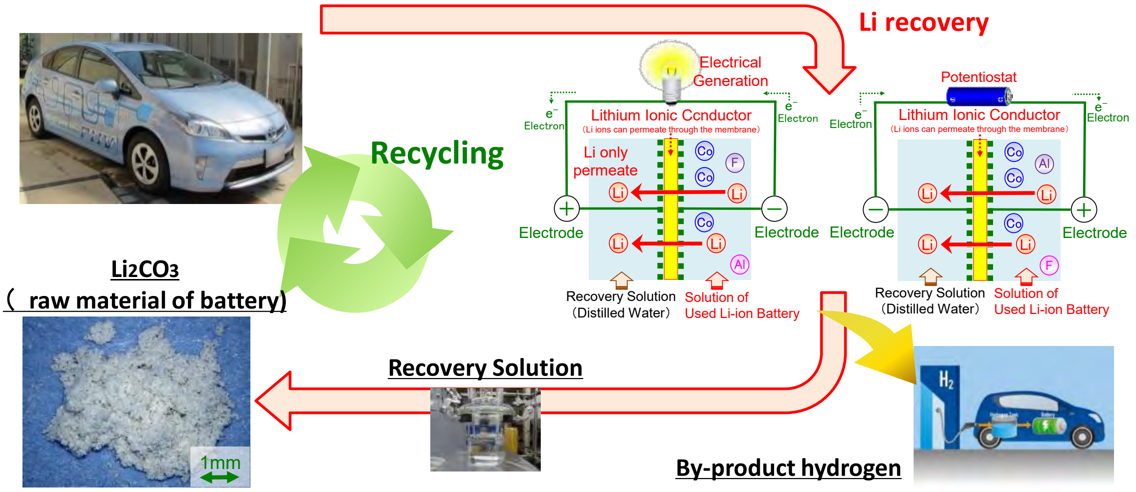

Fig.1 This schematic draw is Li recovery Technology from used Li-ion battery solution using Li separation method by ionic Conductor; LiSMIC. Lithium carbonate (Li_2CO_3) as a raw material for Li-ion batteries is produced from Li recovery solution. And then, H_2 gas is generated as a by-product on the Li recovery side.

Bioelectrocatalysis for Electrosynthesis

Shelley D. Minteer
University of Utah
315 S 1400 E Rm 2020
Salt Lake City, UT 84112
minteer@chem.utah.edu

Electrosynthesis of commodity and fine chemicals is an emerging area. Bioelectrocatalysis has only recently been considered for this application. This talk will discuss the advantages of bioelectrocatalysis for electrosynthesis with examples ranging from ammonia production to pharmaceutical products and intermediates. In the last 5 years, there have been extensive studies and new materials designed for catalytic reduction of nitrogen to ammonia. This is a challenging reductive transformation for traditional electrocatalysts and photocatalysts, but nature can provide an inspiration. Nitrogenase is the only enzyme known to reduce nitrogen to ammonia. This talk will discuss electroanalytical techniques for studying nitrogenase electrochemistry, including both mediated bioelectrocatalysis and direct bioelectrocatalysis. Then, this talk will discuss electrode materials innovation for interfacing these complex proteins with electrode surfaces as well as using them for electrosynthesis of ammonia as well as other value-added products (i.e. chiral amines, chiral amino acids, etc.). Finally, this talk will discuss the use of enzyme cascades for enzymatic bioelectrosynthesis and synthetic biology for microbial bioelectrosynthesis of ammonia and other value-added products.

Electrochemical systems for the treatment of contaminated water: limitations, challenges and prospective

Jelena Radjenovic[1,2], Natalia Sergienko[1,3], Nick Duinslaeger[1,3], Giannis Florjan-Norra[1,3], Luis Baptista-Pires[1,3]

[1]Catalan Institute of Water Research, c/Emili Grahit 101, Girona, Spain

[3]University of Girona, Girona, Spain

To minimize the effects of water pollution and alleviate water scarcity, urban water infrastructure will have to be re-invented through implementation of innovative low-cost, energy efficient decentralized water and wastewater treatment systems, and use of alternative water resources. Distributed treatment systems need to be compact, highly efficient, cost-effective, sustainable, robust and autonomous. Among the available technologies, electrochemical systems have the most potential to be used for decentralized treatment of (waste)water. Electrochemical systems do not use chemical reagents, do not form a residual waste stream, operate at ambient temperature and pressure, are robust, versatile and have a small footprint. Yet, to advance from laboratory experiments to practical implementation, there are two key, long-standing challenges that need to be addressed: *1)* high energy consumption and cost; given that most contaminants are present at low concentrations, their electrochemical reactivity in the conventional flow-by two-dimensional (2D) electrochemical reactors is subject to pronounced mass transfer limitations, and *2)* formation of toxic halogenated byproducts in the presence of halides. Three-dimensional (3D) reactor design is characterized by the high electrode surface area to reactor volume ratio and significantly improved reactor efficiency, with a larger effective surface area available for electrolytic degradation of contaminants and reduced mass transfer limitations. Yet, low electrocatalytic efficiency and stability, and high cost of electrode materials are hampering the implementation of 3D electrochemical systems.

In the scope of the ERC Starting Grant ELECTRON4WATER, we are developing 3D electrode materials based on low-cost synthesis process, which are tailored for different water treatment applications (e.g, removal of sulfide from wastewater, removal of perfluorinated compounds from groundwater, removal of persistent organic contaminants from wastewater). For example, Mn-oxide based electrodes were developed for selective and reversible oxidation of sulfide from wastewater to sulfur (Sergienko et al, 2020, Appl. Cat. B Environ.). Although Mn oxide-coated electrodes have been extensively investigated and applied in batteries, this study is the first one to employ Mn-based nanostructured material for electrochemical wastewater treatment. We have also developed graphene-based sponge materials for their use as both cathodes and anodes in small, one-pass, flow-through electrochemical filter units that can treat even low conductivity water (e.g., drinking water) (Pires et al, ACS Nano, submitted). One major advantage of the developed graphene sponges is that they do not produce chlorine, chlorate or perchlorate, while oxidizing the persistent contaminants present at trace concentrations in the water. Thus, this material overcomes one major limitation of electrochemical systems – production of toxic chlorinated byproducts in the presence of chloride, and thus has the potential to strongly influence future research on novel electrode materials for electrochemical water treatment.

While nanostructured carbon- and meta-based electrode materials have been the primary research interest across many fields of material science, such as supercapacitors, batteries, solar cells, and sensors, they haven´t been explored as much for environmental applications. In the ELECTRON4WATER project, we are conducting interdisciplinary research and using the findings achieved in other fields of science to contribute towards further development of electrochemical water treatment systems and their application in a wider scale.

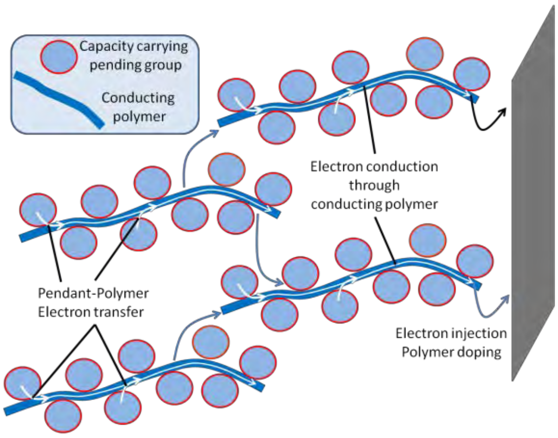
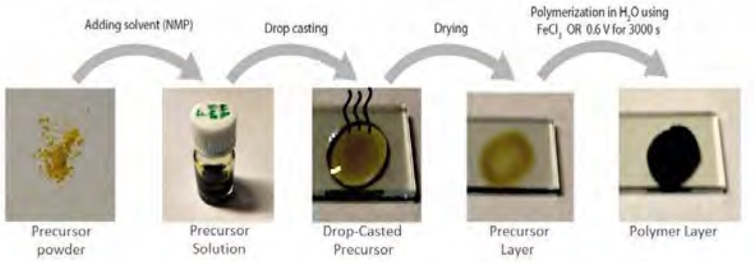
Designing Quinone-based Conducting Redox Polymers specifically for Aqueous Proton Batteries and for Lithium Ion Battery Cathodes

Martin Sjödin, Rikard Emanuelsson, Christian Strietzel, Huan Wang, Mia Sterby and Maria Strømme
Uppsala University, Dept. of Materials Science and Engineering, Div. of Nanotechnology and Functional Materials
Box 534, SE-751 21 Uppsala, Sweden
martin.sjodin@angstrom.uu.se



Conducting redox polymers (CRPs) are conducting polymers that have been decorated with redox active functional groups and they provide an attractive alternative as organic matter based electrical energy storage materials. The purpose of the polymer backbone is two-fold, 1) it prevents dissolution of the redox group and, 2) it renders the material conductive. The redox active pendant groups, on the other hand, provide the material with a well-defined redox reaction as well as a high charge storage capacity. CRPs thus provide a solution to two of the most significant obstacles in achieving powerful and stable battery materials from organic compounds, i.e. materials dissolution and limited electronic conductivity while simultaneously providing a high charge storage capacity. For battery applications it is thus essential that the individual properties of the conducting polymer backbone and the redox group can be preserved and that they operate in synergy in the CRP. One prerequisite for synergetic polymer-pendant combinations is redox matching. As conducting polymers are only conducting in their charged state successful combinations rely on that the pendant group has a redox potential within the conducting region of the polymer backbone. In addition, the CRP must allow mass transport of ions, not only related to the cycling chemistry of the pendant group but also ions related to the doping of the polymer backbone. These requirements put significantly different demands on the polymer design for the development of aqueous proton batteries and for CRPs for lithium cycling cathodes. In this presentation specific CRP design-solutions will be presented that allow for the development of all-organic proton batteries [1,2] and for lithium ion CRP-battery cathodes [3].



In addition, a solution-processing method, termed Post Deposition Polymerization (PDP), for CRP-materials and the underlying principles and requirements for PDP will be presented. Importantly, in PDP the processing step occurs prior to polymerization. After depositing and drying of the repeat-unit precursor onto a substrate polymerization is achieved by oxidative polymerization of the precursor. The PDP-method opens up for a scalable method for the coating of CRP materials onto any substrate and can, for instance, be used to make nanostructured CRP materials.

Guiomar.Hernandez@kemi.uu.se

Eliminating fluorinated electrolytes, susceptible to release toxic and corrosive compounds such as HF, is one step towards more environmentally friendly and safer batteries. Yet, fluorine-containing electrolytes are often considered necessary for enhanced battery performance.[1] Alternatively, replacing the state-of-the-art $LiPF_6$ with fluorine-free salt would reduce cost, increase safety and decrease toxicity, both in the manufacturing and recycling processes.[2] Furthermore, additives in the electrolyte needed to form a stable solid-electrolyte interphase (SEI) are another common source of fluorine, for example fluoroethylene carbonate (FEC), which is particularly important for silicon-based electrodes as they suffer high volume changes upon cycling.[3]

Herein, we investigate the effects of electrolyte fluorination for full cells combining silicon-graphite composite electrodes with $LiNi_xMn_yCo_zO_2$ cathodes, by means of electrochemical testing and post-mortem analysis. The fluorine-free electrolyte is based on lithium bis(oxalato)borate (LiBOB) salt and vinylene carbonate (VC) as SEI-forming additive, while the fluorinated electrolyte is based on the conventional $LiPF_6$ salt with FEC and VC additives. Our results show that although the SEI composition on the anode is very different, both electrolyte formulations are able to stabilise silicon-based electrodes and support stable cycling in full cells (Figure 1). Therefore, fluorine-free alternatives are good candidates for high-energy-density full cells opening new possibilities towards safer, more sustainable and less toxic batteries.

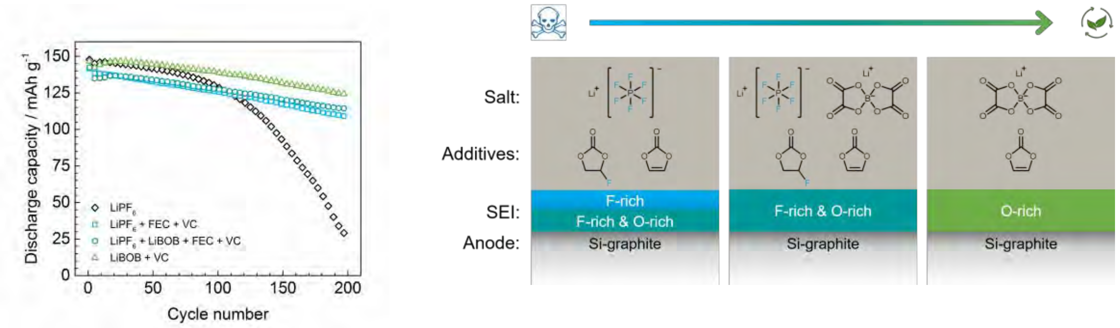

Figure 1. (Left) Discharge capacity of full cells containing different electrolytes: $LiPF_6$ (black rhombi), $LiPF_6$ with FEC and VC additives (blue square), $LiPF_6$ and LiBOB with FEC and VC additives (teal circles), and LiBOB with VC additive (green triangles); and (right) schematic representation of cell constituents and SEI composition.

Abstract

Cationic diodes based on Nafion ionomer coated microhole array substrates are combined with an anion conducting membrane to give an AC-electricity driven desalination or salination system. The combination of cationic diode with anionic resistor allows a 3D-printed four-chamber system to be configured with two internal chambers to extract and/or accumulate salt. Three configurations are demonstrated combining desalination and salination for an aqueous 250 mM NaCl solution. For a proof-of-concept device, 50% desalination/salination is demonstrated. The charge efficiency is estimated to be only 12%, limited mainly due to (i) resistivity lowering rectification, (ii) rectification ratio limitations for the array of microholes, (iii) insufficient stability of ionomer membranes under AC-pulse-driven operation. Perspectives for improvements and for future desalination/salination applications are given.

Reconstitution of *Escherichia coli* ATP-Synthase on Gold Electrodes for Potentiometric Detection of ATP

Modification of electrode surfaces with floating phospholipid bilayers as biomimetic membranes allows reconstitution of membrane-bound enzymes on a controlled way for electrochemical applications. In this way, the catalytic activity of the enzymes associated to transport processes across the biomimetic membrane is combined with the sensitivity of electrochemical detection [1-3].

We report a potentiometric biosensor based on ATP-synthase from *Escherichia coli* reconstituted in a floating phospholipid bilayer over gold electrodes modified with a 4-aminothiophenol self-assembled monolayer. The use of a pH-dependent redox probe on the electrode surface allows a simple, specific and reliable on site determination of adenosine triphosphate (ATP) concentration from 1 μM to 1 mM. ATP is a key molecule as energy vector for living organisms, therefore its detection reveals the presence of microbial colonies. Environments where the existence of microbial pathogens suppose a health hazard can benefit from real time monitoring of such molecule. The broad range ATP biosensor can offer an alternative way of measuring in a few minutes the presence of microbial contamination [4].

Lubricin, an Antifouling Coating for Electroactive Surfaces

Pauline E. Desroches, Anita F. Quigley, Robert M. I. Kapsa, Simon E. Moulton, Saimon M. Silva, George W. Greene
Institute for Frontier Materials, Deakin University, Burwood Campus, 221 Burwood Highway, Burwood, Victoria 3125, Australia

pdesroches@deakin.edu.au

Electroactive surfaces are a significant component in numerous biomedical applications, such as biosensors and implantable devices used as bionic neural interfaces or controlled drug release platforms. The performance and charge transfer efficiency of electrode surfaces, however, can be significantly affected by the fouling caused by non-specific adsorption of proteins at the surface. These adsorbed proteins act both as a passivation layer and an anchoring point for the further attachment of cells. Likewise, the grafting of traditional anti-adhesive coatings to electrode surfaces, typically charge-neutral polymers such as polyethylene glycol or dextran, often lead to the same electrical passivation effects as the proteins they are protecting against[1].

Conductive polymers (CPs) are an attractive material for sensors and neural interface applications due to their high impedance, ionic and electric conductivity, mechanical softness, and actuation response to applied voltages enabling controlled drug release[2]. Unfortunately, CP surfaces are particularly prone to protein fouling when exposed to biological fluids (e.g. blood, perilymph, saliva) leading to compromised performance and shortened working lifespans[3].

In this work, the issue of fouling is addressed by using lubricin (LUB). LUB, a self-assembling glycoprotein and major biolubricant molecules[4] presents promising properties for use as an anti-fouling agent on bionic electrodes. This includes inherent biocompatibility, protein and cell adhesion resistance. LUB coatings have recently been shown to prevent fouling of platinum, gold, and carbon electrodes with minimal impact on electrode electrochemical activity (i.e. passivation)[5,6]. Notably, this work explores the application of LUB with electrochemically grown polypyrrole (PPy) electrodes and investigates several fabrication methods for incorporating LUB into the polymer structure. The PPy/LUB film structures were characterized along with its electrochemical and fouling resistance properties to assess its ability to protect electrode surfaces against the detrimental effects of biofouling in highly concentrates solutions of proteins and bodily fluids such as blood. Electrochemical characterization using $K_3[Fe(CN)_6]$ as redox reporter (Figure 1) suggested that the optimized LUB-coated conductive films exhibited anti-adhesive properties in fouling solutions. These results reveal the potential application of PPy/LUB film for bionic implant application.

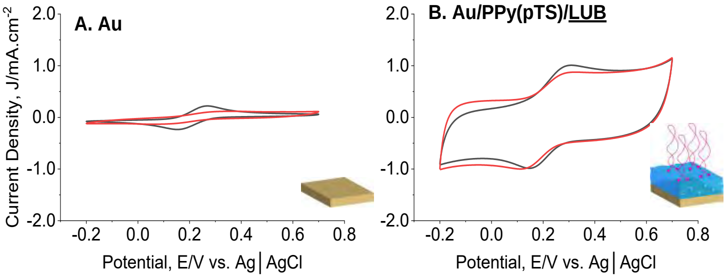

Figure 1: Cyclic voltammograms measured using a scan rate of 100 mV/s and coated gold WE of the oxidation-reduction of a 3.6×10^{-3} mM solution of $K_3[Fe(CN)_6]$ prepared in a nonfouling PBS solution before (black line) and after 2 hours (red line) incubation of BSA protein (5 mg/mL) for a bare gold electrode and a PPy(pTS) and LUB-coated gold electrode. The cycle is the last of 25 cycles

ARC Centre of Excellence for Electromaterials Science, Faculty of Science, Engineering & Technology, Swinburne University of Technology, Melbourne, VIC 3122, Australia - smoraessilva@swin.edu.au

Glucose meters are medical devices that demonstrates the enormous potentiality of electrochemical sensors to operate in whole blood and other biological fluids. Nonetheless, the success of these medical devices has not yet been extended for many other biomarkers.[1] The main impediment to this technology is the nonspecific adsorption of biomolecules such as proteins or even whole cells, which leads to surface biofouling. Biofouling, in the case of electrochemical sensors, may cause a reduction in sensor selectivity by interfering with the interaction of target species with the electrodes surface, or may result in variations in sensor sensitivity by hindering electrode transfer pathway of redox active species.[2] This ultimately leads to sensors failure. In the case of glucose sensing, this issue could be resolved by using semi-permeable membranes that are permeable for glucose (as it is a small molecule) but halt proteins from reaching the sensor surface.[1] Nevertheless, a large number of clinically appropriate biomarkers are the same as the fouling species (i.e. proteins), hence semi-permeable membranes cannot be applied. Additionally, semi-permeable membranes are also themselves prone to fouling, reducing hence their transport properties. Therefore, a major issue to electrochemical sensing platforms that needs to function in biological fluids remains the biofouling of electrode surface. This highlights the need for development of sensor surfaces that can function in complex biological fluids for the analytical detection of biomarkers.

Here, we report the use of lubricin (LUB) in response to the biofouling issue. LUB is a cytoprotective glycoprotein present in synovial fluids and coating cartilage surfaces in articular joints.[3] LUB displays a distinguishing chemistry, conformational and molecular structure, and also the ability of self-assembling in a well-organized manner on substrates from different nature.[4] When attached to a conductive surface, LUB presents the capability of preventing biofouling and at the same time allows good electrochemistry with the advantage of a simple and one-step coating preparation.[5] This makes LUB an interesting surface coating for electrochemical biosensing. In this work, the detection of electroactive species, benzodiazepines, is reported. The prepared electrodes showed a good analytical response in biological fluids such as saliva and whole blood, being able to detect very low concentrations (as low as picomolar) of the investigated analytes. Square wave voltammetry was used as excitation technique for the quantification. In these sensors, LUB works as both, antifouling agent as well as an active component for the analyte detection. Aiming the compatibility with the point-of-care, reduced graphene screen-printed electrodes was used as a substrate to the LUB functionalization (Figure 1).

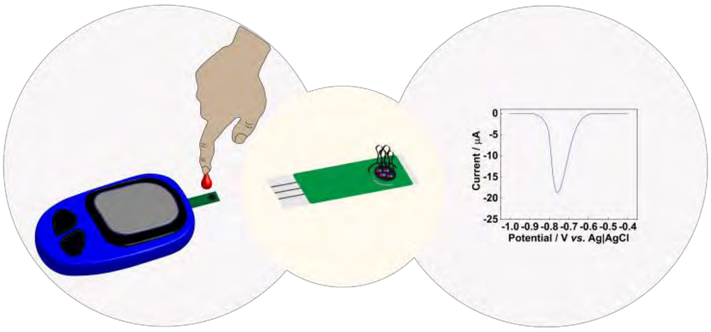

Figure 1 – Schematic representation of the sensing platform. LUB is self-assembled on a reduced graphene oxide to allow the detection of electroactive species in biological fluids. The excitation technique used for measurements is square wave voltammetry.

Toward the definition of new hybrid proton exchange membranes for PEMFC: from NMR molecular dynamic studies to electrochemical performances

Isabella Nicotera, Cataldo Simari, Ernestino Lufrano

University of Calabria

Department of Chemistry and Chemical Technology, Via P. Bucci, 87036 Rende (CS), Italy

isabella.nicotera@unical.it

Highly hydrophilic nanostructures, most of them layered-type (smectite clays, layered doubled hydroxide-LDH, graphene oxide-GO), have been properly synthesized and organo-functionalized to interact with a ionomer in order to prepare advanced nanocomposite membranes for PEMFC applications. As nanofillers in Nafion® polymer, they can modulate the nature of water confined in the nanosized ionic channels with the result that the hybrid membranes show high proton mobility in dehydrating state. Additionally, many efforts are devoted in the development of alternative ionomers to commercial Nafion, based on non-fluorinated macromolecules with adequate mechanical strength, high proton conductivity and stability in the aggressive environment of a working fuel cell. Studies on hybrid membranes based on sulfonated Polyethersulphone (PES) and Polysulfone (PSU) will be presented.[1,2]

The 2D nanofillers of interest are those with a layer-like morphology characterized by a high aspect ratio (large lateral dimensions and small thickness), and hydrophilic functional groups on the surface in order to provide more sites for the coordination of water molecules and to build long-range proton transfer pathways inside the membrane.

LDHs and smectite clays are anionic and cationic minerals, respectively, with a unique combination of swelling, intercalation and ion exchange properties. Appropriate organo-functionalizations by using simple chemical methods with organic/inorganic guest molecules have been operated. Noteworthy is a hybrid material obtained by rooting CNTs (decorated with RSO3H groups) on smectite plates, providing an outstanding effect on the protons transport in the nanocomposite membrane due to the formation of an appropriate network which favors the Ghrotthus-type mechanism.[3]

Graphene Oxide (GO) is characterized by the presence of oxygen–containing moieties, mostly hydroxyl, epoxy and carboxyl groups on the carbon sheets. Organo-modified GO was synthetized and tested as nanofiller for the creation of novel hybrid nanocomposites with enhanced proton transport.[4]

The barrier property of such 2D-materials was also valuated to reduce the methanol crossover (critical issue in the DMFCs). The exfoliation and dispersion of the layers throughout the continuous polymeric matrix can significantly increase the tortuosity of the methanol's diffusion path. Moreover, a higher order's degree in the arrangement of the filler's platelets, e.g. aligned parallel to the membrane surface, may further reduce the detrimental effect of the methanol permeation as a consequence of the greater obstruction and increased tortuosity of the fuel diffusion path.

With this aim, a mechanical alignment of GO and LDH lamellae within the polymer matrix has been attempted and anevidence of lamellae's alignment at the nanoscale was obtained through the Magnetic Resonance Imaging combined with Rheology (Rheo-MRI) technique, an effective and elegant method, as well as original for such investigations, to study the organization of nano-lamellae dispersed in a polymeric solution under the shearing.[5,6]

NMR was widely used to investigate molecular dynamics through direct measurements of self-diffusion coefficients (Pulse Field Gradient–PFG technique), relaxation times (T_1 and T_2) and spectral analysis, in order to achieve a systematic understanding at a fundamental level of the effects of dimensionality and organization of these nanofillers on the physico-chemical, mechanical and electrochemical properties of the membrane electrolytes.

Local Electrochemical Measurement with 3D Printed Solution Flow-type Microdroplet Cell

Kei Sakata, Bilal Muhammad, Masatoshi Sakairi
Graduate School of Engineering, Hokkaido University
Kita-13, Nishi-8, Kita-ku, Sapporo, Hokkaido, Japan
njuakeikei_429@eis.hokudai.ac.jp

Metal materials are widely used and have advanced properties, such as high strength, high corrosion resistance and flatness. Non-uniformity of materials play an important role in these properties. In order to investigate the non-uniformity, it is necessary to perform a higher resolution analysis. Therefore, electrochemical technology in a small area is required. One of the techniques is a electrochemical micro-cell. The electrochemical micro-cell has been attracting attention as a measurement method on a small surface area. The Electrochemical micro-cells are classified into two types, a meniscus type and a gasket type, due to the difference in the structure of the capillary tip and the sample electrode[1), 2)]. These two types of electrochemical micro-cells have enabled us to investigate small surface area. However, in these two types, when intense electrode reaction occurs, the change in the solution concentration near the sample surface becomes remarkable. In this case, a concentration gradient is generated in the solution inside the capillary, so appropriate measurement and chemical reaction cannot be performed. To solve this problem, Lohrengel et al. developed a gasket-type electrochemical micro-cell with a θ-shaped glass capillary[3)]. Solution supply and ejection could be performed using two channels. Fushimi et al. developed a dual capillary solution flow-type microdroplet cell (Sf-MDC)[4)]. It has a coaxial double tube structure in which two capillaries with different diameters are combined, the solution is supplied from the inner capillary, and the solution is collected by the outer capillary. Using Sf-MDC, Sakairi et al. controlled the area and thickness of porous-type aluminum anodic oxide[5), 6)]. Hashizume et. al. investigated SCC mechanism near fusion line by Sf-MDC[7)]. This Sf-MDC is very useful for various area selective electrochemistry applications. However, the structures of previous Sf-MDC are very complex and difficult to fabricate. Therefore, in this study, 3D printing was applied to fabricate Sf-MDC and local electrochemical measurements were carried out by fabricated Sf-MDC.

Sf-MDC was designed using computer-aided design software and fabricated by 3D printer. A platinum wire and an Ag / AgCl wire were inserted inside the cell as counter and reference electrodes. The cell equipped with the electrodes was attached to a microscope (Fig. 1). Using this setup, it was possible to control precisely the measuring position and carry out the area selective electrochemistry.

The surface state before and after the electrochemical measurements was observed, and the immersion potential measurements and the electrokinetic polarization measurements were performed on materials using 10 mM NaCl. The immersion potential and the polarization curves of aluminum alloys were observed. The obtained curves showed fluctuations, depending on the material location.

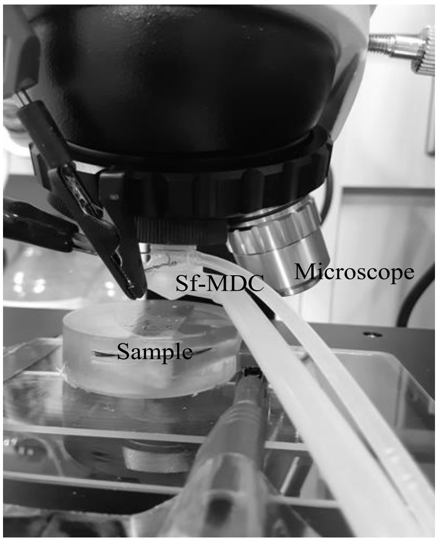

Fig. 1 Sf-MDC fabricated by 3D printer attached to optical microscope.

DNA/carbon-based super lattice electro active hierarchical self-assembled nano networke for biomedical detection and bio sensing

Aboulfazl Mirzapoor[1]
[1]Department of Nanobiotechnology, Faculty of Biological Sciences, Tarbiat Modares University, P.O. Box 14115-175, Tehran, Iran
a.mirzapour@modares.ac.ir

In this study, a new effective and DNA and DNA like polymer based self-assembled and hierarchical nanostructures was designed that can be used for bio sensing applications. SWNT-DNA hybrid Nano structure fabricates by region selective covalent combined between DNA and SWNT Nano particles These hybrid Nano structures have different electrochemical properties compare of alone SWNT and DNA single strand. Electrochemical behavior of SWNT-DNA hybrid Nano structures are studied by cyclic voltammetry and impedance spectroscopy technique. Due to wire shape SWNT-DNA hybrid Nano structures have favorable electrical properties could be used in fabrication of genomic biosensor which was detected mismatch and abnormality in ds-DNA. In other attempt, a three-dimensional (3D) hierarchical architecture for aerographite bio electrodes was fabricated by template-directed self-assembly. The superlight aerographite was functionalised with guanine (G) rich polymer loaded with glucose oxidase (GOx) thorough π-π interactions of electron pairs of the guanine ring and the electron cloud of aerographite. These superlight and hierarchical graphene based nanostructure detected glucose in solution with satisfy sensitivity.

The diferrocenylborinic acid (Fc_2BOH) contains two interconnected and communicating redox centres. The boron bridge between two ferrocenyls is able to interact with other analytes as nucleophiles, diols etc. [1] The main aim of our work was to describe the fundamental electrochemical behaviour of such system with two redox centres in relation to model analytes as fluoride. We also wanted to widen knowledge about intramolecular communication between joint redox centres.

Fc_2BOH has been synthesized in good yield *via* an improved synthetic path. Its physicochemical characterisation was carried out using NMR, HRMS, FTIR, X-ray crystallography, and then by electrochemical methods. These revealed the desired two one-electron oxidation processes for the two electronically coupled ferrocenyl moieties. The redox properties of Fc_2BOH in homogenous phase (organic media) was contrasted to those in heterogeneous phase. For this purpose, a new concept of modification of electrode recently developed by Marken's group [2] has been utilized – Fc_2BOH was incorporated into a lamellar film of 2D titanate nanosheets on a glassy carbon electrode. Data from cyclic voltammetry and from square wave voltammetry confirmed that the bridging boron can bind to nucleophiles (hydroxide, fluoride) upon oxidation of the ferrocenyl groups.

An immobilization in 2D-titanate nanosheet film has proven as a good modification technique as these were successfully employed to host Fc_2BOH on a glassy carbon electrode. In the presence of disodium sulphate in aqueous electrolyte, a stable reversible voltammetric response was observed. In the presence of sodium fluoride, "bound" and "unbound" states of Fc_2BOH were observed at higher scan rates (above 0.1 Vs^{-1}). Mechanism of interaction has been proposed and discussed and sensing applications suggested.

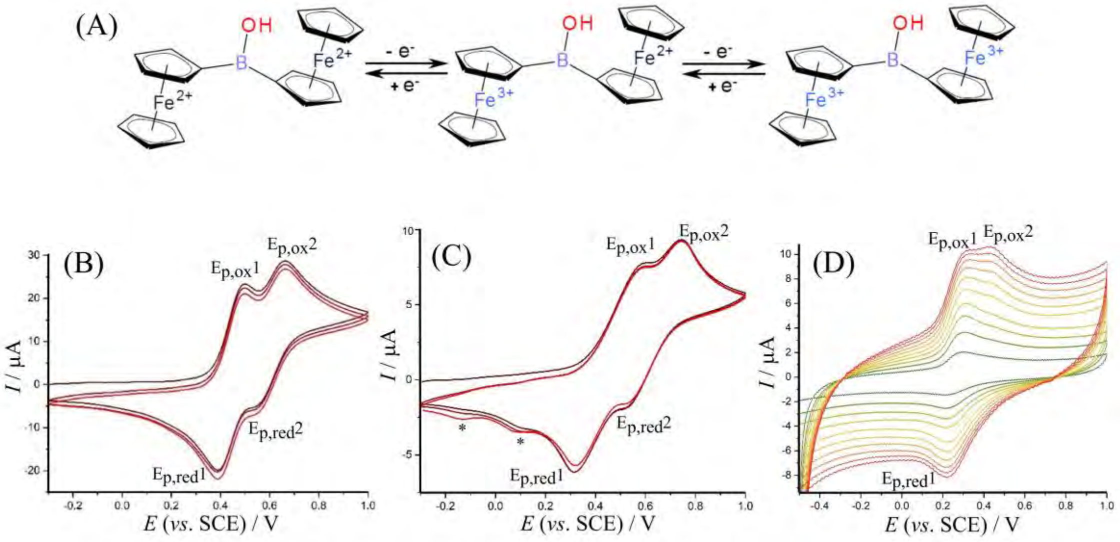

Figure: Redox properties of Fc_2BOH (A) in homogenous (B – in acetonitrile, C – in dichloromethane) and heterogeneous phase (D – immobilized in 2D-titanate nanosheets).

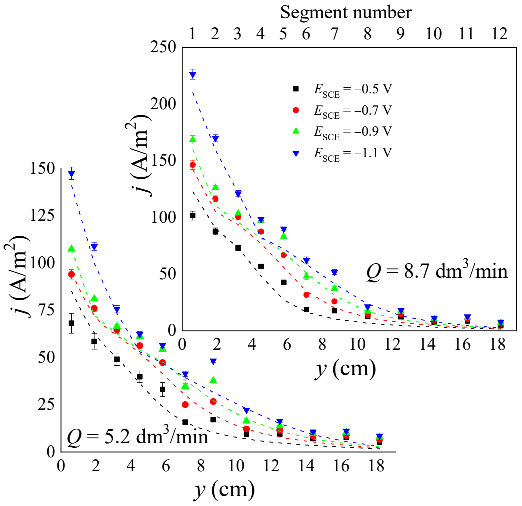
Modified Hydrocyclone as Electrochemical Reactor: Modelling, Characterization and Applications

A. N. Colli, J. P. Fornés, O. González Pérez, J. M. Bisang
Universidad Nacional del Litoral, CONICET
Programa de Electroquímica Aplicada e Ingeniería Electroquímica (PRELINE)
Facultad de Ingeniería Química, Santiago del Estero 2829, S3000AOM Santa Fe, Argentina
e-mail address: ancolli@gmail.com

Many electrochemical industrial processes take place under a mixed kinetic control, such as: electrochemical wastewater treatment or inorganic-organic electrosynthesis. These situations demand for extensive research efforts in order to develop electrochemical reactors with good mass-transfer conditions. Thus, it is pretended to maximise the space time yield of the reactor and to become more uniform its potential distribution with the aim of to avoid, as much as possible, the presence of secondary reactions or electrode degradation.

Hydrocyclones are often used in the chemical industry when different phases need to be separated. These devices are characterised by their constructive easy, without moving parts, and simple operation. The double helical flow existing in the interior of a hydrocyclone suggests improved mass-transfer conditions. Thus, it has been proposed as an electrochemical reactor,[1] being the cylindrical-conical casing operated as working electrode whereas the counter electrode is placed at the overflow. The proposal has two additional aspects: (i) if a solid is produced at the working electrode, depending on particle size, it can be separated from the spigot and (ii) the hydrocyclone shows a low-pressure region in its central part, known as air core, which becomes appropriate for the introduction of a gas phase. Therefore, it can be considered as an alternative reactor for a two-phase operation.

In this work, a mathematical model to calculate tertiary current distributions in electrochemical reactors is presented taking into account the potential and concentration fields together with the hydrodynamics under laminar or turbulent conditions. Multiple reactions with different kinetic controls are considered at both electrodes. The computational algorithm solving the model was implemented in OpenFOAM.



The model was validated by using some test reactions from dilute solutions employing a supporting electrolyte,[2] but also without it in order to study the effect of ionic migration. The experiments were carried out in a modified hydrocyclone with a segmented cathode, 12 segments. A close agreement between experimental and predicted current distributions was obtained as it can be concluded from the figure on the left-hand side, which compares theoretical, dashed lines, and experimental, points, current distributions for different values of both volumetric flow rate and applied cathodic potential. In the figure, the test reaction was ferricyanide reduction.

The modified hydrocyclone was also examined as an alternative reactor for the electrochemical processing of two-phase systems. Experimental measurements demonstrate an appropriate hydrodynamics of the equipment. Mass-transfer measurements corroborate the good performance of the cylindrical body of the hydrocyclone. Copper electrodeposition[3] and sulphur dioxide reduction to colloidal sulphur[4] were used to check the behaviour of the reactor, being it promising for these tasks.

New tools for the rational development of metal-sulfur batteries

Rinaldo Raccichini, Liam Furness, James W. Dibden, Nina Meddings, He Li, John Lampkin, John R. Owen, and Nuria Garcia-Araez
University of Southampton
Highfield Campus, SO17 1BJ, Southampton, United Kingdom
n.garcia-araez@soton.ac.uk

Metal-sulfur batteries have an outstanding theoretical specific energy, but their development is hampered by their complicated and not fully understood reaction mechanisms, in which a variety of polysulfide species are formed in the pathway of the reduction of sulfur to metal sulfide. Performance improvements can be obtained by tuning the electrolyte properties, e.g., in terms of polysulfide solubility/speciation. Consequently, in order to guide a rational method for electrolyte optimization, we have developed a reliable analytical method that enables the determination of the total solubility of polysulfide species and the average chain length of polysulfide species in the polysulfide solutions, which are key properties that critically affect battery performance and, in particular, the role of polysulfide species as intermediate species [1].

However, the performance of metal-sulfur batteries is also critically affected by the interplay between electrolyte formulation and electrode composition. To study such effects, we have recently demonstrated the use of a simple impedance-based method of analysis of porous electrodes, using a transmission line model with only two fitting parameters, to quantify the rate of ion transport within the porous electrode, which we have shown is a key property determining the electrode performance [2,3]. Figure 1 illustrates the physical meaning of the model, with electrons travelling through the carbon conductive additive (in **black**) and ions (e.g., Li$^+$) travelling through the electrolyte filling the pores (in **blue**). Interestingly, we found that the electrode/electrolyte combinations that resulted in faster ion transport were also the ones leading to optimal battery performance, thus providing the bases for the rational design of high-performance batteries.

For the direct detection of polysulfide species formed during the operation of metal-sulfur cells, we have also developed a novel cell design incorporating a reliable and highly sensitive electrochemical sensor. With the use of a glassy carbon sensor material, the detection of polysulfides is achieved with unprecedented sensitivity [4,5].

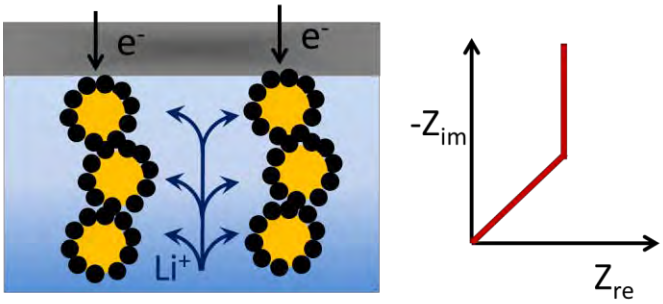

Figure 1. Illustration of the meaning of the transmission line model used to characterize sulfur-carbon composites for Li-S battery applications and Nyquist plot of the associated impedance spectrum.

Giulia.Moggia@uantwerpen.be

The ambition to convert our fossil-fuel economy into a decarbonized economy will inevitably pass through the use of renewable energy platforms, such as wind, water, sun and nuclear fission. Similarly, also the production of chemicals is meant to reduce its dependence on a petroleum based feedstock, promoting instead the use of bio-waste (up to 138 million tons per year in the European Union [1]), which seemly fits in the concept of circular economy. The selective oxidation of glucose to gluconic acid, and its subsequent oxidation to glucaric acid are potentially key steps in the biomass-to-chemicals value chain for the numerous application of glucaric acid, for example, in the production of metal complexation agents, biodegradable polymers and detergents [2]. Nowadays the major challenge for the bio-based chemical production of glucaric acid is the lack of a suitable conversion technology [3]. Especially when compared to the already settled petrochemical technologies based on fossil resources, the conversion of renewable carbon to chemicals is the most undeveloped and complicated of all biorefineries [3]. The most promising technique up-to-date is the electrochemical oxidation, which involves the transfer of electrons in the reactions, eliminating the use of high O_2 partial pressure or of hazardous oxidants. Additionally, it can be operated under mild conditions and allows control over the selectivity by tuning the electrode potential. In our recent work we demonstrated the correlation between the oxidation potential and the reactivity of the functional groups of glucose for three selected metal electrodes [4]. The best selectivity to the products of interest was obtained on gold where a low oxidation potential (0.55 V_{RHE}) leads to the selective production of D-gluconic acid, while a more positive potential (1.30 V_{RHE}) promotes the further oxidation to D-glucaric acid [4].

Here, we investigated the impact of the operational parameters (pH, substrate concentration, cell voltage, temperature and reaction time) on the two oxidation steps separately (respectively starting from glucose and gluconic acid) with as final aim to identify those conditions that ensure an optimal selectivity to glucaric acid. Our results show that while the selectivity of the first oxidation step is highly dependent on the pH and temperature of the electrolysis, the second step is mainly affected by the applied potential during the electrolysis experiment. The best selectivity that could be obtained in the first oxidation step to gluconic acid was 97.6%, at 0.55 V_{RHE}, 5°C and pH=11.3; and in the further oxidation to glucaric acid was 89.5% at 1.10 V_{RHE}, 20°C and pH=12.5.

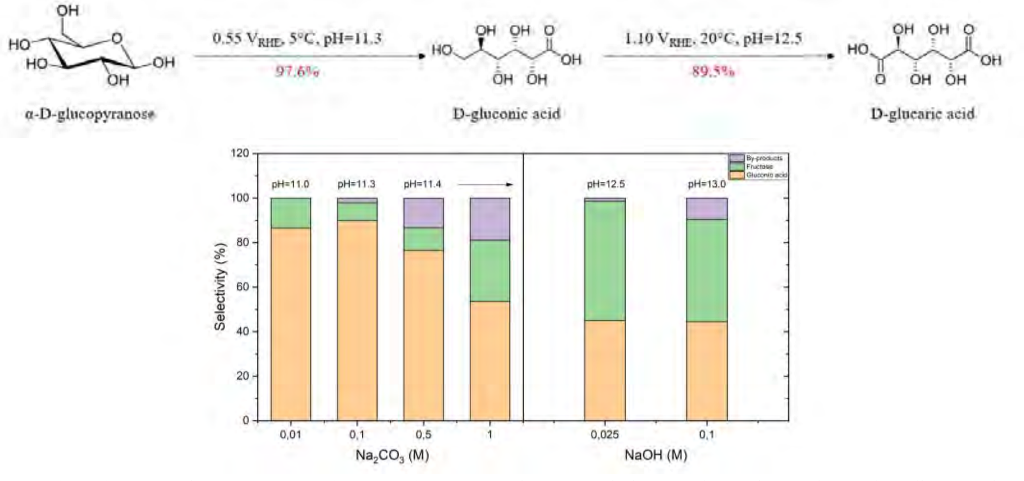

Figure 1: (Top) Reaction scheme, (bottom) change in selectivity as function of pH for first oxidation

DNAzyme Based Sensor for the Detection of Metal Ions in Solutions Using Resistive Pulse Sensing

Imogen Heaton, Mark Platt
Loughborough University
Department of Chemistry, Epinal Way, Loughborough LE11 3TU
i.heaton@lboro.ac.uk

Based on the Coulter counter principle, resistive pulse sensing (RPS) measures particles on a particle by particle basis as they traverse a nanopore providing information on particle size, concentration and charge. RPS has been used to measure a large variety of analytes such as proteins, DNA, and metal ions. The use of DNAzymes for the detection of metal ions has been demonstrated for multiple targets.

Currently most strategies rely on the use of fluorescence to measure the cleavage of DNA upon target metal binding. RPS offers a label free sensing method as it can resolve the changes from ssDNA to dsDNA. Here we develop the use of DNAzymes with RPS technologies for the detection of calcium ions in solution.

We present the initial testing which indicates the ability to measure calcium ions binding with our DNAzyme before the DNA undergoes re arrangement as demonstrated through changes in the particle speed, figure 1b. We demonstrate the change in speed to be proportional to the amount of Ca2+ present, figure 1d, and our assays selectivity over a mixture of other metal ions. The work allows for future development of the assay for environmental testing and the ability to multiplex it previously designed metal ion aptamers.

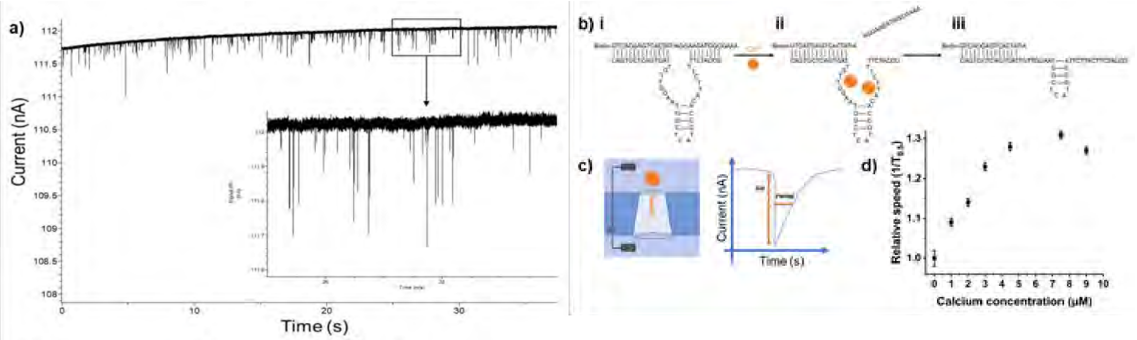

Figure 1. (a) Example of a baseline current and blockade events caused by the carriers translocating the pore, inset showing 25 – 30 s. (b) Schematic of the DNAzyme binding with Ca2+ ions before rearranging. (c). Schematic of a particle traversing the RPs device and the signal produced. Blockade magnitude Δip, and full width half-maximum are shown. (d) Relative particle speeds normalised to blank DNAzyme functionalised particles vs. varying amounts of Ca2+ ions from 1 – 9 µM.

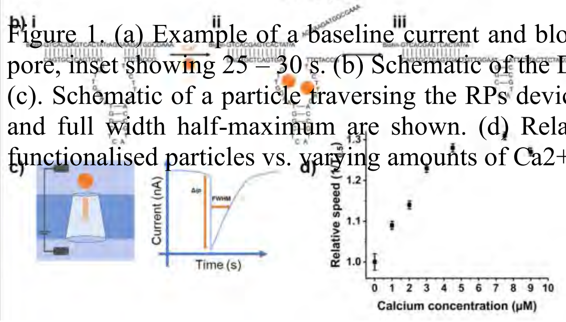
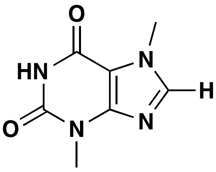


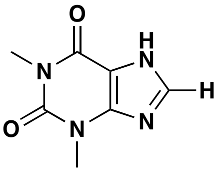
Natural Methylxanthines: Multifacet Starting Materials in Electroorganic Synthesis

Marta Feroci
Dept. Scienze di Base e Applicate per l'Ingegneria (SBAI), Sapienza University of Rome,
Via del Castro Laurenziano, 7, 00161, Rome, Italy
marta.feroci@uniroma1.it

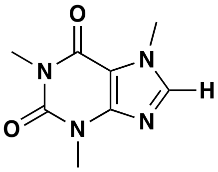
Natural methylxanthines (caffeine, theophylline, theobromine) are abundant natural compounds present in more than 60 plants, cocoa, tea and coffee among the most famous. They can be thus considered renewable bio-based reagents.



Theobromine



Theophylline



Caffeine

Their stucture (uracil and imidazole fused rings) can, in principle, be transformed into many different derivatives, not only by functionalization of the nitrogen atoms, but also by opening of one of the two rings. Nonetheless, methylxanthines are molecules particularly resistant to ring chemical transformations, needing very harsh conditions to open one of the two rings.

In this context, electrochemistry can play an important role as it allows the methylxanthines structure transformation under quite mild conditions.

Although the anodic oxidation of these natural compounds is by far the prevalent electrochemical reaction reported in the literature (and widely used in electrochemical sensors), also their reduction is possible, both in the absence and in the presence of the imidazole nitrogen alkylation prior to the cathodic reduction.

This presentation will deal with the various possibilities to transform theophylline and caffeine by electrochemical means, by both anodic and cathodic reactions, evidencing analogies and differences with the reactivity of the same species carried out by classical chemical reactions.

Monitoring of Vancomycin and Gentamicin Treatment Using Electrochemical Sensors

Bogdan Feier, Adrian Blidar, Cecilia Cristea
"Iuliu Hațieganu" University of Medicine and Pharmacy, Department of Analytical Chemistry
No. 4, Pasteur str., 4000349, Cluj-Napoca, Romania
feier.george@umfcluj.ro

Vancomycin (VAN) is a glycopeptide antibiotic, with bactericidal action towards Gram-positive bacteria, in particular enterococci, streptococci and staphylococci. VAN is indicated parenterally for the treatment of severe infections caused by bacteria resistant to other antibiotics and for the prophylaxis of postoperative infections [1]. Gentamicin (GEN) is an aminoglycoside antibiotic, widely used as prophylaxis and treatment in many clinical situations, like severe infections with a wide range of Gram-negative bacilli, against staphylococci and certain mycobacteria [2]. The treatments with VAN or GEN can lead to ototoxicity, nephrotoxicity and bacterial resistance to antibiotics, needing a therapeutic monitoring of these antibiotics that maximizes efficacy, reduces toxicity and the spread of the antibiotic resistance.

The purpose of this study was the development of fast and sensitive methods for the electrochemical analysis of VAN and GEN from biological samples (human serum and urine).

Two strategies were used for the electrochemical detection of VAN. First, involving a battery of tests, the complex electrochemical fingerprint (CEF) of VAN was achieved, incorporating the electrochemical behavior of VAN at different commercially available screen printed electrodes, at several electrolytes, at successive analyses, after simple pretreatment, using both the anodic and cathodic peaks.

The second method was based on the interaction between VAN and gold. Thus, a hybrid graphene-gold nanostructures electrode was employed for the direct VAN detection by anodic oxidation and for the indirect VAN detection, using the electro-active gold nanostructures as probe to monitor the changes in their cathodic signal due to the interaction between gold nanostructures and VAN.

In order to explain the electrochemical behavior of vancomycin, the mechanism of the VAN anodic oxidation was elucidated by high performance liquid chromatography coupled with mass spectrometry analyses of the products obtained after small scale electrolysis and a two-step electrochemical-chemical mechanism was proposed.

The electrochemical behavior of GEN was studied using different electrochemical techniques, different electrolyte solutions and several screen printed electrodes (SPE): carbon-based (C-SPE), graphene-based (G-SPE), platinum-based (Pt-SPE), gold-based (Au-SPE) and carbon-based modified with gold nanoparticles (AuNP-SPE). A sensitive and selective electrochemical method was developed using the GEN anodic oxidation in alkaline medium at the C-SPE.

To facilitate a fast and simple electrochemical detection of VAN and GEN from human serum and urine, different treatments of the biological samples were tested. The human serum and urine containing Van or GEN were treated with different protein precipitation agents, liquid-liquid extraction and different solid phase extraction procedures and the influence of each treatment on the electrochemical signal of VAN or GEN and of the interferents was tested. Also, the electrochemical analysis of VAN and GEN from human serum and urine was optimized in terms of electrode material, electrolyte and electrochemical technique in order to eliminate/diminish the electrochemical signal of the interferents from these complex matrices.

The anodic oxidation behavior of Fe-6Cr during potentio-dynamic polarization in pH 4.5 Na_2SO_4 solution was investigated by electrochemical ellipso-microscopy. Active, passive, and trans-passive states of the Fe-6Cr surface showed heterogeneous oxidation behaviors depending on the substrate micro-structure, electrode potential and solution convection. Enhancement of mass-transport by solution injection in the latter half of the active state resulted in acceleration of passivation of the Fe-6Cr surface. The passivity-current density of the surface passivated by intentional convection was reduced to almost half of the current density of the surface that had been in the passive state in a stagnant solution, and the surface passivated by intentional convection showed better resistance against pitting in a chloride-containing solution. The improvement of passivity of the surface was attributed to the formation of a Cr-enriched passive film by a decrease in the thickness of the diffusion layer in the latter half of the active state.

Electrochemical imaging of E.coli biofilms using Soft-Probe-Scanning Electrochemical Microscopy

Biofilms are slimy layers composed of attached microbial cells, which are embedded in a matrix of extracellular polymeric substances providing protective functions. Biofilms secreted by the microbes play a major role in the manifestation of severe infectious diseases. It has been estimated that about 80% of chronic microbial infections in the human body are due to bacterial biofilm formation. Biofilms are of serious universal concern because they provide increased protection against antibiotics, which can be 10-1000 times higher than observed in free-floating cells. They represent also a host defense system against competing microbes and external physical and chemical factors.[1] Biofilms are usually analyzed by using fluorescence imaging, which has limitations because it does not allow long-term observations of different biofilm developmental stages. Here we demonstrate that electrochemical detection is a suitable method to overcome this limitation.

We present electrochemical imaging of *E. coli* biofilm development and long-term monitoring of biofilm metabolic activities using soft-probe scanning electrochemical microscopy (SECM). Soft probes are made of thin flexible insulating plastic films with embedded carbon microelectrode. They are brushed in a gentle contact mode over the biofilm surface guaranteeing a constant working distance while the biofilm remains intact. Biofilms were grown for up to ten days on various substrates including glass, plastics and metals. The oxidized form of redox-active species was reduced by the metabolic activity of the biofilm. This allowed SECM feedback mode imaging (Fig. 1). Finally, the advantages and perspectives of using soft probes towards the potential mapping of metabolic communication molecules in biofilm communities will be discussed. Finally we aim at developing methodologies for using electrochemical methods for the disinfection of bacterial biofilms.

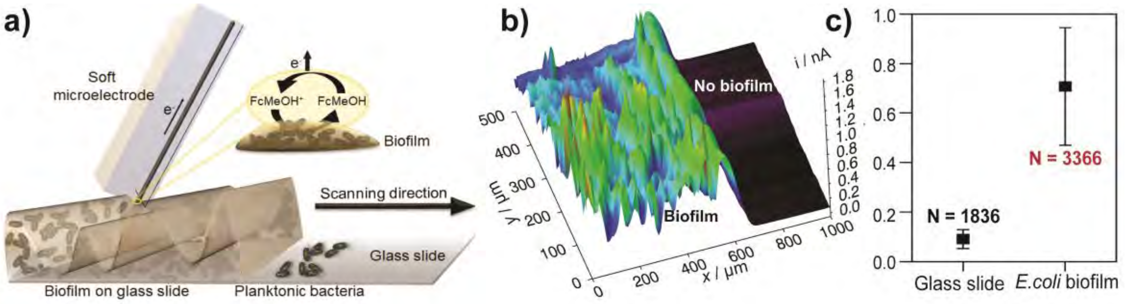

Figure 1. a) Schematic representation of SECM feedback mode imaging of a biofilm using FcMeOH as redox mediator. b) Feedback mode Soft-Probe-SECM image. c) Mean currents ± standard deviation values over the *E.coli* biofilm and bare glass. Experimental details: working potential $E_T = 0.4$ V, probe translation speed = 25 µm/s, step size = 10 µm, 2.5 mM FcMeOH in 100 mM PBS (pH = 7.4).

Multifunction Nanostructured Coatings for Corrosion Protection. Contribution to a Sustainable Technology

Mário G. S. Ferreira, João Tedim
mgferreira@ua.pt

Department of Materials and Ceramic Engineering, and CICECO – Aveiro Institute of Materials,
University of Aveiro, 3810-193 Aveiro, Portugal

The active corrosion protection of metallic substrates can be achieved by addition of corrosion inhibitors to protective coatings. However, direct mixing of an inhibitor with coating formulations can lead to important drawbacks decreasing barrier properties of the coating and diminishing activity of the inhibitor. Also, soluble inhibitors can cause phenomena like osmotic blistering or be leached out spontaneously to the environment, which limits long-term performance and is environmentally pernicious. To overcome this problem and have controlled release of inhibitor different strategies of inhibitors storage in nanocontainers have been developed in order to produce smart self-healing coatings. Successful use of this technology could allow the replacement of Cr VI traditionally used in coatings and other surface treatments, as this is a hazardous health and environmental product.

In this work novel protective nanostructured coatings with self-healing ability are presented. This effect is obtained on the basis of nanocontainers that release entrapped corrosion inhibitors in response to local pH changes or presence of corrosive species. The development of new nanocontainers for organic and inorganic green corrosion inhibitors is described, especially the most promising from industrial point of view, based on Layered Double Hydroxides (LDH). The combination of different of these nanocontainers in the same coating system has proved to be effective to accomplish further functions as antifouling and sensing. Potential use of materials that exist in nature will also be reviewed.

Electrochemical Plasmonic Optical Fiber Probe for Real-time Insight into Coreactant Electrochemiluminescence

Jingxian Yu,[1] Peipei Jia,[1] Shengping Wang,[2] Heike Ebendorff-Heidepriem,[1] and Andrew D. Abell[1]
[1] ARC Centre of Excellence for Nanoscale BioPhotonics (CNBP), Institute of Photonics and Advanced Sensing (IPAS), School of Physical Sciences, The University of Adelaide, SA 5005, Australia
[2] Faculty of Materials Science and Chemistry, China University of Geosciences, Wuhan 430074, China
E-mail address: jingxian.yu@adelaide.edu.au

Electrochemical surface plasmon resonance (ESPR) is a powerful technique for defining dynamic changes in chemical composition and morphology of functional interfaces by correlating spectral information with voltametric characteristics of the electrode processes.[1, 2] However, conventional Kretschmann prism-based surface plasmon resonance (SPR) configurations require sophisticated apparatus and complex optics. Here, we present a versatile flow injection ESPR device that incorporates a plasmonic and conductive fiber optic probe, for which a gold nanohole array film is integrated onto the endface of a conventional optical fiber via template transfer. The coreactant-based $Ru(bpy)_3^{2+}$ / tripropylamine (TPrA) electrochemiluminescence (ECL) system, is chosen to unravel electrochemically-induced real-time interfacial information, since such an approach is increasingly employed for clinical assay analysis and the associated ECL mechanism is an active area of investigation. The ESPR observations provide novel experimental evidence to support the proposition that ECL reactions undergo an oxidative-reduction pathway. Moreover, the ESPR peak shift exhibits a broader linear detection range of TPrA concentration (0 - 20 mmol L^{-1}), compared to the ECL and SPR techniques. This study clearly demonstrates that the novel fiber optic ESPR device presents as a reliable and multimodal spectroelectrochemical platform to gain mechanistic insights into complicated chemical processes and provide sensing capabilities, while offering great simplicity, portability and miniaturization.

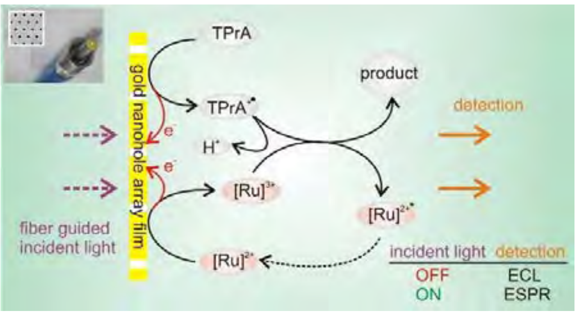

Figure 1. (Top-left) SEM image of the gold hexagonal nanohole array film and optical fiber tip after a gold nanohole film transferred. (Centre) Fiber optic ESPR device, and oxidative-reduction pathway for the coreactant ECL system. (Bottom-right) Multiple modes for signal detection.

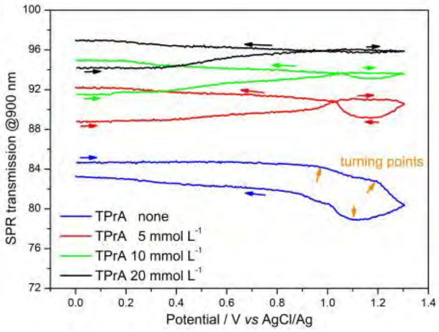

Figure 2. SPR transmission intensities at 900 nm in 1.0 mmol L^{-1} $Ru(bpy)_3Cl_2$ and 0.1 mol L^{-1} PBS (pH = 7.4) solutions containing a varied concentration of TPrA at a scan rate of 50 mV s^{-1}.

Teaching electrochemistry without Fake News

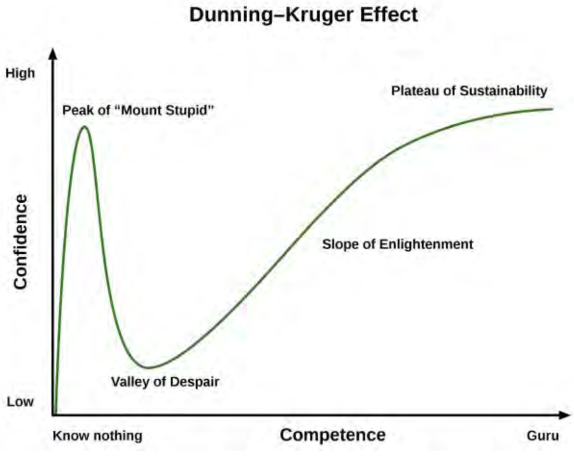
Hubert H. Girault,
Laboratoire d'Electrochimie Physique et Analytique
Ecole Polytechnique Fédérale de Lausanne, CH-1951, Sion, Switzerland
Hubert.girault@epfl.ch

As the teaching support of electrochemical science has moved from textbooks, to slides and on-line information providers, many concepts of electrochemistry have become simplified to the point of becoming totally wrong.
Indeed, a textbook usually took many years of preparation and was thoroughly reviewed. The information was reflecting the knowledge of the time but could generally be trusted. Nowadays, fewer textbooks are published and many teachers gather their teaching material from on-line sources.

Here, we shall review some FAKE NEWS that propagate through the literature and unfortunately to lecture notes.

The most damaging fake news is that of the HOMO-LUMO semantic to express the redox stability of an electrolyte in a battery. It started in a publication from well-known scientists and propagated virally.
Another fake news is again a HOMO-LUMO semantic to express the solvent re-organisation energy in electron transfer theory.
A less damaging fake news consists of saying that the current reaches a maximum in linear sweep voltammetry because the reactant concentration drops to zero at the electrode. This is not the case…
Other fake news are based on an obsolete vocabulary. A classic example is the use of NHE to refer to SHE; indeed, very few are still familiar to the concept of normality in solution chemistry.

Many students find electrochemistry to be a difficult subject in their curricula. Indeed, electrochemical reactions take place at a surface and a basic knowledge in solid state physics and of electrolyte solution chemistry is required to understand interfacial reactions with the difficult concept of electric potentials (so many of them: inner, outer, surface, redox, electrode, Nernst, Donnan, Galvani, Zeta, ..)
In many *cursi*, electrochemistry is not taught any more by physical chemists to physical chemists, but to a much larger audience with a much more disperse background. This requires a rewriting of old concepts in a unified approach. The presenter still wanders where he is on the Dunning-Kruger curve below (Courtesy of Wikipedia), but nonetheless will advocate for the teaching of the Fermi level of the electrons in solution to present electrochemical science in a unified framework.



Development of a European Master Programme Curriculum in Fuel Cell and Hydrogen Science and Engineering

K. Bouzek, M. Paidar, R. Steinberger-Wilckens
University of Chemistry and Technology Prague
Technicka 5, Prague 6 166 28, Czech Republic
bouzekk@vscht.cz;
University of Birmingham, School of Chemical Engineering, Centre for FC & Hydrogen Research
Edgbaston, Birmingham B15 2TT, UK
r.steinbergerwilckens@bham.ac.uk

Hydrogen related technologies, like *e.g.* fuel cells and water electrolysis, are currently rapidly progressing to reach full market application. This fact is indicated by an exponentially growing number and size of demonstration activities, as well as by growing interest on side of the industry. Motivation for this trend clearly follows from the policy of reduction of CO_2 emissions, as well as dependence on the politically instable regions exporting fossil fuels. It is, however, necessary to keep in mind the important aspect that hydrogen technologies, as a typical representative of novel hi-tech processes, depends very significantly on the availability of correspondingly trained operators, not mentioning development, production and installation teams. For the moment, preparation of respective staff is not secured in a sufficient quantity and very often also quality, in sense of required broadness of knowledge. The target of the described activity is to overcome this obstacle.

The progress to the final target consists of several steps requiring the cooperation of a spectrum of institutions able to cover the relevant topics in required broadness. The methodology used in the present case may be described as follows:

- Identification of the outline structure of the programme proposed,
- Identification of the suitable partners having expertise in the related fields,
- Setting up the detailed study programme curriculum broken down to the individual lectures,
- Producing content for the programme developed,
- Piloting the programme proposed at the selected universities,
- Collecting feedback from the students as well as from the teachers involved in piloting,
- Producing a final version of the programme content,
- Applying for programme accreditation.

As the most relevant degree of study, a Master programme was selected for this project. This is because a Masters degree allows more substantial specialisation on hydrogen technologies based on engineering fundamentals obtained during the Bachelor degree study. A second initiative is oriented towards continuous professional development (CPD). Both these activities allow to train a significant number of specialists needed for the transition to the hydrogen economy implementation quite rapidly.

The course content elaborated is prepared in the way to be available in a repository and organised such as to allow high quality distance learning. A limitation is represented by at least 20 % of the course content to be delivered at the participating University locally in face-to-face fashion. Participation of partners from various European countries ensures translation of the materials produced to a number of languages in order to make them more attractive for the students as well as for the Universities. Project core partners will provide the necessary support towards the realisation of the study programmes and in keeping the content up to date.

This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking under grant agreement No 779730. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme, Hydrogen Europe and Hydrogen Europe research.

Boosting Aqueous Zinc Batteries by Intercalation Chemistries at High-Voltage

Huang Zhang,[1,2,3] Xu Liu,[2,3] Bingsheng Qin,[2,3] Stefano Passerini [2,3]
[1] Institute of Flexible Electronics (IFE), Northwestern Polytechnical University (NPU), 127 West Youyi Road, Xi'an, 710072, Shaanxi, China

[3] Karlsruhe Institute of Technology (KIT), P.O. Box 3640, 76021 Karlsruhe, Germany
Email: iamhzhang@nwpu.edu.cn (H.Z.); stefano.passerini@kit.edu (S.P.)

Aqueous batteries are highly desirable for large-scale energy storage. However, the energy density and cycling stability are major issues for their applications. Rechargeable aqueous zinc batteries have a direct advantage as they can employ Zn metal as negative electrode.[1] However, their development is plagued by the reversibility of Zn anode and a limited choice of positive electrodes, which often show inadequate cycling life and low energy density. Recently, the concept of highly concentrated electrolyte enables the wide electrochemical stability window of aqueous solution, providing the basis for the development of high voltage aqueous batteries.[2,3]

Here we demonstrate the intercalation reactions in optimal aqueous electrolytes for high-voltage aqueous zinc batteries. The designed aqueous concentrated electrolytes can manifest superior Zn stripping/plating reversibility, combined with a promising electrochemical stability window. Firstly, we investigated the reversible anion intercalation reaction in graphite positive electrode for aqueous zinc battery, as a concept of dual-ion battery. This cell offers a high operating voltage and unprecedented cycling stability with comparable Coulombic efficiency. Further, we report the high-voltage intercalation reaction of V_2O_5 positive electrode using a concentrated gel polymer aqueous electrolyte for zinc batteries. Quasi-solid-state Zn/V_2O_5 batteries employing such an electrolyte, reach a high operating voltage of 2.2 V, resulting in a specific energy of 326 Wh kg^{-1} at 20 mA g^{-1} based on cathode mass, and a capacity retention of 93% over 600 cycles at 500 mA g^{-1}. Moreover, the cell well performs in the 0-40 °C temperature range without significant energy loss. These results may open up the development of high-voltage aqueous Zn batteries employing intercalation-based positive electrodes leading to potentially high energy, high reversibility and high safety.

Since the discovery of practical sulfide superionic conductors in 2016 [1], all-solid-state batteries (ASSBs) have been considered as one of the most promising candidates for next-generation batteries. ASSBs are not only high-powered but also electrochemically stable. These properties enable a wide selection of high-capacity active materials, some of which are incompatible to liquid-state batteries. In contrast, ASSBs have a difficulty in making contact interfaces between solid particles, even though this is a negligible problem for liquid-state batteries. Repeated charge / discharge cycles cause disconnects in inter-particle interfaces, resulting in shortening battery life. This degradation phenomenon is derived from a crack propagation phenomenon in a heterogeneous powder mixture, and accurate prediction is extremely difficult to deal with existing simulation methods. Solving the problem of interfacial contact and preventing degradation are one of the most important issues toward the practical application of ASSBs.

Recently, battery degradation research by data-driven approach was successful in accurately predicting battery life in various charge / discharge patterns [2]. This indicates that the data-driven approach is more effective than a simulation-based approach in predicting battery life. However, the input data in this study was acquired from mass-produced and identical batteries with extremely low variance of properties that meets the product standard. In other words, this study provides optimal control methods for suppressing degradation of the identical batteries, but does not provide a better battery design to extend its life.

Therefore, we studied a new data-driven method to explore a better electrode design. As experimental insights, ASSBs' lives differ in different manufacturing processes, even though the design values and materials composition of the samples are completely same. One of the causes is considered to depend on a microstructure inside a battery, particularly spatial distribution and relative positions of each materials [3]. Therefore, we acquired 17,700 scanning microscope (SEM) images from 177 various design of batteries in order to investigate the relationship between the microstructures and the batteries lives. In this presentation, we discuss the results of recognized degradation patterns through image generative model using two pairs of images from fresh and degraded batteries.

Knowledge of the conductance properties of individual molecules is indispensable for the development of future molecular electronic devices. We have studied a series of molecules based on oligophenylene molecular wires containing tripodal anchoring groups which differ in the position of thiols (*meta* versus *para*) on the aromatic rings of the tetraphenylmethane tripod (see structures below). The conductance of individual molecules was obtained by the scanning tunneling microscopy break junction method. Density functional theory combined with the non-equilibrium Green's function formalism was used to understand charge transport properties and provide most probable metal-molecule-metal junction geometries. It was shown that in the molecules studied in this work the most probable molecular junction geometry is the following: three thiolates of the tripod are anchored to one electrode and a single thiolate of the oligophenylene wire to another one. The junction formation probability for *meta* functionalization was 68 % and that for *para* 55 %, respectively. Nevertheless, the conductance-distance histograms for both molecules show two peaks, where a high conductance peak G_H represents the conductance through a tripodal platform, whereas the low conductance peak G_L represents conductance along the molecule through the tripod-linked molecular wire as described above. Single molecule conductance for *meta* functionalized wire is $\log G_H/G_0$ (meta) = –3.7 ± 0.6 and $\log G_L/G_0$ (meta) = –5.8 ± 0.5 and that for *para* functionalized wire is $\log G_H/G_0$ (para) = –3.9 ± 0.6 and $\log G_L/G_0$ (para) = –5.6 ± 0.5, respectively. These results indicate that *meta* substitution leads to a more stable junction compared to *para* molecules, whereas *para* functionalized tripodal anchoring group has better conducting properties. Experimental and theoretical results will be further discussed in terms of the suitability of these types of molecules as supporting conductors for additional molecular electronic elements important for the future molecular electronics design.[1–4]

Electrochemical Processing for Small-Scale Robotics

Prof. Salvador Pané
Materials for Robotics, Institute of Robotics and Intelligent Systems, ETH Zürich
Tannenstrasse 3, CLA H9, 8092, Zürich, Switzerland
vidalp@ethz.ch

We live in a world increasingly surrounded by robots such as robotic surgical systems, flying drones, autonomous planetary rovers, and robotic appliances. An emerging family of robotic systems are untethered micro- and nanorobots. These tiny vehicles can move either by harvesting chemical fuels present in their swimming environments or by means of external energy sources. One of the ultimate goals of small-scale robotics is to develop machines that can deliver drugs, or realize other medical missions in confined spaces of the human body. Other applications include water remediation or "on-the-fly" chemistry. The recent rapid developments in small-scale robotics is undeniably related to advances in material science and manufacturing. However, while many applications have been demonstrated, aspects such as complex locomotion, multifunctionality, biocompatibility and biodegradability need to be further investigated for the successful translation of these devices to real applications. To this end, new material-based concepts and novel fabrication schemes are urgently required.

Electrochemical processing techniques have played a significant role in the development of materials for small-scale robotics. Electroless, electroforming, electrodeposition and anodization – to name a few – have been widely used as batch manufacturing approaches for the fabrication of micro- and nanorobots. In this talk, I will introduce some of our latest developments in small-scale robotics using electrochemical processing techniques. Particularly, I will show how 3D printed microtemplates can be exploited to produce complex robotic microstructures made of electrodeposited rigid metals, soft polymers and combinations of these. As a result, topologically complex metal-organic structures can be realized with sub-micrometric resolution. I will also demonstrate that metal-organic interlocked micromachines can solve several practical challenges in small-scale robotics. We will show that high magnetic responsiveness, drug loading capabilities, biocompatibility, on-demand shape transformation, and multi-locomotion modes can be embedded in a single microrobotic machine.

Mixed-Valence CoMn Layered Double Hydoxides Nanoparticles as Efficient Electrocalalysts for Hydrogen Peroxide Sensing

Christine.Mousty@UCA.fr

Among the nanomaterials reported in the literature for electroanalytical applications, hybrid and biohybrid materials or nanocomposites based on layered double hydroxides (LDH) have been used as electrode modifiers for sensing environmental pollutants or small biomarkers, such as glucose or hydrogen peroxide[1,2]. LDH are lamellar materials made by the stacking of positively charged brucite-like layers separated by intercalated charge-compensating anions and water molecules. They are represented by the general formula $[M^{2+}_{1-x} M^{3+}_{x}(OH)_2][X^{m-}_{x/m},nH_2O]$ with M^{2+} and M^{3+} being divalent and trivalent metal cations, respectively and X^{m-} the anionic species. Interestingly, the LDH have a unique inorganic structure that can combine mixed-valence transition metal cations (i.e. NiFe, NiCo, CoMn, CoFe, etc.) in its framework. These LDH containing transition metals are, since very recently, under great investigation, in particular for their electrocatalytic behavior for water splitting, as well for electroanalytical applications[2,3].

A series of Co_RMn-LDH ($1 \leq R \leq 5$) was synthesized by the coprecipitation method. The formation of LDH phases is confirmed by powder X-ray diffraction (XRD) and infrared spectroscopy (FTIR). The energy dispersive X-ray analysis (EDX) confirms the total coprecipitation of Co and Mn and the X-ray photoelectron spectroscopy (XPS) gives evidence of the joint presence of Co(II), Co(III), Mn(II), Mn(III) in the LDH structure. The Rietveld refinement of the structure using the XRD data reveals that the sample with a Co:Mn ratio 3:1 displays a pure LDH phase having an unusual trivalent metal composition, with a M(II):M(III) near 1:2 and a high content of CO_3^{2-}/OH^- charge compensating anions in the interlayer.

When compared with the other Co_RMn-LDH, the Co_3Mn-LDH displays the best redox properties in an alkaline medium (0.1 M NaOH) and in a neutral pH (0.1 M Tris buffer at pH 7). An in-depth study of the Co_3Mn-LDH obtained after electrochemical oxidation was performed and its electrocatalytic behaviour for H_2O_2 oxidation at neutral pH was evaluated using cyclic voltammetry and chronoamperometry. The Co_3Mn-CO_3 modified electrode exhibits good electrocatalytic performance in terms of sensitivity 30 mA M^{-1} cm^{-2} and a detection limit of 86 µM. These values can be compared to those reported for electrochemical sensors based on other LDH or mixed spinel oxides, showing the interest of bifunctional CoMn-LDH in sensing H_2O_2 in neutral pH under oxidation condition. Finally, Co_3Mn-LDH was used as immobilization matrix for glucose oxidase (GOx) to build bioelectrodes which have been tested for the electrochemical detection of glucose.

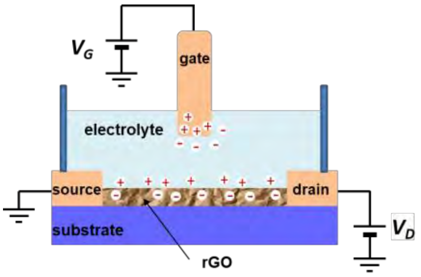

Figure 1. EG-GFET configuration scheme with inkjet-printed rGO as the active layer.

Graphene and its derivatives have been extensively studied and used for a wide range of applications thanks to their outstanding characteristics: high values of charge mobilities, high electronic sensitivity toward outside interactions and excellent conductivity.[1] Used as the active layer in electrolyte-gated graphene field-effect transistors (EG-GFET; Fig. 1), its charge carriers density can be modulated with an appropriate gate voltage.[2] In this work, the inkjet-printing technique is employed for the deposition of the graphene active layer in the GFET structure, using our own formulation of graphene oxide (GO) printable ink. This allows us to obtain an EG-GFET in a timely, effective manner and at low cost. The as-printed GO layer is then electrochemically reduced (rGO), using an *in-situ* approach that we developed on the bottom-contact configuration of GFETs[3,4]. Morphology of the printed layer as well as its electrical properties are studied (Fig. 2a). Reduction degree is observed to significantly affect the charge transport in rGO, leading both to the control of charge carriers' mobility as well as its doping level. In terms of applications, we study this EG-GFET for the life cycle monitoring of photosynthetic organisms (Fig. 2b). During the photosynthesis (under illumination of the cyanobacteria *Anabaena flos-aquae* here studied) oxygen is released in the solution and reduced at the gate, which permits its detection in terms of increase of the device output current. On the contrary, during the respiration process (occurring in the absence of light) there is a decrease of oxygen concentrations due to its consumption by cyanobacteria, resulting in a decrease of the device current. Furthermore, we study and present the effects of water pollutants on the metabolism of cyanobacteria.

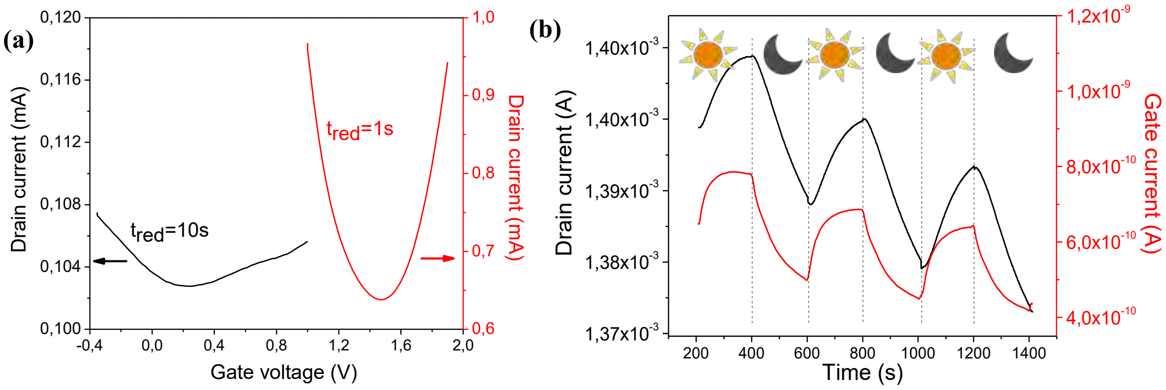

Figure 2. **(a)** Electrical characterization of rGO for different reduction times (arrows showing the corresponding current axes of each transfer curve). **(b)** Chronoamperometric study of cyanobacteria's metabolism in the presence (current increase) and absence of light (current decrease) in rGO-EG-FET configuration.

Electron Transfer Kinetics in a Deep Eutectic Solvent.

Fangchen Zhen, Lucie Percevault, Ludovic Paquin, Emmanuelle Limanton,
Corinne Lagrost, Philippe Hapiot

Univ Rennes, CNRS, ISCR – UMR 6226, F-35000 Rennes, FranceAddress
Philippe.hapiot@univ-rennes1.fr

Since their initial proposition, Deep Eutectic Solvents (DES) are receiving an increasing interest as new class of solvent for numerous applications ranging from synthesis, electrochemistry to extraction, etc.[1] Common DES are often composed of a salt and a hydrogen bond donor. They are now considered as possible electrolytic media because of their inherent ionic conductivity associated to excellent solubilizing properties. Moreover, they are easy to prepare, low cost and possibly environmental friendly.

Electron transfers (ET) rate in these media is a key parameter for many proposed electrochemical applications. In this work, Electron Transfer (ET) kinetics in Ethaline that is one of the most common DES (1:2 Choline Chloride + Ethylene Glycol) have been investigated with the example of two common redox couples (ferrocene/ferrocenium and ferrocyanide/ferricyanide). Accurate analysis of a fast electron transfer in such media is a challenging task because of a lower viscosity and conductivity that required a careful treatment of the residual ohmic drop.

Rate constants are discussed in the framework of the Marcus-Hush theory and compared with values in molecular solvents or common ionic liquids.[2] They were found to be close to the values reported in organic solvent for ferrocene oxidation or in water for ferrocyanide oxidation. In that sense, Ethaline appears to be more similar to a molecular solvent than to an ionic liquid.[3,4] We could connect this observation with another observation concerning the small variations of the diffusion coefficients with the charge of the solute as observed previously in Ethaline and in Reline.[5] This behavior is in sharp contrast to the observations in ionic liquids where diffusion coefficients vary with the charge carried by the solute because of specific interactions between the molecules and the ions of the ionic liquids.
When considering DES for electrochemical applications, the fast electron transfer is a strong advantage of these media for example in energy storage systems or electrochemical sensors where the current density or time response is a key parameter.

Energy Conversion and Storage:
Novel Materials and Operando Methods

Héctor D. Abruña
Cornell University
Dept. of Chemistry & Chemical Biology, Baker Lab.
Ithaca, New York 14853-1301
hda1@cornell.edu

This presentation will deal with the development of new materials and *operando* methods for energy conversion and storage with emphasis on fuel cells and battery materials and technologies. The presentation will begin with a brief overview of the methods employed. Particular emphasis will be placed on the use of X-ray diffraction (XRD), X-ray absorption spectroscopy (XAS) X-ray microscopy and tomography and transmission electron microscopy (TEM) under active potential control. The utility of these methods will be illustrated by selected examples including electrocatalysts for the oxygen reduction reaction (ORR), hydrogen oxidation reaction (HOR) and spectroscopic studies of Li/S and Li/Se batteries and Li metal deposition and dendritic growth. The presentation will conclude with an assessment of future directions.

Enabling multivalent batteries by organic cathodes

Robert.Dominko@ki.si

Classical insertion chemistry in multivalent batteries has only limited success due to different difficulties connected with a diffusion of highly polarizable multi valent cation, with a charge transfer reaction due to strong solvation, and electrolyte components that are not compatible with high voltage cathode materials based on oxide framework. Much better and stable electrochemical activity can be obtained by use of redox active organic polymers. Although organic materials possess low volumetric energy density, in the combination with high volumetric energy density metal anodes (magnesium, calcium or aluminum), still can offer highly interesting battery system with practical application. Moreover, multivalent organic batteries are attractive due to sustainability, safety and environmental aspect connected with decreased CO_2 release. As in the case of insertion cathode materials, multivalent organic batteries have only limited choice of electrolytes, since they need to have non-nucleophilic character, excellent ability for stripping and deposition and suitable electrochemical stability.

In this presentation, overview of recent achievements in our group on the field of organic multivalent batteries will be discussed with a focus on the proper selection of battery components in order to achieve electrochemical properties attractive for the commercialization.

Sustainability of battery components is becoming nowadays an overriding parameter for storing renewable energy at large scale. Towards that ambitious goal, several strategies are currently being explored. One of them is the use of aqueous electrolytes that are theoretically cheaper, safer and less toxic than their organic counterparts. However, the major limitation towards the development of aqueous electrolytes is the narrow thermodynamic electrochemical stability window (ESW) of water (1.23V). Although, it can be kinetically extended to 1.5V when using salts in diluted solution, it remains not competitive when compared to organic solvent. Owing to this limitation that translates into poor energy density, Li-ion aqueous systems, as introduced in 1994 by Dahn, and coworkers could never be marketed [1].

To alleviate this issue, Suo *et al.* [2] proposed in 2015 an aqueous electrolyte made with a high salt concentration (21mol/kg), denoted *Water-in-salt* (WiSE), which they claim to enlarge the operating potential window to 3V and possesses a conductivity close to that of classical organic electrolyte (ar. 10mS/cm). Following this initial discovery, Yamada *et al.*[3] then showed that *Water-in-bisalt* enables to build batteries with a potential up to 3.1V. Both studies have renewed interest for studying aqueous systems. Nevertheless, a few question dealing with practicality of such findings remained. Herein, we carried out a systematic study to assess the practical viability of 20mol/kg LiTFSI *Water-in-salt* electrolyte. To do so, two couple of electrodes were chosen to decouple the influence of *WiSE* on cell performances : Mo_6S_8/*WiSE*/LFP was chosen on the cathodic side and $LiTi_2(PO_4)_3$/*WiSE*/NMC_{622} on the anodic side to study how the competing water reduction (HER) and oxidation (OER) affects the system performance. Electrochemical tests were performed to estimate cell performances as a function of concentration, temperature and cycling rate. The influence of parasitic reactions on battery performances was studied by online electrochemical mass spectrometry (OEMS), while cyclic voltammetry and self-discharge experiments enabled the assessment of SEI stability.

Thus, we found that water reactivity it not suppressed by the used of WiSEs with continuous generation of gas upon charge. Indeed, continuous SEI dissolution is monitored, which leads to drastic self-discharge and poor efficiency at low C-rate. This systematic study therefore leads us to conclude that *Water-in-salt* electrolyte cannot be used for practical application in Li-ion battery.

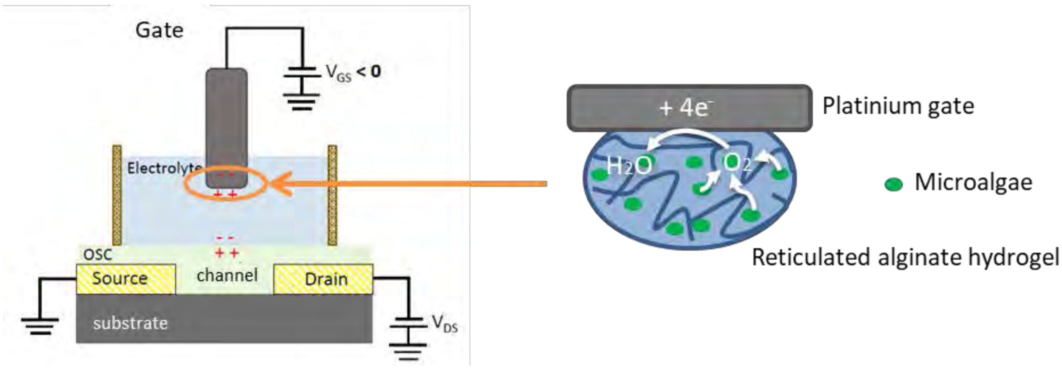
Water-Gated Organic Field Effect Transistor for Monitoring of Photosynthetic Organisms

Benoît Piro, Jérémy Le Gall, Roberta Brayner, Giorgio Mattana, Vincent Noël
ITODYS, UMR CNRS 7086, Université de Paris
15 rue Jean-Antoine de Baïf, 75013 Paris, France.
piro@u-paris.fr

Organic Electrochemical Transistors (OECTs) are frequently reported for cell monitoring[1]. In contrast, Electrolyte Gated Organic Field Effect Transistors (EGOFETs) have never been described for that kind of application. However, water-gated OFETs seem perfectly adapted for this because they can operate directly in a cellular culture medium, thanks to the conventional dielectric layer being replaced here by water[2]. They are possibly more sensitive than OECTs due to their much higher *on/off* ratio (several thousands instead of several tens).

In this work, we first demonstrate that not only the gate potential can trigger the source-drain current, which is the generally accepted mode of operation, but that the current flowing at the gate can also be used, providing that the gate/electrolyte capacitance stays significantly lower than that of the electrolyte/semiconductor interface.

As an example of application of this new mode of operation, we aim to demonstrate here that monitoring microalgae photosynthesis is possible through the direct measurement of photosynthetic O_2 production thanks to its electroreduction on the EGOFET's gate. Microalgae (*Anabaena flos aquae*) are tapped within an alginate hydrogel[3,4] grafted on the platinum gate. While doing photosynthesis, microalgae produce O_2 that is electroreduced on the gate; the resulting current significantly decreases the gate/electrolyte potential drop and symmetrically increases that of the electrolyte/semiconductor interface, leading to an increase of drain current.



EGOFET structure under negative polarization and strategy of gate modification

Beyond this proof of concept, a possible application is the environmental monitoring of pollutants cocktails through their deleterious influence on the metabolism of photosynthetic organisms such as microalgae or cyanobacteria. This also paves the way for novel applications of EGOFETs in the field of amplification of redox reactions in general.

Biotic/Abiotic Photo-Bioelectrochemical Cells for the Generation of Electrical Power

Omer Yehezkeli
Technion, Israel Institute of Technology
Haifa, Israel
y.omer@technion.ac.il

The photosynthesis process converts light energy into useful fuels (hydrocarbons) by coupling light and dark cycles. This Fundamental process enables the earth's energy demands in the last 3.5 billion years. The light cycle coined “Z-scheme”, facilitate efficient light-induced charge separation processes, which lead to the generation of chemical fuels. While photosystem II coupled to electrodes can oxidize water to evolve oxygen and generate photocurrent, photosystem I can be utilized in both directions to generated anodic or cathodic photocurrents. The direction can be controlled by an applied bias, utilization of redox mediators or the use of electron donor (or electron acceptor). In the last few decades, numerous attempts to mimic the photosynthetic process have been realized using different scientific approaches drawn from different disciplines, but the quest for a sustainable world is still in its course.

Here we present the development of biotic/abiotic based photoelectrochemical cells, which facilitate photoinduced electrical power generation. The developed cathodes which are based on Photosystem I or Bilirubin Oxidase facilitate efficient oxygen reduction reactions. By coupling those developed cathodes to BiVO4 based photoanodes, bias-free, donor free photo(bio)electrochemical cells that generate electrical power can be obtained.

Two major configurations will be discussed and presented:

a. A donor-free photobioelectrochemical cells for the generation of light-triggered electrical will be presented. The developed oxygen reduction biocathodes are based on bilirubin oxidase (BOD) originates from *Myrothecium verrucaria* (MvBOD) and a thermophilic *Bacillus pumilus* (BpBOD). Methods to entrap the bilirubin oxidase with ABTS redox molecules in a polydopamine layer will be presented and a pH-independent, positively charged pyrene-betaine linker Both developed polydopamine/ABTS/MvBOD and the pyrene-betaine/BpBOD biocathodes were further coupled with BiVO4/cobalt-phosphate water oxidation photoanodes to construct biotic/abiotic photobioelectrochemical cells, generating power outputs of 0.74mW/cm^2 and 0.85 mW/cm^2, respectively.

b. We further show the development of a layer-by-layer photocathode configuration, which utilizes a thermophilic photosystem I for the generation of electrical power. Two redox-active polymers were used, polymethylene blue (pMB) which acts as an electron donor and poly-butyl-viologen, (PBV) which acts as an electron acceptor and as a catalyst for oxygen reduction. The redox-active polymers enable improved stability, improved PSI trimers integration on the electrodes and facilitates efficient charge separation processes. The developed photocathodes were further coupled to BiVO4 for the construction of donor free, bias-free photo(bio)electrochemical cells.

Abstract

Nanofilms have increased a considerable interest in fuel cell due to their high electrocatalytic performance. Electrochemical atomic layer deposition (E-ALD) is low temperature and a low-cost electrodeposition technique which sequentially produces nanofilm materials [1]. In this work, E-ALD cycles were used to electro-synthesize rarely BiTePd nanofilm on Au substrate via alternated surface limited replacement (SLRR) of copper underpotential deposition (Cu-_{UPD}) and repetitive execution of oxidative Te-_{UPD} and reductive Bi-_{UPD}. In order to set optimal potentials for E-ALD cycles, the electrochemistry profile of Au and Pd surface in Te^{4+} and Bi^{3+} solutions was investigated using cyclic voltammetry (CV). It appeared that the atomic layers of Bi, Te may form via UPD and overpotential deposition (OPD) respectively. The resulted deposits consist of unitary (Te, Pd), binary (BiPd, TePd) and ternary (BiTePd) nanofilms. All the deposits exhibit the typical Pd signatures, with the varied current response and potential shift of Pd-O oxide around -0.2 to -0.16 V vs. Ag/AgCl. The detailed studies of structure-composition were obtained using XRD, SEM-EDS, and AFM. TePd and BiTePd exhibit nanodendritic structure with alloy and elemental phases textured epitaxial along Pd-Au (111) orientation. EDX evidenced the presence of all deposited elements. Moreover, ternary and binary nanofilms showed higher electrocatalytic activity and stability towards EOR than unitary Pd confirmed by the following trend (peak current and onset potential): BiTePd (1.26 mA, -0.55 V)> TePd (0.527 mA, -0.535V)> BiPd (0.24 mA, -0.39 V)> Pd (0.135 mA, -0.35 V) obtained from CV and Chronoamperometry (CA). The incorporation of Bi and Te on Pd surface improved interfacial charge transfer during EOR using electrochemical impedance spectroscopy (EIS). These results encourage the use of ternary BiTePd nanofilm electrocatalyst for application in alkaline direct ethanol fuel cells (DEFCs).

Abstract: Due to the wide spread development of chemical, electronic, metallurgy and energy, considerable hazardous heavy metals-bearing wastewater and solid waste are directly or indirectly discharged into the environmental. In order to overcome the drawbacks of long process-flow and large chemicals requirements in conventional treatment technologies, novel electrochemical metal extraction techniques are developed in this study including alkaline electrochemical oxidation processes (A-EAOPs) and cyclone electrowinning (emew® cell). Efficient and selective metal extraction is achieved from refractory spent SCR catalysts and vanadium slag via in-situ generated reactive oxygen species (ROS), while controllable Cu, Te, Se powdery products are obtained from dilute multi-component wastewater. Besides, the electrochemical recovery mechanism and behavior are revealed using in-situ dynamic X-ray synchrotron imaging and fluid flow calculation techniques, particularly in the complicated HCl effluents. Based upon the systematic investigations of reactors, mass transfer, phase transition and electrochemical reactions, the process-mechanism-products (PMP) rational design of electrochemical metal recovery is proposed rather than simply metal removal.

Keywords: Metal recovery, Reactive oxygen species, Mass transfer, in-situ dynamic X-ray imaging, Process-mechanism-products (PMP)

Phase diagrams under scrutiny – In-situ electrochemical X-ray diffraction unravels layered β-Fe_{1+x}Se as superconductor for all x

Bertold Rasche, Simon J Clarke, Richard G Compton
Institute of Inorganic Chemistry, University Cologne
Greinstr. 6, 50939 Cologne, Germany
bertoldrasche@web.de

Systematic investigations of phase systems and transitions are the foundation of understanding complex physical phenomena such as superconductivity. One example in which the lack of such a systematic knowledge has led to contradictory results is β-Fe_{1+x}Se. The superconductivity of this “simple” two-dimensional, layered structure has been reported to be heavily dependent on the composition and closely related structural transitions, defects and various superstructures with overall very inconsistent results.[1–6]
The difficulties arise from the narrow phase width of β-Fe_{1+x}Se ($0.01 < x < 0.04$), a small deviation from the 1:1 ratio and its manifold of neighbouring phases.[7]
We report the precise post-synthetic control of the composition of β-Fe_{1+x}Se by electrochemistry with simultaneous tracking of the associated structural changes via in-situ synchrotron X-ray diffraction (Figure 1).[8] Via an externally applied potential, electrochemistry allows us to systematically explore the phase system, while affording the high precision needed in this case. We confirm the phase width of $0.01 < x < 0.04$ and identify the superconducting state below 8 K, which in contrast to earlier reports is independent of the composition. However, in a second set of in situ X-ray diffraction experiments, we demonstrate that β-Fe_{1+x}Se forms a new phase in the presence of oxygen above a 100 °C, which has the same anti-PbO type structure but is not superconducting down to 1.8 K. The latter process can be reversed electrochemically to reinstate the superconducting state.
This electrochemical approach takes experiments for two-dimensional materials beyond intercalation reactions,[9,10] and exploits the exquisite control provided by electrochemistry.

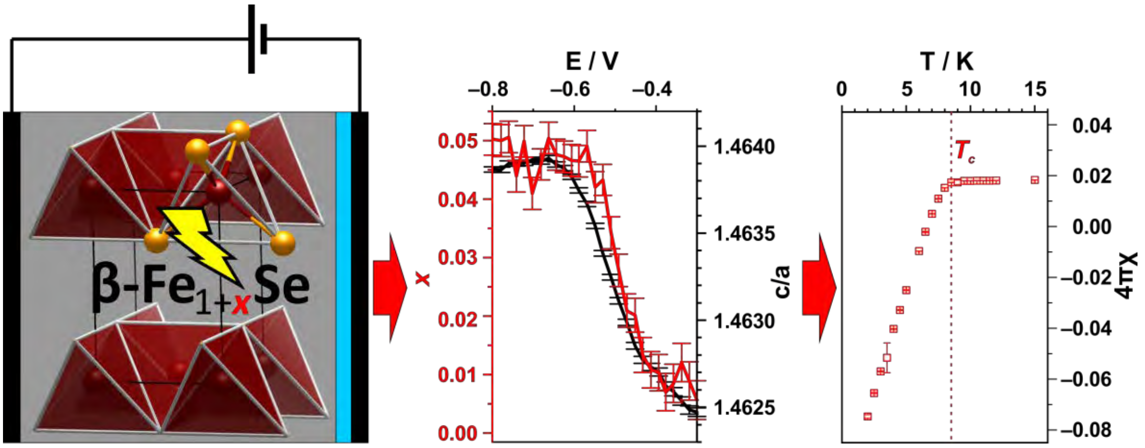

Figure 1: The composition of β-Fe_{1+x}Se (left) is electrochemically varied within its phase width (center: red). Simultaneously, the structural changes are monitored via X-ray diffraction (center: black). Independent of the composition, the superconducting transition temperature remains unchanged (right).

In the last decade, the rise of synthetic biology has driven the efforts to construct artificial allosteric protein switches in order to detected and quantify natural and artificial chemistries in vitro and in vivo. Typically, this involves construction of chimeric enzymes via insertion of a regulatory receptor domain into the biocatalytic reporter domain. Construction of such chimeric enzymes utilizes the recombinant DNA technology that is a core technology of protein engineering [1].

Herein, we report on the bioelectrocatalytic properties of pyrroloquinoline quinone-dependent glucose dehydrogenase fusion with calmodulin (PQQ-GDH-CaM). This protein is catalytically inactive in its ground form but can be activated by the addition of calmodulin binding peptide that induces its conformational transition and activation, as shown in Figure 1. The PQQ-GDH-CaM was immobilized onto highly porous gold (hPG) produced electrochemically [2] by using a bifunctional linker, namely 4-mercaptobenzoic acid further activated through 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide and N-hydroxysuccinimide (EDC/NHS) coupling to covalent bind the PQQ-GDH-CaM chimeric enzyme [3].

At first, we characterized the switchable features of PQQ-GDH-CaM by simply exposing it to the activating peptide. Subsequently we devised an approach to use proteolytic activation of a caged-peptide to generate activating peptide for PQQ-GDH-CaM. Furthermore, the system was utilized to study different pathways for PQQ-GDH-CaM triggered activation according to different logic gates in order to realize multipurpose biosensors (e.g., glucose detection, peptide detection etc.) [4].

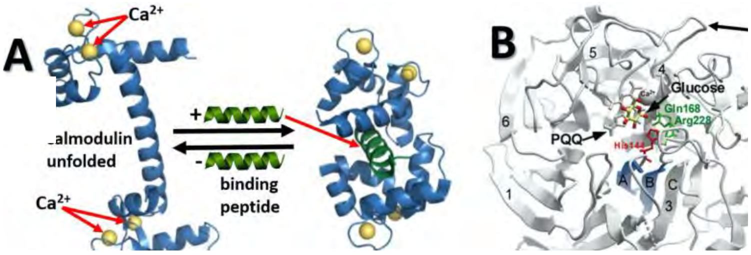

Figure 1. Activation mechanism of PQQ-GDH-CaM by the addition of calmodulin binding peptide

jlipkows@uoguelph.ca

Valinomycin, a cyclic peptide, was incorporated into a biomimetic lipid membranes either tethered (tBLM) to or floating at the surface of a gold (111) electrode. Electrochemical Impedance Spectroscopy (EIS) was used to study the ionophore properties of the peptide and polarization modulation infrared reflection absorption spectroscopy (PM-IRRAS) was employed to determine the conformation and orientation of valinomycin in the membrane. The combination of these two techniques provided unique information about the ionophore mechanism where valinomycin transports ions across the membrane by creating a complex with potassium ions and forming an ion pair with a counter anion. The ion pair resides within the hydrophobic fragment of the membrane and adopts a small angle of ~22° with respect to the surface normal. This study provides new insights explaining the valinomycin ion transport mechanism in model biological membranes.

Nano-Crystalline Graphene Electrodes for Anthracene Sensing

Antonio Radoi[1], Octavian Gabriel Simionescu[1], Camelia Albu[2], Carmen Ciobanu[1], Cristina Pachiu[1], Cosmin Romanitan[1], Sandra A. V. Eremia[2], Mihaela Kusko[1]

[1] National Institute for Research and Development in Microtechnology – IMT Bucharest, 126A Erou Iancu Nicolae Street, 077190, Voluntari, Romania
[2] Centre of Bioanalysis, National Institute of Research and Development for Biological Sciences - Bucharest, 296 Splaiul Independentei, Bucharest, 060031, Romania
antonio.radoi@imt.ro

The nano-crystalline graphene (NCG) shares electrical characteristics matching few-layered graphene in terms of sheet resistance, meanwhile the electrochemical features, reflected by the heterogeneous electron transfer rate constant, are closer to the highly oriented pyrolytic graphite (HOPG - basal plane). Therefore enhancement of redox transfer at NCG electrodes is promoted through an increase of the availability of edges, obtained under a pre-activation step, thus obtaining redox features comparable with the glassy carbon electrode (GC). The advantages related to the use NCG as electrode material are ascribed to its reproducible PECVD synthesis achievable on large surfaces (wafers of several inches), its peculiar characteristics being suitable to compete with robust electrodes made of carbon fabric.

Polyaromatic hydrocarbons (PAHs) are a class of organic compounds made of hydrogen and carbon atoms accommodated in two or more fused aromatic rings, the most common known PAHs being naphthalene, fluoranthene, pyrene, phenanthrene and anthracene. Their occurrence in oils, coals, tar deposits and persistence as by-products of fuel burning made PAHs one of the most important groups of pollutants, being identified to be teratogenic, carcinogenic, and mutagenic [1]. For such a reason, anthracene is one of the 16 PAHs which are monitored routinely for regulatory purposes [2].

Graphene based nanomaterials are expected to possess properties that make them very efficient tools for the development of electrochemical sensors due to the excellent mobility of electrons in honeycomb sp2-hybridized carbons, being well known that electro-catalysis readily occurs on graphene [3].

Plasma-enhanced chemical vapour deposition (PECVD) allowed growth of graphene and N-doped graphene domains on SiO_2, consisting of densely packed nano-sized islands[4]. The Raman spectrum of the nano-crystalline graphite film, made of graphene domains, showed peaks at 1357 cm^{-1} (D band), 1600 cm^{-1} (G-band), 2695 cm^{-1} (2 D band) and 2944 cm^{-1} (D + D' bands), suggesting crystalline arrangement of graphene domains, and a certain degree of disorder.

Preliminary electrochemical investigations of NCG and N-doped NCG electrodes revealed the ability to sense anthracene and behave similar to GC electrode in terms of linear working range and applied working potential.

Motivation:

As a broad market penetration of lithium-ion-batteries becomes reality in a multitude of applications, safety and reliability are major issues that have to be ensured. In recent years, especially driven by the demands and rapid growth in the field of electro-mobility, the trend in the development of Li-ion batteries goes towards the manufacturing of large-format cells to increase system energy density. In such large-format cells, thermal gradients and an inhomogeneous state-of-charge (SOC) and current distribution over the cell-stack become more significant. This can present a severe challenge regarding cycle stability and safety, which can lead to a more pronounced aging behavior as function of location in the electrode stack. In turn, it can induce performance losses, compromise lifetime and constitutes a safety issue as local hot-spots can develop at positions with higher impedance or local current density, encompassing an increase in temperature and the risk of triggering thermal degradation.

Obtaining information on how material properties, cell engineering and charge/discharge parameters influence such gradients is critical to maintain inside a safe operating window, to optimize performance and to facilitate longer lifetime.

Methodology:

To gain better insight in the above phenomena, a combination of modelling and experimental investigation, complemented by post-mortem analysis of aged cells is mandatory [1]. At the core of this work is the development of a segmented current collector which is coated by the active material and inserted into the pouch-cell as part of the electrode stack. This proprietary development [2] facilitates the real-time monitoring of local current density as function of operating conditions and facilitates performing local impedance spectroscopy on each segment distributed over the electrode. An exemplary image of this is presented in figure 1. The so-obtained knowledge is of considerable value for scientists, cell manufacturers and users, as it allows insights into locally resolved aging and the development of critical positions on the electrode surface. The experimental results further serve as validation for impedance-based cell modelling for which locally-resolved impedance data serves as input for simulation of the dynamic behavior of the cell, current density, SOC and SOH distribution during operation. This contribution will present how this combination can help in understanding the inhomogeneities in the cell and how they affect operation, longevity and performance loss of the cell.

Li-ion batteries hold great importance in the process of transitioning to renewable energy. Advancement of battery technology to provide higher energy density and higher rate capability is thought to be necessary to achieve this transition. The objective of the current research work is to investigate of the effects of ionomer-based active polymer binder, in lieu of traditional binder, in the porous cathode of the Li-ion battery.

Li^+ transport within porous electrodes is limited by porosity and tortuosity. The lower effective diffusivity of Li^+, compared with the counter-anion, causes high concentration and potential gradients across the thickness of the cathode, especially at high charge-discharge rates. The depletion of the Li^+ cation from the reaction surface of active material limits the thickness of the active material that is effectively utilized at a given rates, and thus limits practical rates. Here, covalently tethered anionic ligands titrated with Li^+ are investigated to mitigate this Li^+ depletion. Ion transport properties (transference number, diffusivity, conductivity) have been characterized and used in the simulation of the multiphysics system.

For making active polymer binder functionalized nanoparticles and Poly(STFSI) were mixed with the cathode slurry. Experimental charge-discharge cycling result of the modified composite electrode (active polymer binder based) at different C-rate and thickness has been investigated and compared with the control electrode of similar thickness and porosity. The effect of active polymer on increased capacity of modified cathode is evident, after comparison.

A predictive microscale multiphysics model of the investigated system has been put in place. The governing PDEs, constitutive laws and the interface conditions (Butler-Volmer and Donnan equilibrium) that describe the electro-chemo-mechanical system have been solved numerically. A purposely written Matlab Package script has been developed and Matlab PCT has been used for parallel computing, to implement the numerical method. The discharge voltage profile and distribution of ion concentration and electric potential across the battery have been simulated. Comparison of discharge voltage profiles between the mathematical model and experimental results validate the mathematical model.

The Kinetics Study of Hydrogen Peroxide Electroreduction onto Graphene/Palladium Modified Glassy Carbon Electrode

In present work, we report the synthesis of graphene (G) which is subsequently decorated with palladium (Pd) nanoparticles as a efficient electrocatalyst for electrochemical reduction of hydrogen peroxide (H_2O_2). The structure of obtained nanohybrid material (G-Pd) was examined by XRD technique. The graphene/palladium composite material was immobilized on the surface of a glassy carbon electrode (GCE) for the electroreduction of hydrogen peroxide (H_2O_2).

The electroreduction of H_2O_2 was studied by cyclic voltammetry (CV) and square wave voltammetry (SWV), at a potential range of −0.6 to +0.2 V in order to study electrocatalytic behaviour of G-Pd. Voltammetric data are analyzed in the light of the theory for simple irreversible electrode reaction.

The presence of palladium nanoparticles as well as Fe retained during graphene synthesis have a major role in the electroreduction of H_2O_2. The graphene/palladium composite showed pronounced electrocatalytic activity toward the reduction of H_2O_2 in alkaline medium.

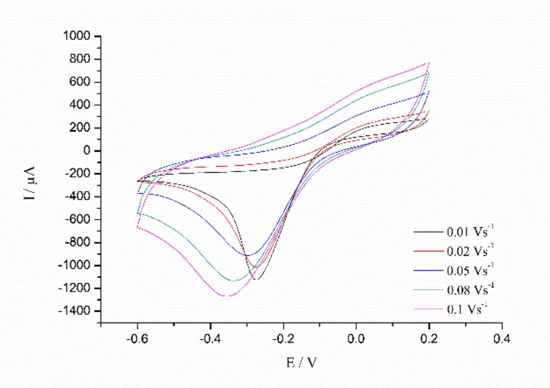

Figure 1. The CV responses of G-Pd GCE in 5 mM H_2O_2, 0.1 M KOH at scan rates 0.01, 0.02, 0.05, 0.08 and 0.1 V s^{-1}

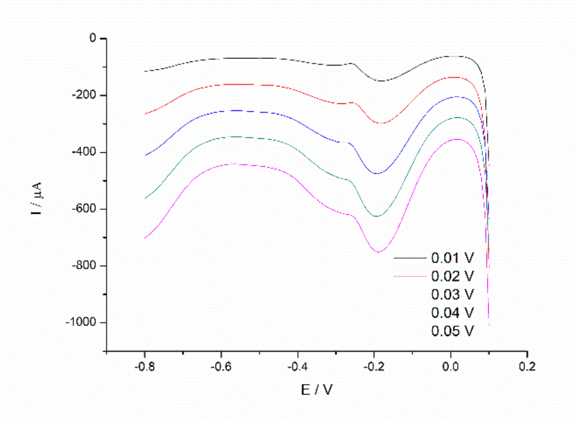

Figure 2. The SW responses of G-Pd GCE in 5 mM H_2O_2, 0.1 M KOH at amplitude values 0.01 V, 0.02 V, 0.03 V, 0.04 V and 0.05 V

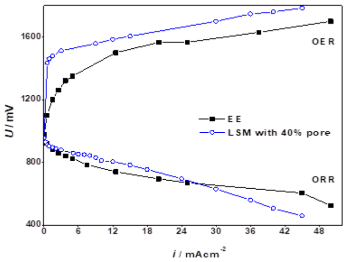
Carbon - free Ceramic Gas-Diffusion Electrodes for Secondary Zn-air Batteries

E. Mladenova, M. Slavova, B. Burdin, E. Mihaylova-Dimitrova, D. Bojchev, D. Vladikova *Institute of Electrochemistryand Energy Systems "Academician Evgeni Budevski", Acad. Georgi Bonchev 10 Str., 1113 Sofia, Bulgaria* e-mail: e_mladenova@iees.bas.bg

Abstract:

In recent years, secondary Zinc-air cells have received considerable attention as promising approach for energy storage of renewable energy. One of their durability problems is the oxidation of the conventional carbon gas-diffusion electrodes [1]. Replacement of the carbon-based material with ceramic one is a possible solution for overcoming this problem which is the aim of this work. An innovative approach which applies solid state "monolithic" gas-diffusion electrode proposed by standard ceramic technology is proposed. The appeared ceramic materials with perovskite structure (LSM and LSCF) provide good mechanical and chemical stability [2-4]. The solid state "monolithic" electrode is produced with 40% porosity which guarantees the necessary gas permeability. A special impregnation procedure ensures the needed hydrophobicity [5].

The testing of the new electrodes in a 1cm^2 half-cell configuration with reference hydrogen electrode. The cell was carried out subjected to cycling at charge/discharge current ± 10 mA/cm^2. The results from the electrochemical tests demonstrate behavior similar to that of the carbon-based etalon GDE. The samples are stable for more than 1000 cycles. These preliminary results demonstrate the applicability of carbon free solid state "monolithic" gas-diffusion electrodes in Zinc-air rechargeable batteries.



Comparison of volt-ampere characteristics during discharge (ORR) and charge (OER) measured on classical GDE (EE) and monolithic monolithic GDEs (LSM)

As an indispensable electrode in electrochemistry, the reference electrode plays a very important role in the basic research and application, which forms an electronic circuit with working electrode to achieve potential measurement and control. Currently, the reference electrodes used for electrochemical measurement in aqueous solution are generally Hg/Hg_2Cl_2, Hg/Hg_2SO_4 and Hg/HgO electrodes. The mercury-based reference electrode has the advantages of stable potential and good reproducibility. However, the electrode material contains mercury, which inevitably produces mercury pollution during the preparation, use, and recycling processes, to harm the environment and human health. In addition, mercury-based reference electrode also has the disadvantages of large temperature coefficient, severe temperature hysteresis, and inability to use at high temperature. Here we introduce Ag/Ag_2SO_4 and Ag/Ag_2O reference electrodes, to be expected to replace Hg/Hg_2SO_4 and Hg/HgO ones, with excellent potential stability, reproducibility, and lower temperature coefficient as well.

Towards Practical Li-S Battery with Dense and Flexible Electrode Containing Lean Electrolyte

Lithium-Sulfur (Li-S) batteries attracted intensive attention as potential candidates owing to its high theoretical energy density (2600 Wh kg^{-1}) and huge natural sulfur resources.[1] The electrochemical behavior of Li-S batteries has been improved through many comprehensive strategies in recent years. Nonetheless, more realistic conditions need careful consideration towards practical Li-S battery, such as areal capacity, flexibility, electrode density, cathode porosity and electrolyte amount. The improvements favor to design real high-energy density Li-S batteries. Higher cathode loading is feasible to increase areal capacity whereas many new issues arise compared with thin-film electrodes, such as fragile cathode structure, increased electrode thickness and decreased ionic/electronic conductivity. Pressure treatment could effectively decrease electrode thickness corresponding to high electrode density and low porosity. Additionally, flexible electrode design potentially extends the application towards flexible energy storage devices.

Recently, S@pPAN has received extensive attention due to its excellent electrochemical performance. Compared with solid-liquid dissolving-deposition mechanism of common S@C composite, S@pPAN reveals unique solid-solid conversion mechanism, which enables high sulfur utilization even at low electrode porosity and lean electrolyte uptake.[2] Herein, we creatively designed a rigid-flexible coupling binder via interaction between guar gum and a novel long-chain binder carboxylic styrene butadiene rubber.[3] With sulfurized pyrolyzed poly(acrylonitrile) (S@pPAN) composite cathode, high areal-capacity cathode was fabricated with enhanced areal capacity of 5.55 mAh cm^{-2} after long cycles. Moreover, the electrode exhibited benign flexibility with a capacity retention near 90% even after 400 times' folding. In addition, remarkable electrode density up to 1.54 g cm^{-3} corresponding to cathode porosity of 13.3% and low electrolyte amount to 1.00 ml $g^{-1}_{composite}$ were proven feasible for a practical Li-S battery.

The Lithium-Sulfur (Li-S) battery has been considered as the most promising next generation energy storage system because of advantages such as high theoretical specific capacities, abundant sulfur resources, low cost and environmentally friendly[1]. For a typical Li-S battery with elemental sulfur cathode which we call as mobile sulfur, there are a number of shortcomings, such as polysulfide dissolves in the electrolyte and renders the "shuttle" effect, which leads to the loss of active materials, poor electrochemical performances, low sulfur utilization and low Coulombic efficiency. However, there is another sulfur cathode, we call it stationary sulfur, sulfurized pyrolyzed poly(acrylonitrile) (S@pPAN) which was firstly synthesized via heating the mixture of sulfur and PAN under inert atmosphere[2, 3]. The S@pPAN delivered excellent compatibility with carbonate electrolyte, high utilization of active material, and long cycle life. It is due to the fact that the material does not dissolve and has no shuttle effect of polysulfide during cycling.

Herein, we adjusted PAN precursor with high molecular weight to prepare S@pPAN with high sulfur content. For the PAN with high molecular weight, the longer main chain can form a larger conductive network and offer additional space to accommodate more sulfur molecular in the process of heating cyclization. The cathode S@pPAN, which was prepared by high molecular weight PAN precursor up to 555000 (555k), accommodated amorphous S ca. 55 wt%. It delivered reversible specific capacity of 901 mAh g^{-1} which was calculated based on whole composite at 0.1 C under 50°C with sulfur utilization over 98%, along with stable cycling and good high rate capability. Therefore, synthesizing PAN with high molecular weight as precursor is a promising strategy to effectively enhance the amorphous sulfur content in S@pPAN, which will lead to high specific capacity, stable cycling, and finally high energy density for Li-S full batteries.

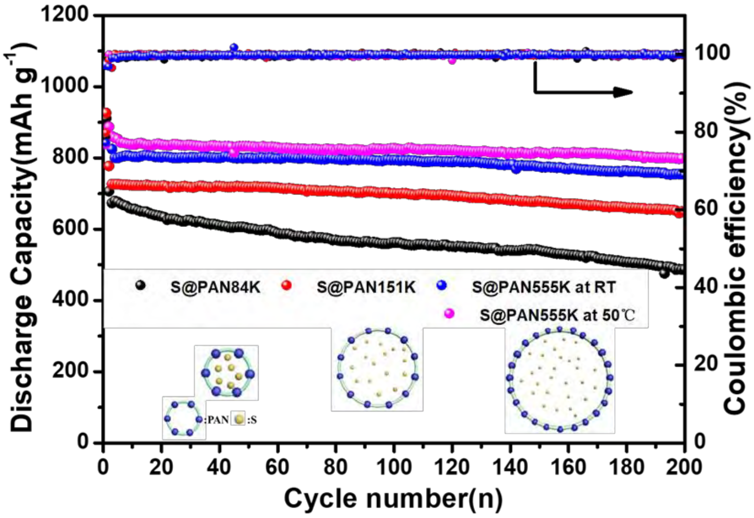

Figure.1 Cycling performance at 0.2C and Schematic of S@pPAN synthesized by PAN precursors with different molecular weights(where the number following PAN indicates its molecular weight)

Fuel cell electric vehicles (FCEVs) have received substantial attention for its high energy efficiency and zero emission as a future alternative vehicle type to replace the conventional combustion engine-based vehicles. Direct hydrazine fuel cells (DHFCs) are the promising fuel cell type applied in FCEVs because the carbon-free hydrazine fuel does not produce any carbon dioxide and air pollutant, and its theoretical cell potential (1.56 V), energy density (5.4 kWh L^{-1}), and energy efficiency are higher than that of hydrogen gas in fuel cell system [1-2]. Further, the high catalytic activity of Ni, as an anode catalyst, toward hydrazine than precious metal Pt makes DHFCs more attractive power sources in FCEVs. Despite these strong merits, the optimal membrane-electrode assemblies (MEAs) in DHFCs operating alkaline media have not been established well, which leads to insufficient cell performance. In this research, to pursue high cell performance of DHFCs, we prepared the less oxidized Ni/C catalysts depending on the Ni contents on the carbon supports, and used the Ni/C with moderate metal contents observed for hydrazine oxidation reaction in DHFCs. We examined the effect on DHFCs performance resulting from the water-uptake in cathode and the electrode thickness in anode based on the cell evaluation. The MEAs with the appropriate hydrophobic gas diffusion layer of cathode and catalyst loading of anode showed the enhanced cell power density of 547.8 mW cm^{-2} employing the Ni/C and ultra-low amounts Pt in DHFCs [3].

Effect of ammonium chloride on bismuth electrodeposition from choline chloride-urea deep eutectic solvent (DES) using $BiCl_3$ as source of Bi(III) was investigated. Spectroscopic and thermal studies were performed on the DES in order to understand whether the addition of ammonium chloride affects its behavior; the results of the thermal study do not indicate any significant change except a modification of a cold crystallization peaks at low scan rate. The effect of temperature and NH_4Cl content on electrochemical behavior of bismuth was studied by cyclic voltammetry. Chronoamperometry was used to study bismuth electrocrystallization which indicated that the bismuth electrodeposition in studied conditions evolves with a three-dimensional progressive nucleation. SEM images show that grain size of bismuth deposits decreases while adopting a well-defined geometry as ammonium salt concentration increases. EDS analysis confirms that pure bismuth thin films were obtained and X-Ray diffraction indicates that the bismuth growth follows a preferential orientation along the (012) reticular plane.

Efficient dispersion of M-N-C molecular macrocycles on carbon nanomaterials support is an attractive strategy to noble metal-free Oxygen Reduction Reaction (ORR) electrocatalyst. In recent years, Co phthalocyanine(CoPc) derivatives have been studied as metal complex catalysts for oxygen electroreduction. In particular, CoPc compounds supported with multiwall carbon nanotubes (MWCNTs) have attracted great attention. CoPc is a transition metal macrocycle, and exhibits an unique ORR capability for alternative cathode catalysts, due to its large conjugated molecular structure with strong π-π interactions between aromatic rings.

Compared to most of the studies reported, the synthesis of Fe/Co doped C-N nanotubes in this work is different. Preparation of the catalysts does not involve complex and harsh equipment, and more importantly, it does not need adding pristine carbon nanotubes to raw materials. ,Carbon nanotubes were in situ formed via high temperature pyrolysis of a mixture of CoPc, ferrocene and dicyandiamide. The ORR behavior of Co-Fe-N-doped CNT catalysts is evaluated by employing the rotating disk electrode (RDE) method. Under alkaline conditions, it shows an onset potential of 0.01 V close to that of commercial Pt/C

The oxygen reduction reaction (ORR) is traditionally carried out with noble metals (such as Pt) or non-noble metals as catalysts. However, these metal-based catalysts often suffer from multiple disadvantages, including high cost, low selectivity, poor stability and detrimental environmental effects. Here, we prepared a non-metallic oxygen reduction catalyst doped with nitrogen and phosphorus via direct heat treatment of a mixture of starch and dicyandiamide, followed by a further heat treatment with the addition of triphenyl phosphorus to get graphene co-doped with nitrogen and phosphorus. Graphene, one-atom-thick layers of sp^2 -hybridized carbon atoms packed in a honeycomb lattice, is now renowned for its fascinating electronic properties. Since phosphorus has a lower electronegativity than carbon, i.e., higher electron-donating ability, it is of great significance to explore the unique properties of phosphorus-doped graphene, which is of great significance in electrocatalyst development.

The ORR behavior of the prepared N-P-doped grapheme catalysts is evaluated employing the rotating disk electrode (RDE) method. Under alkaline conditions, it shows an onset potential of -0.04 V which is higher than many catalysts doped with metals andis close to that of the commercial Pt/C.

Abstract

With the growing demand for energy and the increasing concerns about environment pollution from fossil fuels, research interest in energy conversion from sustainable energy sources is stimulating and sustaining. Electrochemical reaction can be used to store electrical energy efficiently via chemical bonds. For example, energy can be stored by electrochemically splitting water to form hydrogen and oxygen, whose subsequent recombination can provide clean electrical energy with the only by-product of water. However, the efficiency of hydrogen fuel generation from water splitting is severely limited by the sluggish kinetics of the oxygen evolution. Therefore, an efficient electrocatalyst for the oxygen evolution reaction (OER) is needed to afford high current at low overpotential and improve the energy conversion efficiency. Although Iridium oxide (IrO_2) and ruthenium oxide (RuO_2) are widely recognized as the most active electrocatalyst for OER, the scarcity nature as well as high cost have limited their widely application seriously. Therefore, it is urgent to develop low-cost alternatives as highly efficient electrocatalysts for OER process.

Here, we have prepared a novel kind of pyrochlore $Y_2Ru_2O_{7-\delta}$ electrocatalyst with high activity and stability toward OER in strong acidic media. $Y_2Ru_2O_{7-\delta}$ electrocatalyst shows an ultralow onset overpotential of less than 240 mV in 0.1 M H_2SO_4 solution and stable chronopotentiometric performance under constant current density. This study provides an effective choice for the design of high performance electrocatalyst for water electrolysis.

With the growing of environmental problems, the development of fuel cells and metal-air batteries is becoming more and more important. Oxygen reduction reaction (ORR) is an important and key process for energy conversion and storage systems. Noble metal-based materials, such as Pt and Pd, are still the most efficient catalysts for ORR. Nevertheless, their large-scale applications were hindered by their rarity, high cost and low tolerance to fuel crossover. Therefore, developing highly active and cost-effective catalysts as alternatives for ORR is significant for both practical applications and academic researches.

In this paper, we firstly prepared a bimetallic doped metal-organic frameworks, and then hydrothermally mixed it with urea to obtain the porous product by pyrolysis. The SEM images of the CoNi-MOF are presented in Fig.1.(a,b) and the SEM image of the corresponding CoNi-MOF@Urea is presented in Fig.1(c). Fig.1(d) shows that the CoNi-MOF and CoNi-MOF@Urea had superior catalytic activity for oxygen reduction in alkaline condition. Catalytic activity of CoNi-MOF@Urea for oxygen reduction is close to that of commercial Pt/C.

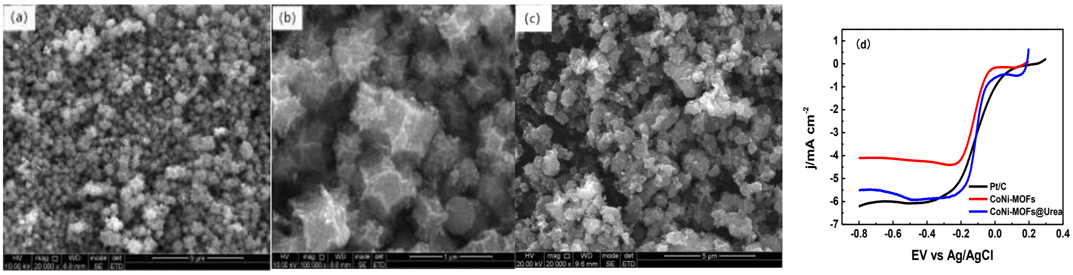

Fig.1.(a,b,c)The SEM images of all preparede catalyst ,(d) The ORRLSV curves for CoNi-MOF, CoNi-MOF@Urea and commercial Pt/C (20 wt %) at a rotation speed of 1600 rpm.

Anthropogenic climate change and environmental pollution problem, caused by the booming depletion of fossil fuels, make it urgent to develop renewable energy storage and conversion technologies. Among diverse technologies, metal-air batteries play a significant role for the conversion from chemical energy to electric energy due to their high theoretical power density and environmental friendliness. The cathodic oxygen reduction reaction (ORR) in metal-air batteries is so sluggish in nature that we usually need Pt-based electrocatalysts to accelerate the ORR kinetics for their commercial application, even the metal Pt is extremely precious and scarce. Therefore, exploring electrocatalysts with excellent ORR catalytic activity and stability to replace the Pt-based catalyst is extremely urgent.

Herein, we use the one-pot synthesis method to synthesize a bimetal (Fe and Co) doped yolk-shell hollow carbon sphere using dopamine, cobalt chloride hexahydrate and ferric chloride as carbon, cobalt and ferric source respectively. Results show that the catalyst has an excellent electrocatalytic activity for oxygen reduction reaction (ORR) in 0.1 M KOH solution. The synthesis procedure is shown in Fig.1a, and the linear sweep voltammetry (LSV) curves in 0.1M KOH with a scan rate of 5 mV/s are presented in Fig.1b.

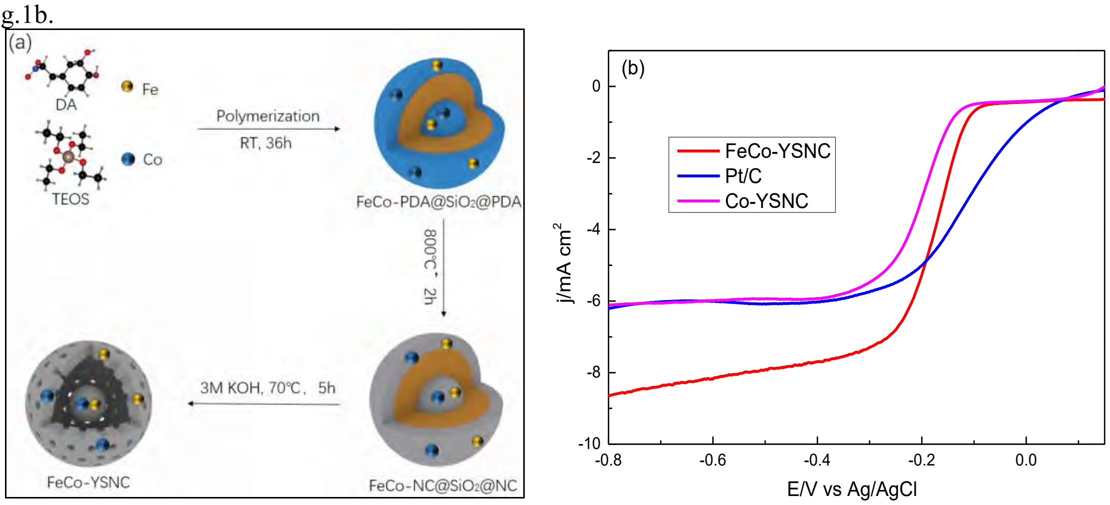

Fig.1. Synthesis procedure of FeCo-YSNC (a) and LSVs of FeCo-YSNC, Co-YSNC and Pt/C at 1600 rpm in 0.1M KOH (b).

Economic development and technological advancement are accompanied by increasingly prominent problems of environmental pollution and energy crisis, which has accelerated the inevitable transformation of the energy structure from traditional fossil energy to renewable energy. Oxygen reduction reaction (ORR) plays a key role in renewable energy conservation and storage technologies. Platinum (Pt) and platinum (Pt)-based catalysts are widely considered to be the most effective catalysts for ORR. However, limited by high cost, rare source and declining activity made it in great demand to develop an alternative catalyst to precious metal platinum.

Under this background, we have developed an effective ORR electrocatalyst as shown in Fig.1a and b, which is composed of non-noble metals nickel and cobalt as active materials, assembled from carbon hollow spheres and carbon hollow nanotubes. First, the nickel and cobalt co-doped hollow carbon sphere was prepared by using silica balls as hard template, dopamine hydrochloride as carbon source and nitrogen source. Subsequently, using nickel and cobalt as growth sites, composites from hollow carbon spheres and hollow carbon tubes were prepared. The rotating disk electrode (RDE) measurement was performed to assess the electrocatalytic activities regarding ORR of the prepared catalyst by comparison with commercial platinum carbon.

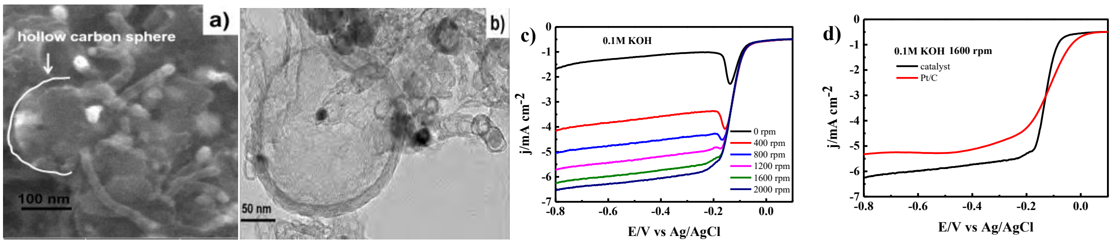

Fig. 1. SEM image of catalyst (a); TEM image of catalyst (b); RDE polarization curves of the prepared catalyst in O_2-saturated 0.1 mol • L^{-1} KOH at different speeds (c) and comparison of prepared catalyst with Pt/C at 1600 rpm (d).

The most important material use in implants for total hip replacement is a cobalt-chromium-molybdenum alloy (known as CoCrMo). The important property which makes this material suitable for implants are: biocompatibility and appropriate strength, stiffness, hardness, and wear resistance, together with high elastic modulus [1]. The composition of this alloys lays in the range of 26-30 at.% Cr, 2.9-4.1 at.% Mo together with other minor alloying elements (C, Si, Ni, Mn) and Co.

In order to investigate a broader compositional range around the composition of bulk CoCrMo, in this work a ternary compositional range from the cobalt, chromium and molybdenum metallic system was obtained by means of co-sputter deposition. Energy-dispersive X-ray spectroscopy revealed a compositional matrix containing Mo (3-10 at.%), Cr (17-48 at.%) and Co (46-79 at.%). The microstructure analysis of respective alloy compositions was undertaken with the help of high resolution scanning electron microscope. A sharp change from spike or conical to a refined grain and compact microstructure was achieved with the increase in Cr content. Higher Mo content was responsible to induce further grain refinement. Crystal structure investigation via X-ray diffraction exhibited weak and broad peaks matching the rt HCP and ht FCC structure of Co at all compositions. Addition of Mo and Cr was responsible by a slight shift in the respective peaks. Electrochemical experiments e.g. open circuit potential (OCP), Tafel extrapolation, cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) were utilized to examine the corrosion properties of various alloy compositions in Ringer`s solution at 37 ºC. A special flow type scanning droplet cell microscope (FT-SDCM) containing three electrodes setup was utilized to perform the experiments. Furthermore, to study the role of chromium and molybdenum during passive and transpassive dissolution (CV experiments) and ICP-OES was directly coupled with FT-SDCM. To investigate the enrichment or dissolution of a specific metal, the instantaneous dissolution rate of each metal was converted into the normalized dissolution with respect to Co. No considerable passivation was observed at the higher Co content (above 70 at.%) regardless of Cr and Mo concentrations. Active to passive dissolution significantly drops as the Cr content becomes higher whereas, on the other hand increase in Mo content improved the transpassive dissolution above 0.6-0.7 V vs SHE. Alloys in the range of (7-10) at.% Mo (40-48) at.% Cr (complementary Co) show improved corrosion resistance and dissolution which make them suitable for further testing and biomedical application.

Two Routes for Extracellular Electron Transfer in *Enterococcus faecalis*

Lo Gorton, Galina Pankratova, Lars Hederstedt
Lund University
P.O.Box 124, SE-22100, Lund, Sweden
Lo.Gorton@biochemistry.lu.se

Bacterial electrochemistry is currently a much expanding research field with many fundamental as well as practical implications in e.g., biotechnology and analytical chemistry [1-4]. Most commonly Gram negative bacteria have been investigated, however, also Gram positive bacteria have during the last few years been at focus [4,5]. We have previously shown that the Gram positive lactic acid bacterium *E. faecalis* is a weak electricigen [6] and that both monomeric redox mediators and redox polymers, when added to the system, can largely increase the rate of extracellular electron transfer from the bacterial cells to electrodes [7-10].

In this presentation it will be demonstrated that electrons generated in glycolysis can be transferred to electrodes via two different pathways [11]. The finding is of interest and value to those active in several fields of microbiology, such as environmental, applied, and medical microbiology. Our research results, which are based on molecular genetics, biochemical and electrochemical studies, also contribute to basic knowledge in microbiology and physiology.

amanda.garcia@tno.nl

The development of green industrial processes has been attracting more attention in the last years and it requires renewable energy sources. Large-scale electrification of the energy and chemistry sectors is a crucial condition for the transition from a society based on fossil resources to a sustainable society based on renewable building blocks. Transformation of CO_2 into chemicals has been intensively studied over the past decades because this molecule can be used as C_1 feedstock in electro-organic synthesis due to its abundant, cheap, renewable and non-toxic nature[3–5]. Of particular interest of this molecule is the synthesis of two- to four-carbon atom products (C_2-C_4). Concerning the synthesis of C_2-C_4 products, tartaric acid (TTA) attracts attention because it is an important product used in the textile printing, dyeing, pharmaceutical and food industries[11]. In the past years, the price of TTA and its salts has varied as much as 50 %, as might be expected when the source of the raw material is a by-product of another industry.

Herein we describe a study of the electrochemical reduction of oxalic and glyoxylic acids towards a feasible green and sustainable production of tartaric acid in aqueous and/or acetonitrile solvent using silver and lead electrodes.

Our results show that on the silver electrode, for both oxalic acid and glyoxylic acid, the reduction reaction is more favorable towards the dimerization step, leading to tartaric acid, due to the increase in the local pH, while on the lead electrode the step involving the protonation of the intermediate is more favorable, leading to the formation of glycolate.

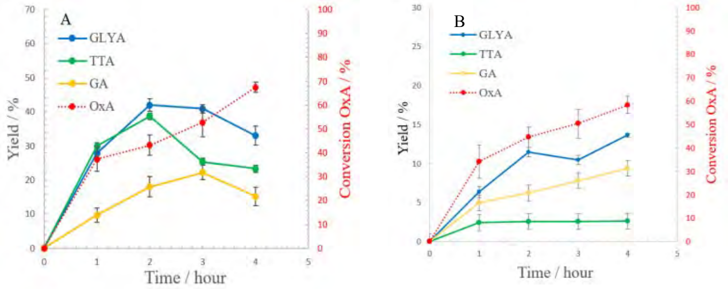

Figure 1. Calculated yield and conversion of OxA and the main liquid products detected by HPLC on Ag (A) and Pb (B) electrodes in ACN solution + 0.1 M TEACl + 0.1 M OxA.

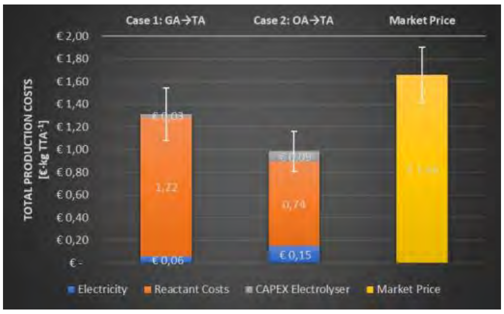

Figure 2. OPEX, CAPEX and Total Production Costs for TTA for Case 1 (from GLYA) and Case 2 (from OxA), and Market Price for TTA from vendors.

Techno-Economic Analysis shows that tartaric acid production from glyoxylic acid and from oxalic acid via electrochemical synthesis can be a potential process at industrial scale. In the present case, the oxygen evolution reaction was chosen as the reaction at the other electrode for practical reasons, but oxygen is a low-value product. Another anodic reaction with a more valuable oxidation product can be selected to increase the profitability of the overall electrochemical process, and thereby decrease the total production costs of tartaric acid.

Pt based materials with high specific surface area have attracted increasing attention as a result of their high activity and durability for electrocatalysis, because of their high surface area, more active sites and high electrical conductivity.[1, 2] Herein, amorphous PtNiP/graphene nanoclusters were successfully prepared by a simple process that hypophosphite-assisted co-reduction method to electrocatalyze methanol oxidation. The diameter of PtNiP/graphene nanoclusters was about 0.92 nm. The morphology and structure of PtNiP/graphene nanoclusters were characterized by transmission electronic microscopy and x-ray photoelectron spectroscopy. Benefiting from the size-confined growth mechanism and the doping of P, PtNiP nanocluster was anchored uniformly with controllable size on the surface of graphene. Meanwhile, P was used to form PtNiP alloy and adjust the electronic structure of Pt. The as-prepared PtNiP/graphene catalyst exhibits excellent mass activity as high as 826.1 mA•mg$^{-1}_{\text{Pt}}$, which is 2.58 times higher than commercial Pt/C and excellent durability after 1000 cycles CV test.

Nanoporous RuO_2 is very promising to achieve the activity and stability of electrocatalyst for oxygen evolution reaction (OER) in acidic medium, but it is still challenging[1]. This article reports a nanoporous RuO_2 catalyst with high catalytic performance in acid OER. The RuO_2 catalyst is prepared by a simple and effective ammonia-induced pore formation method, which has a large number of micropores/mesopores. As a self-supporting electrocatalyst, the nanoporous RuO_2 has excellent acid OER activity. The overpotential at 10 mA cm^{-2} is 215 mV. More importantly, the overpotential difference of the OER of this catalyst before and after accelerated stability testing was only 35 mV, and it did not show significant deactivation or decomposition. Therefore, the catalyst can be used as an efficient OER electrocatalyst in acidic media.

Advanced Filter Membrane Separator for Aqueous Zinc-Ion Batteries

Yao Qin, Yougen Tang, Haiyan Wang*
Hunan Provincial Key Laboratory of Chemical Power Sources, College of Chemistry and Chemical Engineering, Central South University
Changsha, China
E-mail: wanghy419@csu.edu.cn

Aqueous zinc-ion batteries with low cost and inherent safety are considered to be the next-generation energy storage device. However, it is suffering from poor cycling stability and low Coulombic efficiency caused by the serious zinc dendrites during the cycling. In this work, a porous water-based filter membrane is firstly proposed as separator due to its good toughness and uniform pore distribution. Compared with conventional cells with glass fiber separator or filter paper, the cells with filter membrane show a longer cycle life. The results demonstrate that the symmetrical cell using a filter membrane can cycle over 2600 hours with a low voltage hysteresis of 47 mV. Moreover, aqueous Zn//$NaV_3O_8 \cdot 1.5H_2O$ cell based on the filter membrane is constructed, which demonstrates a high capacity retention of 83.8 % after 5000 cycles at 5 A g^{-1}. The mechanism research results reveal that the excellent dendrites inhibiting the ability of the filter membrane should be attributed to its uniform pore distribution rather than its composition. This work proposes a filter membrane separator and reveals the great influence of separator on the zinc stripping/plating process, which will shed light on the development of high-performance aqueous zinc-ion batteries.

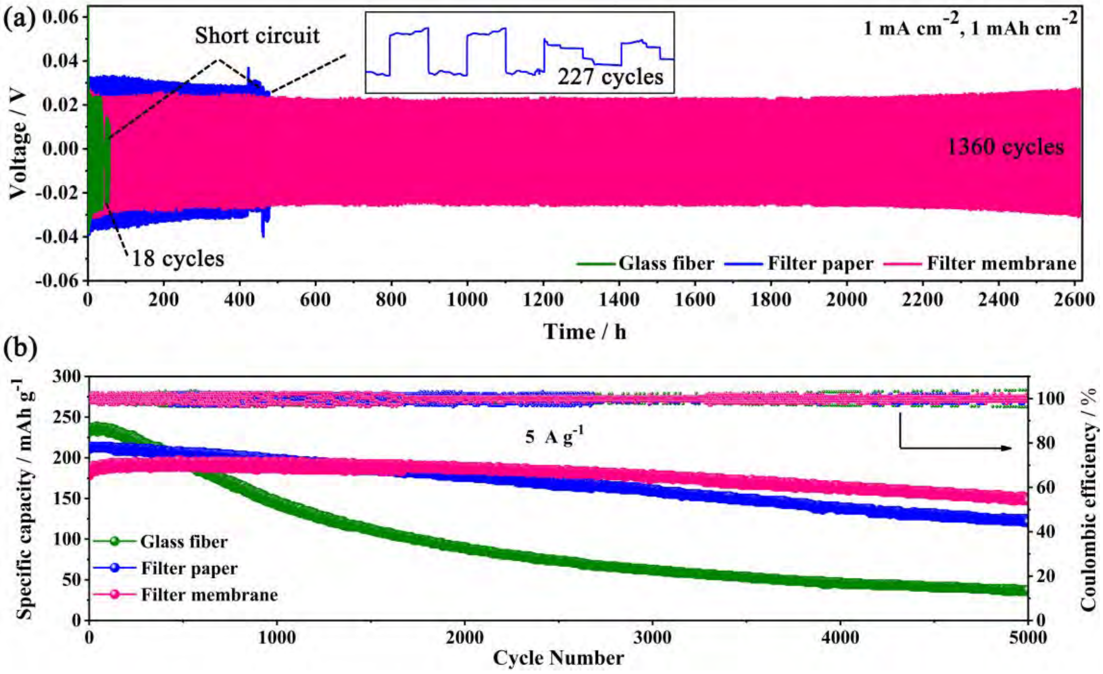

Figure. The cycling performance of cells with different separators. (a) Zn//Zn symmetrical cells at the current density of 1 mA cm^{-2} with areal capacity of 1 mAh cm^{-2}. (b) Zn//$NaV_3O_8 \cdot 1.5H_2O$ full cells at 5 A g^{-1}.

$Ti_3C_2T_x$ modified graphene foam as a lightweight interlayer for improved lithium-sulfur battery

Ruowei Yi, Chenguang Liu, Yinchao Zhao, Li Yang*, Cezhou Zhao
Department of Chemistry, Xi'an Jiaotong-Liverpool University
Suzhou, Jiangsu 215123, China
Li.Yang @xjtlu.edu.cn

Lithium-sulfur (Li-S) batteries have high specific capacity and energy density overweigh the commercial lithium ion batteries [1]. Besides, the elemental sulfur also surpasses other cathode materials for its low-cost, natural abundance and environmental benignity [2]. Nevertheless, Li-S batteries still have several crucial drawbacks: the poor electrical and ionic conductivities of sulfur species seriously retard the redox reaction. In addition, the so called "shuttle effect" brought by the dissolution of polysulfides can degrade the capacity and stability performance [3]. To overcome these obstacles, one special strategy is to build a functional interlayer between the cathode and the separator [4]. Here, the highly conductive lightweight graphene foam (GF) was modified by the $Ti_3C_2T_x$ (MXene) colloid and the resulted GFMX interlayer inherited their merits as lightweight and polysulfide-attractive. With this GFMX interlayer, the cell presented 867 mAh g^{-1} after 120 cycles with 88.8 % retention, which exceeds the pristine one's capacity by 32.8 %.

Lowering the Pt catalyst loading in fuel cell cathode without sacrificing the cell performance remains topical for fuel cell development, which will largely reduce the capital cost of the technology. This, in the meantime, is also highly challenging, since lowering the Pt loading not only reduces the overall kinetics of oxygen reduction reaction (ORR), but also causes serious mass transfer issue in high current density domain (HCD). Herein we overcome this difficulty by obtaining a highly active and stable Pt cluster based catalyst, where the catalyst loading reduction is completely compensated by the extraordinarily high electrochemical specific area (358.6 m^2 g_{Pt-1}) and the high dispersion of the platinum clusters. The Pt clusters, with average size of 1.3 ± 0.4 nm and atomic ultization rate up to 32.81%, are highly stabilized due to the strong anchoring effect of the N, P doped carbon nanosheets. As a result, the final Pt-9.3@NPC catalyst not only outcompetes the commercial Pt/C catalysts in terms of activity, but is also more stabilized during potential cycling. Even further, the cell assembled using Pt-9.3@NPC as cathode catalyst (0.1 mg_{Pt} cm^{-2}) conveys much higher fuel cell performance (837 mW cm^{-2}) in H_2/Air mode than the counterpart commerical catalysts (472 mW cm^{-2}), clearly evidencing the success in surmounting the mass transfer problem.

Ecological and economical stationary energy storage system based on aqueous zinc-ion batteries

W. Peters, M. Kronsbein, J.-F. Drillet,
DECHEMA-Forschungsinstitut
Theodor-Heuss-Allee 25, 60486 Frankfurt, Germany
willi.peters@dechema.de

The replacement of fossil energy sources by wind and solar power is dependent on ecological and economical large scale energy storage solutions such as pumped-storage, hydrogen and batteries. Besides established systems such as lead-acid, Ni-MH and Lithium-based systems, additional emergent electrochemical systems are needed to satisfy increasing demand.

In the conventional zinc-ion battery (ZIB), an energy-dense metallic zinc anode (820 Ah/kg; 5854 Ah/l) is combined with an aqueous electrolyte ($ZnSO_4$) and preferably with a δ-MnO_2 cathode (308 Ah/kg) to form an environmentally benign, non-toxic, non-flammable and low cost battery (<50 €/kWh). Most battery components are readily available as raw materials as well as high quality commercial products. Recycling processes for zinc and partially for MnO_2 are established. All ecological concerns are addressed within this battery chemistry. Thus, remaining economical and technical challenges are cycling stability of the ZIB and its scale-up to commercially available battery formats. The increasing amount of ZIB publications indicates the potential of this highly promising battery chemistry. Multiple studies were able to achieve a high electrochemical stability by demonstration of 1000-8000 charge/discharge cycles. [1,2] However, these results have been achieved in coin cell design containing low amount of active material and have not been demonstrated in larger battery formats yet.

This work aims at developing a prismatic ZIB cell and electrode manufacturing based on aqueous inks excluding the toxic and expensive NMP solvent. After establishing a homogeneous and stable ink composition, the electrodes were coated and tested first in coin cell design. Hereby, MnO_2 capacity of 300 mAh/g at a loading of 5 mg/cm² and current density of 60 mA/g (C5) was achieved that is close to theoretical value. Furthermore, we studied influence of the electrolyte composition on corrosion of the zinc anode (H_2 evolution), MnO_2 dissolution/deposition as well as battery component stability. Corrosion experiments in 1 M $ZnSO_4$ at 80°C for 8 weeks have been performed for commercially available passive and active cell components, such as binders, separators, current collectors, cell casings and gaskets. Conventional current collectors such as aluminum and copper underwent complete decomposition or severe corrosion. Stainless steel components (1.4404, 1.4310), titanium and others demonstrated very high corrosion stability.

Eco-friendly Chitosan: Anticorrosion Film on aluminum alloy 6061 Via a Facile Method of Pyrolysis

Yanwei Zeng, Zihao He, Linghui Yang, Qunjie Xu*

Shanghai Key Laboratory of Materials Protection and Advanced Materials in Electric Power, Shanghai University of Electric Power, Shanghai 200090, China

e-mail: xuqunjie@shiep.edu.cn

As an environmentally friendly multi-carbohydrate material, chitosan contains a great amount of amino and hydroxy functional groups in the molecular structure. A highly corrosion-resistant carbon film doped nitrogen was successfully prepared on the surface of aluminum alloy 6061 (AA 6061) by pyrolysis. Corrosion behavior of the as-prepared film was studied via EIS, Tafel polarization curve and equivalent circuit in 0.5 M H_2SO_4 and 2 ppm HF. The corrosion current density of carbon film on AA 6061compared that of bare AA 6061 was down dramatically from 8.356×10^{-5} $A\cdot cm^{-2}$ to 7.461×10^{-8} $A\cdot cm^{-2}$,which reveal good corrosion resistance. The surface morphology and composition were characterized by field emission scanning electron microscopy (FE-SEM) and its affiliated energy dispersive spectrometer (EDS), atomic force microscope (AFM), X-ray diffraction (XRD), Raman spectrum, fourier transform infrared spectroscopy (FT-IR) and X-ray photoelectron spectroscopy (XPS), respectively. The results illustrate that the as-prepared film on AA 6061 was a nitrogen-doped graphitized carbon film and exhibited a very high protection inhibition of 99.91%.

The dehydrogenate splitting of formic acid (FA) offers an ideal solution to H_2 storage and on demand releasing in a mobile fuel cell, where catalysis is at the heart of efficient hydrogen delivery. Lack in fundamental knowledge on catalytic interface has bottlenecked the design and development of effective catalysts with both high conversion efficiency and selectivity. In our recent work, we present our effort to understand the nature of active sites for the Pd catalysts,[1] based on which the relationship between the concentration of the substrate and the performance has been discussed. Here we propose that the saturated formate solution with few formic acid could keep the catalyst stay in the best performance, which could make the hydrogen produced longer and faster if the formic acid could be supplied in the same rate.

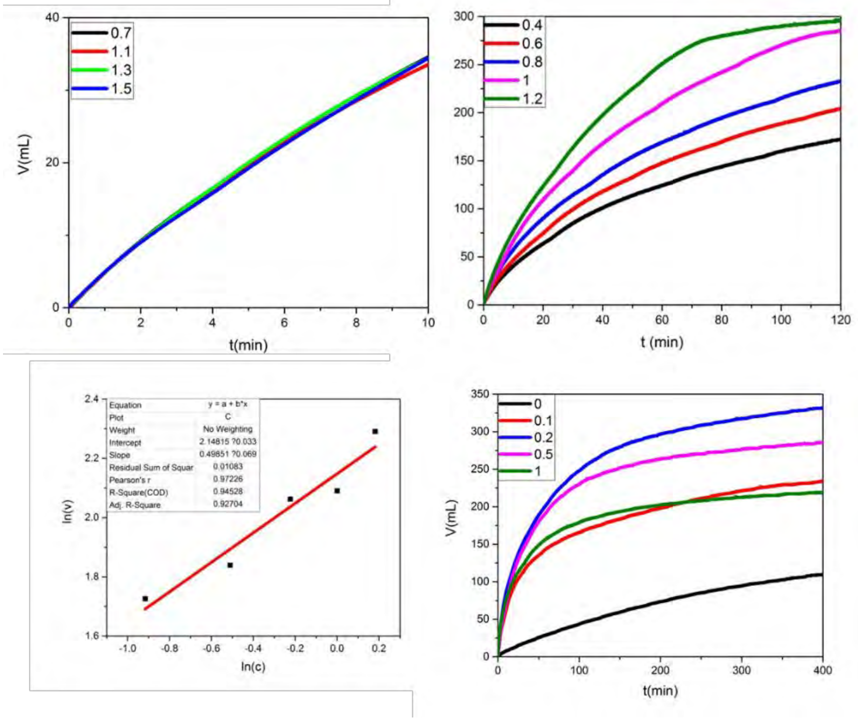

Fig.1 Relationship between the activity and the substrate, (a) HCOOH-Pd/C, (b) HCOONa-Pd/C, (c)linear relationship in (b), and(d) performance in the saturated formate solution with few HCOOH.

Hydrogen is an ideal energy carrier to replace the conventional energy based on fossil fuels, where its high efficiency production constitutes the cornerstone of the sustainable hydrogen economy.(*1, 2*) Currently, the cathode reaction, i.e., the hydrogen evolution reaction (HER) process relies heavily on platinum-based materials, thus impeding the water electrolysis from wide spread application, due to the scarce and high price of Pt.(*3*) Molybdenum disulfide (MoS_2) is reckoned as one of the most positive low-cost HER catalysts to replace platinum-based precious metals in acid media.(*4*) Unfortunately, some issues preclude MoS_2 from being truly applicable including limited active sites, poor conductivity and lack of intrinsic activity.(*5*) Herein, we report a Cu, Pd co-doped MoS_2 nanomaterial as an efficient and stable HER electrocatalysts, which partially resolve the above-mentioned problems and leads to high overall performance. Specifically, we improve the electric conductivity of the MoS_2 by Cu dopant and realize the phase transition of MoS_2 from pristine 2H phase to stable 1T phase by Pd dopant. More importantly, we increase active site density to facilitate fast electrocatalytic Faradaic process via synergistic effects of Cu and Pd doping, and tune electronic energy states of MoS_2 to improve HER intrinsic activity. In acidic media, the performance of Cu-Pd-MoS_2 catalyst in terms of a low overpotential (-93 mV) at 10 mA cm^{-2}, a small Tafel slope of 77 mV dec^{-1}, and an excellent stability is better than that of single-doped catalysts.

Ethanol electrooxidation reaction (EOR) proceeds via a multistep process. Platinum is a good electrocatalyst for the first electro-oxidation step, in acid medium, the adsorption of ethanol is followed by platinum catalyzed dehydrogenation. However, platinum is poor electrocatalyst for ethanol C–C bond break. The last step is the adsorbed CO electro-oxidation to CO_2. Hence, the strategy to enhance the rate of the last elementary oxidation step is to combine platinum with a second metal, specially an oxophilic metal. While Pt_1Rh_1 alloy nanodendrites exhibit superactivity for EOR [1], rhodium alone is a non-active catalyst. Nonetheless, sub-monolayers of Pt (up to 5 %) onto Rh single crystal surface, showed an unexpected enhancement in the activity and the stability of the EOR [2]. Inspired in the excellent performance of rhodium/platinum, bimetallic nanostructured catalysts were synthesized on carbon-dispersed (Black Pearls 2000®-Cabot Corp.) using chemical reduction from metal precursors achieving low Pt content (in mass) compared to Rh ($Rh_{27\%}Pt_{4\%}C_{69\%}$, $Rh_{27\%}Pt_{6\%}C_{67\%}$, and $Rh_{27\%}Pt_{9.5\%}C_{63.5\%}$), and dispersed pure Pt ($Pt_{5\%}C$ and $Pt_{50\%}C$). TGA/DSC scans in air atmosphere from 30 to 1000°C confirmed the Rh and Pt percentages in the nanoparticles. The XRD results indicated the formation of alloyed polycrystalline Rh and Pt nanoparticles [1]. Also, from the Debye-Scherrer equation [1], for the (111) XRD peak, crystallites of ca. 3.8 nm size were calculated for all samples. From HR-TEM images were observed well-dispersed ≈ 5 nm (sphere-like) nanoparticles. Cyclic voltammetry was performed in 0.5 M H_2SO_4, in the presence and absence of ethanol, in a potential range of 0.05 – 1.10 V (RHE), at 50 mV s^{-1}, the 50th cycle was recorded for all electrodes. The main processes observed in the absence of ethanol were hydrogen adsorption/desorption and formation/reduction of metal oxides. In presence of ethanol (0.5 M), it was possible to observe that small amounts of Pt ($Rh_{27\%}Pt_{9.5\%}C_{63.5\%}$) presented an onset potential, in the first cycle, of 0.39 V and 0.50 V for RhPt and Pt/C, respectively. A high non-normalized activity, 1.93 mA (RhPt) and 1.01 mA (Pt/C) at 0.6 V (RHE), were observed. During the subsequent scans, the RhPt electrodes demonstrated a progressive increase in the anodic and cathodic oxidation current densities whereas the Pt/C remains the same or diminishes in the case of $Pt_{5\%}C$. This fact is so interesting, once the low Pt load embedded in Rh was capable to promote an unexpected and superior EOR result, even if the major component (Rh) is inactive. Thus, the low amount of Pt facilitated the ethanol electrooxidation reaction probably by a bifunctional surface during cycling, achieving the best active site configuration without any performance decreasing of these electrodes cycle to cycle [2]. Additionally, from the distance determination between crystallographic planes by HR-TEM, it is possible to suggest that the lattice strain effect associated with the bifunctional surface effect are responsible for the unexpected high catalytic performance of the RhPt nanoparticles.

Though solid polymer electrolyte (SPE) water electrolysis hold the promise in the field of clean energy conversion and utilization, the sluggish anodic oxygen evolution reaction (OER) is the bottleneck for its large overpotential[1]. Herein, we present a Ti doped RuO_2 catalyst with a highly active Ru-O-Ti structure. Attribute to the electron withdraw effect of Ti, Ru in the Ru-O-Ti possess a higher charge density compared with the Ru-O-Ru structure in the undoped one, which can significantly promote the potential determine step of OER on RuO_2 according to the traditional adsorption evolution mechanism (AEM)[2]. Thanks to this unique structure, our best catalyst needs only a low overpotential as 159 mV to reach a current density of 10 mA cm^{-2} in 0.5 M H_2SO_4 electrolyte. Besides, the stable Ti species introduced can work for a long time with only a small amount of dissolves (2.42 % dissolution of Ti after 30 h chronopotentiometry tests at 10 mA cm^{-2}). Full water splitting test imply that a voltage as low as 1.42 V is required to deliver 10.0 mA cm^{-2} for the electrolysis assemble, which is significantly superior to the full cell with bare IrO_2 as anode. We argue that the Ru-O-Ti structure unit introduced by trace Ti doping are responsible for the exhibited superior OER activity.

Hydrogen energy technology with hydrogen as an energy carrier is gaining more and more attention due to its advantages such as non-pollution and high energy density(*1*). Among them, hydrogen evolution reaction is one of the cleanest and most sustainable hydrogen production technologies, as a necessary prerequisite for the future economic development of hydrogen energy(*2*). However, its development is subject to the expensive price of precious metals. One of the ideas is to reduce the loading and increase the atomic utilization rate. Single-atom catalyst is the limit that can be reached at present-the theoretical atom utilization rate 100%-so that each metal site can adsorb H atom and produce hydrogen(*3*). Here, we use phosphomolybdic acid with varying valence effect as a soft reducing agent to reduce Pt(IV) to monodisperse Pt atoms. With the increase of the strong reducing agent $NaBH_4$, the low-valence Mo increase, so there is a greater probability of reducing Pt(IV). Through high-resolution transmission electron microscopy and mapping, it can be determined that Pt exists in monodisperse form. PMA and GO construct an interface that is easy to load with Pt, which greatly improves the stability of the catalyst. Although the overpotential is still not as good as JM-Pt/C-20%, its mass specific activity is dozens of times.

Doping the second metal into iridium oxide offers great opportunities for an efficacious regulation of electrocatalytic activity and stability for oxygen evolution reaction (OER).[1, 2] Here, a novel kind of Gadolinium-doped IrO_2 catalyst with high specific surface area and lots of defects is synthesized by a simple template-free ammonia complex-based method. For 5%-Gd-pIrO_2, the overpotential to achieve 10 mA cm^{-2} is only 287 mV and this catalyst exhibits excellent stability under operating conditions. The exceptional performance is derived from its decreased remarkably crystallinity, abundance electronic defects of iridium and oxygen vacancies controlled by two charge compensating mechanism, boosting the kinetics of oxgen evoluction reaction. We believe this strategy can be extended to multifarious material systems for creating defects in nanoparticles.

In order to improve proton exchange membrane fuel cell (PEMFC) performance and to increase the cell's lifetime, it is necessary to examine the operation of a PEMFC for analyzing performance losses especially the contaminant effect in the different processes inside the fuel cell with suitable techniques. The AC impedance technique, also known as electrochemical impedance spectroscopy (EIS), is a powerful nondestructive technique utilizing in PEMFC studies. In this study, propene at a concentration of 100 ppm as the contaminants were used in the cathode to study the contamination effect in PEMFC. Disregarding the current direction, the redox reactions of propene only account for at most 0.2 % of the total current at the cathode. Using an EES, we illustrated the contamination effect in terms of influence at both R_{ct} and R_c. This work has the great effect on helping use EIS to examine the PEMFCs. [1-2]

The hydrogen-energy society demands a cheap and stable production of hydrogen in which highly-efficient electrocatalysts are of paramount importance. The Ru is cheaper while generally displays inferior performances compared to state-of-the-art Pt for hydrogen evolution reaction (HER). Herein, we discover controlling content of Cl^- can decrease toxic effect on Ru/C catalyst and the ration micro/mesopores can avoid the agglomeration of Ru, which is beneficial to increase performance for HER. We prepared Ru/C catalyst with ruthenium chloride and acetylacetonate, and found that ruthenium acetylacetonate has better performance. The catalyst prepared with ruthenium trichloride washed with ammonia water has 18 mV performance improvement. Therefore, it is concluded that Cl^- does have toxic effect on Ru/C catalyst, and it can be eliminated by high temperature or ammonia water washing; the appropriate proportion of the micro mesopores can avoid the aggregation of Ru, be beneficial to the performance improvement for HER.

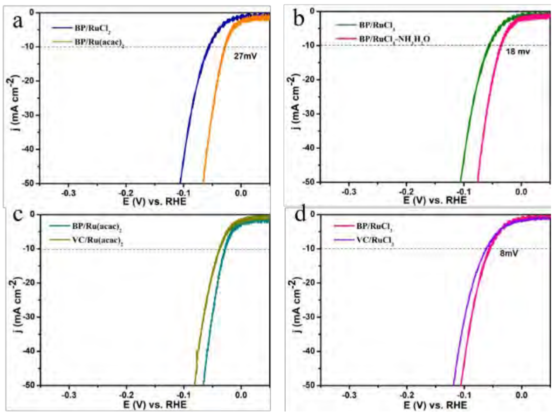

Fig.1 HER polarization curves of Ru/C, (a) different metal sources, (b) Ru/C of after ammonia water washing, (c) and (d) different carbon carriers from the same metal source.

Alkaline aluminum-air batteries show great potential for energy storage applications because of their high theoretical energy density and low cost. However, they are suffering from severe anodic self-corrosion and the gelation of electrolyte which greatly reduce the practical energy density and shelf life. Herein, we firstly construct an efficient high-energy alkaline Al-air battery based on high-concentration potassium acetate-potassium hydroxide electrolyte and prototype optimization. The self-corrosion of Al anode is greatly suppressed owing to the special hydrate structure in such electrolyte. The Al-air battery with optimum electrolyte demonstrates remarkable increased discharge capacity of 2324 mAh g^{-1}, and the constructed miniaturized Al-air battery enables an outstanding system energy density of 436.1 Wh kg^{-1} (compared with 85.8 Wh kg^{-1} of normal electrolyte) after integrating a discharge product removing system. This work opens up a new direction for the practical realization of high- energy, low-cost, and high-efficiency alkaline Al-air battery and other aqueous metal-air batteries. [1-4]

Revisiting Electrocatalysis of Acetaldehyde Oxidation Reaction with Wide Frequency ATR Surface enhanced IR Spectroscopy

Xian-Yin Ma, Sai Duan, Wen-Bin Cai
Shanghai Key Laboratory of Molecular Catalysis and Innovative Materials, Collaborative Innovation Center of Chemistry for Energy Materials, Department of Chemistry, Fudan University, Shanghai 200433, China
E-mail: wbcai@fudan.edu.cn

The adsorption and reaction of acetaldehyde on Pt electrode is of considerable interest in surface chemistry and electrocatalysis, since acetaldehyde is either an intermediate or a reaction product of ethanol oxidation reaction (EOR) or the anode reaction in direct ethanol fuel cells. The in-depth mechanistic understanding of acetaldehyde adsorption and oxidation on Pt electrode is essential for further revealing the mechanism of more complicated EOR and developing relevant efficient catalysts.[1]

For decades, owing to the application of in situ IR spectroscopy with either external (IRAS) or internal (ATR) reflection mode, it has been suggested that two pathways may be involved in the acetaldehyde oxidation reaction (AOR) on Pt surface in acidic media, that is, the minor C1 pathway leading to the production of CO2 and the dominant C2 pathway to acetic acid. The C1 pathway involves the C–C bond cleavage to form COads and CHx surface species at low potentials, followed by their further oxidation to CO2 at high potentials. The C2 pathway may proceed via the oxidation of surface C1 intermediates before forming acetic acid. Despite the above general consensus, details regarding AOR on Pt electrode yet remains controversial, in terms of chemical identity and configuration of surface C2 intermediates.

Recently, thin and micromachined Si wafers, designed as internal reflection elements (IREs) for attenuated total reflectance infrared spectroscopy, were adapted to serve as substrates for electrochemical ATR-SEIRAS by Burgess' group.[2] The 500 μm thick wafer IREs with groove angles of 35° are significantly more transparent at long mid-IR wavelengths as compared to conventional large Si hemisphere IREs. In this work,[3] in situ ATR-SEIRAS technique incorporating a micro-structured Si wafer window, p-polarized infrared radiation and isotope labelling is extended to revisit acetaldehyde electro-oxidation on Pt electrode in acid media. New spectral features in the fingerprint region are detected, including the γ(C-H) at 1078 cm-1 and the νas(C-C-O) at 913 cm-1 for adsorbed acetaldehyde and the δ(O-C-O) at 689 cm-1for adsorbed acetate, besides the other enhanced and clearly discriminated spectral signals at higher frequencies. The ATR-SEIRAS measurements together with new DFT calculations incorporating the coadsorption of CO and C2 species enable to clarify the structures and roles of the C2 intermediates ((η1(C)-acetyl and η1(H)-acetaldehyde) during acetaldehyde electro-oxidation.

Microelectrode Arrays for Biosensing in a 3Dimensional Cell Culture Scaffold

Karthika Kappalakandy Valapil, Wojciech Mazurkiewicz, Emilia Witkowska Nery
Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw
ul. Kasprzaka 44/52, 01-224 Warsaw, Poland
E-mail: karthikakv@ichf.edu.pl

Microelectrode Arrays (MEAs) were introduced in the 1950s[1,2] and from that moment they are used as a basic tool in electrophysiology, yet their applications for analysis of other types of cell activities is till now rather unexplored. When incorporated in a 3D cell culture scaffold, MEAs provide an adaptable platform for sensing and biosensing of normal cell metabolism; they can also be a convenient tool for recording and simultaneously stimulating electrical activities of a neural network.

Our objective is to develop a novel device that incorporates MEAs in a 3D cell culture scaffold. The device will allow visualizing the gradients and cellular functions inside the cell culture during its growth with the help of MEAs that act as a cell-electrode interface. MEAs will be employed in a cell culture for viability tests through analysis of glucose and oxygen consumption. They will also be used for the investigation of neurotransmission through recording of dopamine and glutamate levels in various points of a neural culture.

The current focus is the fabrication of microelectrode arrays using insulated platinum wires of 15 and 25µm diameters. Stable and reproducible performances are achieved from most of the electrodes tested so far (Fig.1). After optimization of the preparation process of the single electrodes they are connected in meshes of 4, which will be later used for analysis in 3D cell cultures.

Simultaneously, we are also working on the development of glucose biosensors as they can be easily modified to sense other species such as glutamate by mere exchange of the enzyme, yet glucose oxidase is much less expensive and easier to work with than other enzymes from the oxidase family. Apart from glucose oxidase the sensor is covered with a layer of a mediator. We are investigating both Prussian Blue (Fig.2) and a metallopolymer that contains poly(vinylimidazole) (PVI) complexed with [osmium-(4,4'- dimethoxy-2,2'-bypyridine)Cl] (Os-dmo-bpy).[3] As the neural cells will be growing directly on the electrodes, we are not neglecting the possibility of accidental stimulations as the neural culture is electrically active and the potential in standard electrochemical measurements is swept till 1.0 V or higher. Although hydrogen peroxide produced through the reaction with oxidase enzyme can be sensed directly on a platinum electrode, we apply a layer of a mediator to reduce the working potential of the electrode and diminish the chance of accidental stimulation of the culture.

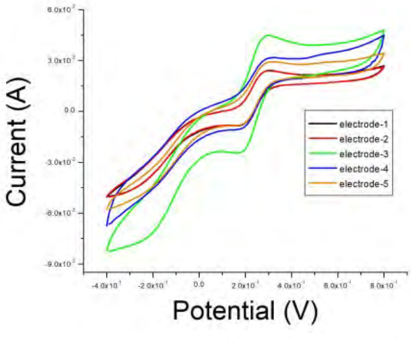

Fig.1 Stable and reproducible performances of five 15 µm platinum microelectrodes in 1mM 1, 1'-Ferrocenedimethanol and 0.1M KCl

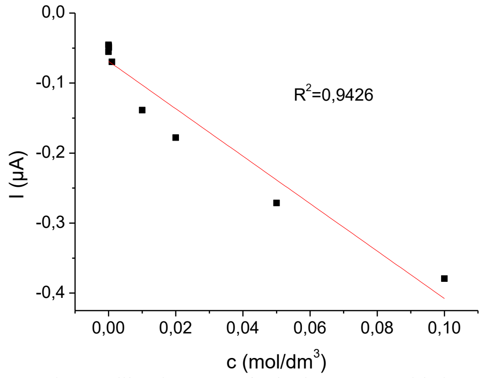

Fig.2 Calibration curve for hydrogen peroxide in PBS Buffer (pH 7.4) measured using Prussian Blue modified glassy carbon electrode vs Ag/AgCl 1M KCl

Multilayered DDM-modified Nickel foam anodes for alkaline water electrolysis

Elitsa Petkucheva, Galin Borisov, Elefteria Lefterova Evelina Slavcheva,
Acad. E. Budevski Institute of Electrochemistry and Energy System - Bulgarian Academy of Sciences,
Acad. G. Bonchev Str.10, Sofia 1113, Bulgaria,
e.petkucheva@iees.bas.bg

Water electrolysis provides a direct pathway for conversion of electrical energy to chemically energy in the form of high-purity hydrogen.

Currently, commercial approach for low temperature water electrolysis is the alkaline water electrolysis (AWE). The alkaline water electrolyzers typically operated in aqueous KOH solutions (c= 25–30 wt% (5.5–6.9 M KOH) and T= 65 °C and 100 °C) where cathode and anode compartments are separated by a porous diaphragm, allowing the conduction of hydroxide ions while separating the product gases.

The AWE offers the distinct advantage of employing relatively inexpensive non-noble electrocatalysts (nickel-based catalysts are most commonly used), which provide for relatively low oxygen evolution reaction (OER) overpotentials and good stability in alkaline media.

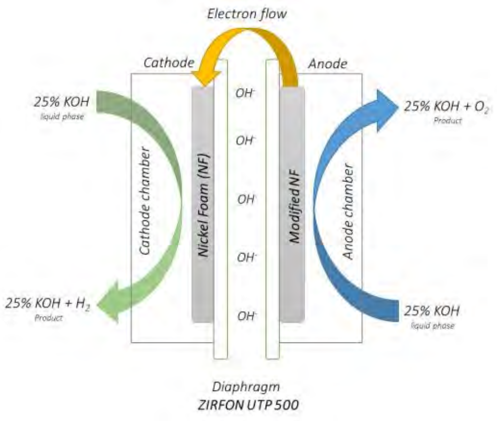

Fig. 1. *AWE setup with immersed porous NF electrodes in zero-gap assembly*

In the present work, a concept for alkaline water electrolyzer with a ‘’Dip and Drying’’modified (DDM) nickel foam (NF) electrodes as anode, a pure NF cathode and a state-of-the-art Zirfon™ separator is presented. The geometric surface of the electrodes was 7 cm^2.

The DDM-NF anode consist 1 mm thick Nickel foam substrate covered with thick micro-pores catalytic layer build from DDM -Nickel powder and PTFE emulsion.

The morphology and the chemical composition of the developed materials/electrodes were analyzed by scanning electron microscopy (SEM) and X-ray difraction (XRD), respectively.

The electrocatalytic activities of the electrodes for the hydrogen (HER) and oxygen (OER) evolution reactions in 1M KOH are investigated by linear sweep voltammetry (LSV), cyclic voltammetry (CV), and chronopotentiometry (CP). Then, the electrodes were fixed in a laboratory made electrolysis test cell and separated by a 0.5 mm thick ceramic diaphragm Zifron Perl 500 (Fig.1). The doping of the diaphragm was performed directly in the cell by circulating 25% KOH solution for 24h at room temperature.

The single cell unit operated in dynamic regime at room and elevated temperatures without any sign of degradation. The current density reached value of 0.150 $A.cm^{-2}$ at 80 ^{0}C and 2V cell voltage.

zxingqun@cqu.edu.cn

Abstract : Understanding the interfacial interaction between metal (M) and transition metal oxides (TMO) support is essential for the material design of high performance electrocatalysts. In this study, we constructed Pt/TiO_2 composite models with interfacial Pt-Ti and Pt-O bonds respectively, to clarify the interface effect on electronic structures, species ad-desorption and migration properties, HER and HOR mechanism through first-principles calculations. Interfacial Pt-Ti metallic interaction causes more delocalized electron on Pt cluster, which strengthens H and OH adsorption, facilitates *H migration and H_2O dissociation. While interfacial Pt-O covalent interaction affects the localized electronic structure of Pt with deficient electron, which results in an optimum H ad-desorption and complicated *H migration processes. The interface sites and non-interface sites jointly provide an efficient H migration channel and reaction pathway. For HER, Pt-O interaction benefits the Tafel step, and Pt-Ti interaction is favorable for the Volmer step. For HOR, Pt-O interaction contributes to a higher HOR activity and an anti-oxidation ability than Pt-Ti. These results can serve as a theoretical guidance for constructing high performance M/TMO electrocatalysts for HER/HOR by regulating interfacial bond type and proportion.

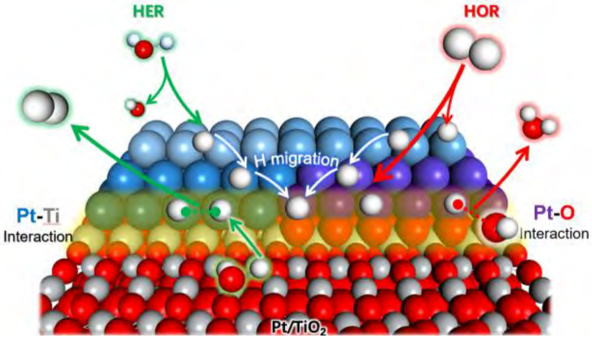

Figure 1 Interfacial Pt-O and Pt-Ti interactions of Pt/Ti contribute two distinct tune effects on HER/HOR.

Fatemeh.shakerihosse@ucalgary.ca

A very high energy density has been reported for the zinc-iodide flow battery [1]. An optimized flow field design for uniform distribution of the electrolyte is desirable for the redox flow battery systems. In order to enhance the performance of a zinc-iodide flow battery, the impact of a new flow field design on the performance of the battery was investigated.

The flow cell used graphite felt electrodes, a Nafion membrane, and had an active area of 5 cm^2. Electroanalytical methods, including cyclic voltammetry (CV), and rotating disk electrode (RDE), were performed to evaluate redox potential, diffusion coefficient and electrochemical reversibility of the electrolyte system.

Charge-discharge characteristics were carried out to investigate cyclability and efficiency of the zinc-iodide battery with and without the presence of flow-through flow field design. The battery cell was tested under constant current density over 40 cycles and test analysis indicated that the efficiency and discharge energy density of the battery improved. Using scanning electron microscopy (SEM) and optical profilometry shows that the presence of flow-through flow field design enhanced the morphology of zinc deposition from a thick and rough deposition to a thinner and soft deposition in the new flow field design. It was also found that due to inhibition of dendrite formation with the presence of flow-through arrangement, a higher range of current density is applicable for the zinc-iodide flow battery.

Electrochemical conversion of carbon dioxide to oxalate and oxalic acid

Suji Jang, Yoonjung Kim, Ji hye Seo, Woonsup Shin*

Department of Chemistry, Sogang University, Seoul, Korea
shinws@sogang.ac.kr

The electrochemical CO_2 conversion technology has merits of the operation at room temperature and atmospheric pressure, and the flexible capability in the scale by stacking and attracts a lot of attention from the industries to capture and convert the CO_2 to useful compounds. Oxalic acid is a reduced dimer of CO_2, and it uses only one-electron per CO_2 for the conversion. It can be one of the most economical and energy-efficient CCU (carbon capture and utilization) processes. We succeeded in producing 0.1 kg/day of the oxalate salt at the current efficiency of 86% in the one-pot cell using a sacrificial anode. Subsequently, the oxalate could be converted to oxalic acid with an efficiency of 75%, by the membrane electrolysis using a three-compartment cell.

Nickel Phosphide Coated with Ultra-Thin Nitrogen Doped Carbon Shell as a Highly Durable and Active Catalyst for the Hydrogen Evolution Reaction

With the aggravating environment pollution and depletion of conventional fossil fuel, the development of clean and sustainable energy, such as solar and wind power, has become a worldwide research hotspot [1]. However, the development of wind and solar energy still face the feasibility problem due to their intermittent nature [2]. Fortunately, water splitting offers an ideal route. Water can be used to store solar and electrical energy to produce hydrogen. This can be realized by electrochemical reactions, which is an efficient method to store electrical energy at scale. Therefore, water electrolysis process plays an important part in the construction of the energy conversion system.

The greatest challenge is the design and fabrication of efficient catalysts for the hydrogen and oxygen evolution reactions of water electrolysis. Although Pt and Pt-based materials are the most effective catalysts for hydrogen evolution reaction (HER) at present, the high cost and low abundance hamper their wider uses. High abundance non-precious catalysts based on transition metals including Ni, Co, Mo, and W are more intensively studied and regarded promising in replacing Pt based materials. Among the varied transition metal based catalysts, transition-metal phosphides, especially nickel and cobalt phosphides, has long been considered as the most effective non-precious electrocatalysts for HER.

To solve the problems mentioned above, herein, highly durable and active Ni_2P nanoparticles with ultrathin N-doped carbon shell are fabricated. With the aim of improving the stability of Ni_2P nanoparticles without affecting their electrocatalytic activity, the number of N-doped carbon layers is controlled. By controlling the thickness, the protective shells are ultrathin (as low as 4 layers) and permeable for the reactant molecules, which avoid catalytic active sites being blocked. In addition, the effect of N dopant on the catalytic activity of the hybrid material is also discussed. As recently published, the sulfur incorporation into transition metal phosphides leads to more optimal ΔG_H* (0.096eV), and achieves the balance of hydrogen adsorption and detachment on Ni sites. Inspired by the similar electronegativities of N and S, herein, N is doped into the carbon matrix to optimize the ΔG_H* of Ni_2P towards better HER activity.

Enhancing Electrode Durability, Process Intensification, and Co-Conversion for Efficient Electroreduction of CO_2

Paul J.A. Kenis
Department of Chemical and Biomolecular Engineering, University of Illinois at Urbana-Champaign
600 South Mathews Avenue, Urbana IL, 61822
kenis@illinois.edu

Today fossil fuels serve as the major feedstock for the production of intermediates, chemicals, and fuels. This approach will not be sustainable for many generations: Accessible fossil fuel reserves are dwindling and the energy-intense thermal / catalytic processes typically employed for chemical production are responsible for a significant fraction of the anthropogenic CO_2 emissions. The use of electrochemical reduction of CO_2 to products such as CO, formic acid, ethylene, and ethanol may be a process that will be key to achieving a more sustainable chemical industry. While techno-economic (TEA) and life-cycle (LCA) analyses of these processes indicates their promise, these also highlight the challenge to compete in terms of cost with present day chemical conversion processes operated at scale [1].

This contribution will elaborate on three approaches to bring electrochemical reduction of CO2 closer to a process that can be implemented at scale, while being economically feasible and (close to) carbon neutral. First, while active and selective catalysts have been developed for products such as CO, formic acid, ethanol, and ethylene, the electrodes that are needed in scalable electrolysis configuration do not exhibit the 1000s of hours of lifetime needed to achieve economic feasibility. This presentation will summarize the range of encountered electrode degradation mechanisms [2], before elaborating on recent work towards (accelerated) durability CO_2 electrolysis testing methods, as well as ways to mitigate electrode degradation.

Second, like many electrocatalytic processes, the electroreduction of CO_2 is highly dependent on the exact operation conditions of the electrolysis process. This presentation will summarize a set of system design rules to enhance CO_2 electrolysis performance (Faradaic efficiency, energy efficiency, conversion efficiency) through fine-tuning of a combination of factors: (i) electrolyte composition and pH; (ii) electrolyte flowrate; (iii) CO_2 feed flowrate; and (iv) catalyst loading.[3] More recently, we have found that the use of mixed electrolytes can be remarkable useful for further process intensification.

Third, upon realizing that 90+% of the total energy required to operate a CO_2 electrolysis cell is consumed at the anode by the energy demanding oxygen evolution reaction, we explored alternative, less energy-demanding options for the anode reaction. We found, for example, that co-conversion of CO_2 (reduction at cathode) with organic waste molecules (oxidation at anode) reduced the overall energy consumption by 40-50%.[4] This presentation will show how this co-conversion process concept can be the starting point for a new generation of chemical manufacturing technology that is significantly more efficient and sustainable (sustainable feedstocks, less greenhouse gas emissions) than the traditional thermochemical processes.

Polyphenols are a large group of organic compounds, that can be characterized by the presence of one or more hydroxylated benzene rings in their structure. In wines two main forms of polyphenols are found; Flavonoids (e.g. quercetin) and Phenolic acids (e.g. gallic and caffeic acid). Because of their useful properties (e.g., antioxidant, anti-mutagenic, anti-carcinogenic etc.) some polyphenols such as curcumin or tannic acid are considered useful reagents, in the treatment of cancer and diabetes. However, other polyphenols such as chlorinated (e.g. 2-chlorophenol) and oestrogenic polyphenols (e.g. Bisphenol) present toxicity and bioaccumulation issues even at low concentrations, thus highlighting the need for simple, selective and highly sensitive electrochemical determination of these for wine analysis, effluent remediation and other purposes.

The aim of this project is the development of an electrochemical biosensor, based on a boron-doped diamond electrode (BDDE) for the determination of tannic acid in aqueous media. The tyrosinase (Tyr-ase) modified electrode was investigated, with special emphasis on the determination of tannic acid. Immobilization of the enzyme onto the electrode active surface confirmed that the enzyme retained its bio-electrocatalytic activity for tannic acid oxidation, which was investigated by means of voltammetric techniques. Tannic acid stock solutions of 5ml were prepared daily, and characterized by attenuated total reflection (ATR) and ultra-violet (UV-Vis) spectroscopy to confirm the functional groups and chemical structure of tannic acid.

A 1.03×10^{-8} M enzyme solution was prepared from a 3.71×10^{-5} M stock solution. Electrode cleaning was done using alumina slurries with particles sizes of 0.05um and 0.3um, with polishing pads. Electrodes were also sonicated in ethanol and water for 5 minutes each, before electro-activation in 1.0M H2SO4 for 15 cycles at 50mV/s and in ultra-pure (Milli-Q) water for 10 cycles at 100mV/s respectively. The Tyr-ase/BDDE biosensor was applied for the detection of tannic acid, and the overall activity of the enzyme was investigated with cyclic and square wave voltammetry. These voltammetric techniques yielded a limit of detection of 0.484mg/L and a limit of quantification of 1.466mg/L with concentrations ranging from 0-6.5mg/L for tannic acid. The biosensor system yielded reasonably high sensitivity and stability for the determination of tannic acid with a standard deviation of 3.25 x 10 -3.

Cambridge, MA 02139, United States
**Corresponding author: bgallant@mit.edu*

Li battery chemistries exploit reactions that occur under very reducing conditions (~ 0 V *vs.* Li/Li$^+$) at negative electrodes, which are held below the electrochemical stability window of known carbonate-based electrolyte systems (0.5-1 V *vs.* Li/Li$^+$),[1] resulting in solvent decomposition at the surface and leading to the formation of a solid electrolyte interphase (SEI). When formed on Li, however, this interphase is unable to fully protect the electrode, resulting in an SEI composition that changes over time.[2] Due to this dynamic nature, its chemistry is challenging to characterize using conventional *ex-situ* surface analysis (*e.g.*, Fourier transform infrared spectroscopy, FTIR; X-ray photoelectron spectroscopy, XPS).[3, 4] Consequently, identifying the chemical mechanisms through which candidate systems for improving Li SEI stability operate – such as the use of highly fluorinated and/or concentrated electrolytes[5] – remains difficult. Fortunately, interphase reactions are known to release gases that are easily detected by gas chromatography (GC) and mass spectrometry (MS),[6] using which we are able to construct a time-resolved picture of the SEI chemistry. Here we show that these experiments can provide valuable insight into the dynamic chemical reaction pathways on Li, yielding an updated picture of factors that contribute to a good SEI.

Our experimental approach consists of a custom-designed electrochemical cell coupled to a GC instrument, which, by sampling the cell headspace periodically, enables *operando* quantification of CO_2, CO, H_2 and C_{1-2} products evolved at Li electrodes. By comparing gas evolution between rest and polarization regimes, we identified a significant increase in the rate of formation of all observed gases when the electrodes are polarized. Using electrodes that we identified to be gas-inert, such as $LiFePO_4$, we identified that the deposition reaction, *i.e.*, Li$^+$ reduction, accounts for nearly all of the gas-releasing interphase reactions, implying that the SEI is only formed electrochemically when Li is plated. We next explored the nature of these reactions by quantifying how the evolution rate of each gas scales with current density, which enabled the distinction between gases that were formed in chemically-limiting reactions and gases that were formed from electrochemically-limiting steps. Because our experiments are able to quantify the abundance of each gas product, we also identified and quantified the branching of specific interphase reactions that occur on Li with conventional carbonate-based electrolyte systems. Then, by rationally tuning the electrolyte (*i.e.,* changing the salt species and/or introducing fluorinated solvents), we discovered and quantified how each component drives specific interphase reactions, and how the ensuing SEI chemistry affects the Faradaic efficiency of the Li electrode over time. In particular, we observed that pathways that promote decarbonylation and/or decarboxylation (*i.e.*, release of CO/CO_2) of the solvent upon reduction correlate with higher Faradaic efficiencies. By varying salt concentration, we further explored how interphase formation pathways are affected by the solvation structure of the electrolyte in the contact-ion and solvent-separated regimes. Thus, our experiments provide a mechanistic picture of how organic solvent-derived products affect SEI chemistry and stability, which can be as important as known ionic phases like LiF.[5]

New electroanalytical methodologies in low conductivity media such as fatty acids alkyl esters, also known as biodiesel, have been of great interest in analytical chemistry. Self-oxidation of pure biodiesel (B100) gives rise to secondary oxidation products so that B100 oxidative stability is a quality criterion that requires regular monitoring. Therefore, rapid and direct quantification of species present in biodiesel is important to allow adjustments and ensure product quality even in production line. A study on oxidation of ferrocene (Fc) in aqueous media by Bond et al (1) showed poor adsorption on the electrode surface so that, even so, the Fc^+/Fc redox pair can be used as a reference system in this medium. In the present study, B100 samples prepared in water in oil microemulsion (w/o ME), containing ferrocene (Fc) as a probe were analyzed using differential pulse voltammetry (DPV) at a Pt ultramicroelectrode (ume), to evaluate oxygen influence in this medium. A µAUTOLAB TYPE III potentiostat/galvanostat provided with a general-purpose electrochemical system (GPES) software has been used in voltammetric measurements conducted in a three-electrode configuration cell. The working electrode was a 10 µm radius Pt disk ume, while a Pt ribbon and a Pt wire were, respectively, the auxiliary and quasi reference electrodes. Successive additions of Fc in w/o ME were made in concentrations ranging from, respectively, 1.2×10^{-3} mol L^{-1} to 2.1×10^{-3} mol L^{-1}. Experimental conditions were: 10 mV amplitude; 50 ms pulse width and 5 mV s^{-1} potential scan rate. All voltammetric measurements were carried out at room temperature without stirring. Influence of oxygen was evaluated de-aerating the system through bubbling nitrogen for 5 minutes. The B100 sample was used within specifications set by the Brazilian National Agency of Petroleum, Natural Gas and Biofuels (ANP). The ME was prepared in % mass/mass with water (9%), B100 (28%) and sodium dodecyl sulphate (SDS):n-pentanol (1:4) (63%). Microemulsion components were mixed sequentially and mechanically stirred until obtaining a clear and homogeneous system. It was observed that a current peak, i_p, which doubles in value with increasing concentration of Fc appears at a potential, E_p, around 0.100 V. In the same scan, around 1.400 V there is a second current peak which also increases with Fc concentration. However, when the system is de-aerated, the first peak remains unchanged whereas the second one practically disappears. This behavior may be indicating that there is a chemical reaction between oxygen and Fc or Fc and some ME component. The first peak could also correspond to oxidation of Fc dissolved in the continuous medium, which requires less positive potentials, while the second one would correspond to ferrocene dissolved into the water droplets. In this hypothesis, the droplets surfactant-cosurfactant envelope would require a more positive potential for its rupture to release dissolved Fc. The results obtained for the redox reaction of the Fc^+/Fc pair in the studied system show a good relationship between Fc concentration and the measured current, as well as influence of oxygen in the medium, as already described for polar organic solvents (2). Thus, it has been demonstrated that preparation of B100 samples as w/o microemulsion enable analysis by differential pulse voltammetry, de-aeration of the medium being recommended.

The increasing energy demand, finite nature of fossil fuel resources and global environmental challenges have promoted the development of alternative energies and green technologies. Proton exchange membrane fuel cells (PEMFCs) are promising alternatives because they convert chemical energy from hydrogen and oxygen (or air) into electricity with high efficiency, high power density, and low or zero pollutant emissions[1]. Several studies have been done to improve the overall efficiency of PEM cell stacks including the development and selection of an adequate catalyst layer, proton exchange membrane, gas diffusion layers and flow channels configurations. Bipolar plates (BP) are one of the most important components in cell stacks because they perform several functions like supply the reactant gases through the flow channels, provide structural support and facilitate water and heat management [2]. Inadequate design of BP leads to bumpy reactant gases distribution, localized hot spots, uneven current density and flooding of the device caused by poor water management [3]. Numerous studies have been done to improve the bipolar plate design, in this context, interdigitated flow fields rise to prevent water flooding phenomenon and promote a better mass transfer through porous media [4]. Biomimetic flow fields, inspired on nature, have been designed to reduce the pressure drop and current distribution, and water removal. In the present work, computational fluid dynamics (CFD) simulations of an interdigitated flow field based on leaf veins was carry out to be tested on a cathodic compartment in PEMFC.

Model development for CFD simulations is based on the Navier-Stokes equations coupled to continuity equation for a free flow through channels and Brinkman equations on porous media; governing equations for mass transfer are described by the Mixture-averaged transport model with the Bruggeman´s correction for porous media and the electrochemical kinetic is represented by the Butler-Volmer equation. The transport equations were solved numerically in 3D by finite element method using the software COMSOL Multiphysics. CFD simulations were carried out in order to analyze the effect of different operation variables on cell performance. Finally, simulation results were validated using experimental. A computer numerical control (CNC) machine with one-way trajectory was used to produce the interdigitated monopolar plate to carry out cathodic experiments with the aim of validating the CDF simulations.

In the presented paper, fabrication, and tests of an electrochemical chemosensor for selective determination and quantification of cilostazol is described. Cilostazol, 6-[4-(1-cyclohexyl-1H-tetrazol-5-yl)butoxy]-3,4-dihydro-2(1H)-quinolinone, is an antiplatelet agent and a phosphodiesterase III inhibitor. It is used for the treatment of intermittent claudication (IC), a preliminary symptom of peripheral arterial disease (PAD). PAD is most commonly caused by atherosclerosis. It affects millions of patients worldwide and is associated with significant morbidity and mortality.[1] Fast, simple and reliable method of this drug determination along with its principal active metabolites is important from the point of view of personalized drug dosage. In order to devise selective chemosensor for determination of cilostazol in biological matrices, molecularly imprinted polymer nanoparticles (nanoMIPs) were prepared by precipitation polymerization of the selected acrylate derivatives and were characterized.[2] Furthermore, density functional theory (DFT) calculations were performed for better understanding of interactions between the acylate monomers and the target analyte, and also with its principal metabolites. The result indicated pre-polymerization complex formation mainly through H-bonding.

In the next step the nanoMIPs were immobilized on the gold electrode. Then, the obtained electrodes were characterized electrochemically and spectrally. Moreover, morphology of the obtained electrodes was studied by AFM microscopy. Finally, the analytical tests of the devised chemosensor were performed.

Funding: Polish National Science Center (grant No. 2015/19/B/ST4/03743).

Rising global warming by CO_2 emissions from fossil fuel combustion and increasing energy demands have led researchers all over the world to focus on developing technologies for clean energy production. Fuel cells and batteries are in the focus of many research groups and have great potential to replace fossil fuel-based technologies for numerous applications. In order for fuel cells to produce high currents, high performing metal-based catalysts for oxygen reduction reaction (ORR), oxygen evolution reaction (OER), hydrogen oxidation reaction (HOR), and hydrogen evolution reaction (HER) are of great importance. In this work, we synthesized manganese oxide-based catalysts as cathode materials for regenerative fuel cell applications. Three catalysts based on Mn_2O_3 were synthesized: Mn_2O_3 in pure form, Mn_2O_3 with anchored Pt nanoparticles (NPs), and Mn_2O_3 with Pt and Ni NPs. Ni and Pt NPs were anchored via microwave irradiation method.[1]

Linear scan voltammetry (LSV) experiments in 0.1 M KOH in ORR potential region clearly show that attaching NPs on pure Mn_2O_3 has a positive effect on limiting current density and onset potential values. For Mn_2O_3 we found limiting current density of -2.31 mA cm^{-2}, while the Pt/Mn_2O_3 sample has shown limiting diffusion current density of -4.00 mA cm^{-2}. PtNi/Mn_2O_3 sample showed a slightly reduced value of limiting current density (-3.17 mA cm^{-2}), but this sample contained only 10 wt.% of Pt and 10 wt.% of Ni NPs, comparing to Pt/Mn_2O_3, which had 20 wt. % of Pt NPs. Pt is well known for its electrocatalytic performance, but also for its high price.[2] LSV experiments performed in the potential region corresponding to OER revealed that all samples exhibit similar behavior in terms of the onset potential of the investigated reaction. After performing IR correction all three LSVs overlapped almost perfectly. The difference could only be observed in maximum current densities that have been reached in each experiment. The highest one is reached with the pure Mn_2O_3 sample, followed by PtNi/Mn_2O_3 sample. The lowest value was shown by the sample containing only Pt NPs. Tested samples showed promising results for both investigated reactions. Having in mind the cost of Pt and comparing its performance with the sample that also contains Ni NPs, we must emphasize the potential of PtNi/Mn_2O_3 catalyst for regenerative fuel cell application. Further analysis should be performed to get better insights into the kinetics of both reactions on these catalysts. Also, one of the main aims of future investigation is testing the stability and their performances in a real regenerative fuel cell.

daniely_reis95@hotmail.com

Titanium-based materials have been extensively studied in a variety of different applications. Among them are studies aimed at the photodegradation of pollutants present in water and wastewater, such as dyes. About 10-15 % of the amount of dye produced in the world is released from the process into the environment, which is an alarming issue from an environmental point of view [1]. Thus, different studies have been carried out in order to promote the total mineralization of pollutants into innocuous compounds, such as CO_2 and H_2O. Due to the limitations of the TiO_2 semiconductor (high recombination rate of photogenerated charges; band gap energy 3.2 eV, anatase phase), modifications by decoration or doping with metals or metal oxides have been evaluated as an alternative to improve this semiconductor [2]. Considering that Brazil has the largest reserve of Nb in the world, holding 98 % of the world's reserves of ore, and its low cost, combined with the advantages related to the structural modification by doping and surface modification, this study proposes the production of photocatalytic oxides nanoscale in Ti14Nb alloy. In the niobium-oxygen system the phases NbO, NbO_2 and Nb_2O_5 are the main ones observed [3]. In general, materials which are modified with Nb shows Nb_2O_5 in the composition of the nanotubes (NT), as well as absorption in the visible region due to doping in the oxide matrix. In this context, this work presents the formation of nanotubular oxide layer (NOL) grown on Ti14wt.%Nb substrate under different preparation methods, cast (BF) and quenching (CT). The influence of substrate type, the temperature on the crystallization of oxides and on the performance of the semiconductor photocatalytic activity used in the degradation of Reactive Blue 4 (RB4) dye was evaluated. The nanotubes were grown on Ti14wt.%Nb substrate by anodization process, using HF solution (0.3%, v/v) under a constant potential of 20 V, reached after a voltage ramp of 2 V min^{-1}. Then, the samples were heat treated at different temperatures from 450 to 650 ° C, in order to optimize the conversion temperature of the amorphous structures, resulting from the anodization process, into highly ordered crystalline structures. The oxide layer grown on Ti14wt.%Nb substrate was characterized by SEM, EDX and XRD. Photoactivity studies were carried out and compared among different heat treatment temperatures using the linear voltammetry technique in 0.1 M Na_2SO_4 solution, pH 3, with potential range from -0,025 to 1,5 V *vs*. Ag/AgCl/Cl^- (3 mol L^{-1}). The evaluation of the performance of the alloy in color removal and degradation of the Reactive Blue 4 (RB4) dye by photocatalytic and photoelectrocatalytic processes under UV/visible and visible light was carried out and compared with the TiO_2 semiconductor. The results demonstrated that the addition of Nb in the oxide layer leads to an increase in the anatase-rutile transition temperature. The presence of Nb_2O_5 was confirmed by XRD and EDX analyzes, which give the material a hybrid behavior (partially doped with Nb), even in small quantities. The sample NT/Ti14wt.%Nb-Q showed better photoactivity compared to the sample NT/Ti14wt.%Nb-C and NT/TiO_2. The best condition obtained for the NT/Ti14wt.%Nb-Q sample was under heat treatment at 650 °C, which presented a current intensity of 1.08 and 0.71 mA cm^{-2} under UV/visible and visible light, respectively. Comparing the electrodes studied, in photoelectrocatalysis (PEC) under UV/visible light, NT/Ti14wt.%Nb-Q was more efficient in the degradation of Reactive Blue 4 (RB4), reaching 66 % reduction of the initial carbon concentration [Co] over 1.5 hours, total discoloration after 20 min and total mineralization after 2 hours; while the sample of NT/Ti14wt.% Nb-C reduced 88 % of [Co] in 3 hours and total discoloration after 30 min. The decolorization data for PEC under UV/visible light were adjusted in the pseudo-first order and a constant rate (*k*) of 0.17 and 0.19 min^{-1} was found for the NT/Ti14wt.%Nb-C and NT/Ti14wt.%Nb-Q, respectively, whose value is almost double the value of the obtained for NT/TiO_2 electrode under the same conditions. The better performance of the NT/Ti14wt.%Nb electrode in photoelectrocatalysis was attributed to the doping of TiO_2 with Nb.

In this work, the detection and quantification of paracetamol was performed by differential pulse voltammetry (DPV) with a cork-modified graphite electrode. The calibration curve and the limits of detection and quantification for paracetamol were estimated. DPV was compared to high-performance liquid chromatography (HPLC) analysis, leading to a satisfactory result in terms of stability and sensitive response. As a novel aim, a combined electrochemical method for environmental application has been developed to oxidize and detect paracetamol using diamond films and cork-modified graphite electrodes. A set of galvanostatic electrochemical oxidation experiments with 1L of Paracetamol solution were accomplished in order to understand the effect of current density, the concentration of the pollutant and the concentration of electrolyte. Applying DPV in an acidic medium with the cork-modified graphite electrode, it was possible determine the concentrations of PAR (ranging from 0 to 1000 µM), with limits of detection of 8.36µM. The optimal operating conditions were achieved at 60 mA cm^{-2}, 100 mg L^{-1} of Paracetamol with 50 mM Na2SO4. Additionally, the evolution of short-chain carboxylic acids of that test was followed over time in order to suggest a possible degradation route. The results were described and discussed in the light of the existing literature.

Gas diffusion electrodes (GDE) produced with carbon matrices have been applied in the hydrogen peroxide electrogeneration and used in electro-Fenton process. In GDE, an increase of peroxide electrogeneration can be achieved by improving the carbon matrix (CM) or by incorporating electrocatalysts in CM. Different CM has been studied, among them, Printex 6L Carbon (P6LC) has a good cost and efficiency ratio, as it has a high surface area and a selectivity for the oxygen reduction reaction (ORR) via 2 electrons. Regarding the new electrocatalysts studied, bimetallic oxides are being applied as electrocatalysts to ORR, due to the synergism between metals as catalysts for ORR. In this study, a new one-step route to obtain $Co_2V_2O_7$ is described, as well as the incorporation in P6LC that is used in the electrochemical study of ORR, and the application of the modified matrix in the GDE. The $Co_2V_2O_7$ was obtained by co-precipitation from the neutralization of solutions containing the precursors. For this, two solutions were prepared (20 mL): A) 0.1 M HNO_3 + 0.2 M $Co(NO_3)_2$ and B) 0.1 M NH_4OH + 0.2 M NH_4VO_3. Both solutions were heated to 80º C. Then, solution A was transferred drop by drop to solution B, under agitation. After all, the material was filtered, washed with deionized water, and dried at 120º C. The material was characterized by XRD. Diffractogram analysis indicates the presence of the monoclinic phase associated with $Co_2V_2O_7$ (ICSD 2357). Any secondary phases were not observed, and thermal treatment was not necessary, unlike the syntheses reported in the literature. The $Co_2V_2O_7$ oxide was added to P6LC by physical adsorption in the proportions of 2.5, 5.0, 10.0, and 15.0 % (w/w). For this, both catalytic masses were mixed with isopropyl alcohol under magnetic stirring for 40 min, dried for 3 h (2 h at 60 ºC and 1h at 100 ºC). Electrochemical measurements (electrochemical impedance and analysis of the ORR efficiency studies) were performed using the porous microlayer technique applied on the glassy carbon disc. The study of ORR was carried out using linear scanning voltammetry coupled to a rotating ring disk electrode (RRDE) system, with a rotation speed of 100 to 2500 rpm. The PL6C presented a maximum current value of 135 µA. The 15% $Co_2V_2O_7$/PL6C had the highest recorded value, 160 µA, followed by the 2.5% $Co_2V_2O_7$/PL6C with 147 µA, a value close to the 5% $Co_2V_2O_7$/PL6C (143 µA). The modification with $Co_2V_2O_7$ tends to improve CM's selectivity, leading to a higher electrogeneration of H_2O_2. Also, the ORR onset is the same for all catalysts, having a value close to -0.15 V vs. Ag/AgCl, which suggests that the modification does not alter the start of the reaction, only increases its selectivity. However, at low potentials of -0.3 V, a displacement of the current recorded on the disk to more negative values are observed. This shift towards that more negative potentials results in greater consumption of electrical energy from the ORR for the H_2O_2 electrogeneration. The PL6C had shown a value of H_2O_2 selectivity (%) equal to 85.0 %. In the modified matrices the values was: 92.0; 91.0; 90.9 and 86.8% to 2.5; 5; 10 and 15%, respectively. With these results and EIS analysis, the modified matrix with 2.5% $Co_2V_2O_7$ was chosen for the production of GDE. The GDE containing 40% PTFE was prepared by mixing the catalytic mass with the PTFE, in 400 ml of ultrapure water under constant agitation for 60 min. The suspension was filtered, and 2 g of the new mixture was placed between two metal plates under 7.5 tons, 290 ºC for 2 h. Then, the study of H_2O_2 electrogeneration was carried out by electrolysis at constant current density (25, 50, 75, and 100 mA cm^{-2}), using GDE (unmodified, only PL6C) and GDEm (PL6C modified with 2.5% $Co_2V_2O_7$). The maximum concentration of H_2O_2 obtained for the GDE was 132 mg L^{-1}, after 90 min at a current density of -100 mA cm^{-2}. For GDEm, an increase of 33.3% in H_2O_2 electrogeneration was observed (176 mg L^{-1}), for the same current density. Analyzing the energy consumption (EC) for GDEm, the value was 86.2 kWh kg^{-1} to $j = -100$ mA cm^{-2}, lower than observed for GDE (116.3 kWh kg^{-1}). However, the density that showed the best ratio between EC and H_2O_2 electrogeneration was -75 mA cm^{-2}, which produced 147 mg L^{-1} of H_2O_2, and EC was 59.4 kWh kg^{-1}. In conclusion, the proposed new one-route was a simple method to produce a new selective material to H_2O_2 electrogeneration. This material can be adsorbed onto CM to increase the performance of GDEs and to decrease the energetic consumption of these electrodes.

On the electrolysis of liquefied lignocellulosic biomass

This work aims at producing electrolytic H_2 and explore the possibility of capturing CO_2 through the electrolysis of liquefied biomass. Lignocellulosic biomass is constituted by three main polymers: cellulose, hemicellulose, and lignin [1]. Biomass is globally used for different energy needs including, electricity generation, heat for domestic and industrial use, and transportation fuels. However, biomass is mostly used through direct combustion [2]. The major obstacle for the utilization of lignocellulosic biomass is the cost-benefit relation of used technologies to process this kind of material and produce fuels and high-added value chemical compounds [1]. The electrolysis process of liquefied biomass powered by renewable energy and, consequently, without CO_2 emissions, has the potential for H_2 production (chemical energy storage) scale-up. Furthermore, the electroreduction of CO_2 is a promising approach for the reduction of CO_2 emissions that is receiving increasing interest from the scientific community, policy makers and the general public [3].

For this purpose, voltammetric, chronoamperometric, rotating disk electrode (RDE), and rotating ring disk electrode (RRDE) studies are employed for the electrochemical characterization of an emulsion constituted by a 1:1 mix of liquefied biomass and a 2 M KOH aqueous solution (for the ionic conductivity enhancement). A small-scale laboratory liquefied biomass electrolyzer is assembled and used to analyze the electrolysis optimal working conditions. Temperature, voltage, and different anode materials (Ni and TiO_2-RuO_2) are studied. In all experiments, gas generation is observed at the Ni cathode side. The results show that when Ni electrodes are used for both cathode and anode the generated current is four times higher than employing a TiO_2-RuO_2 anode. Additionally, the use of higher temperatures (55 ºC) generates two times higher currents than those obtained at room temperature. As, expected, currents were also improved when increasing the potential up to 2.4 V. Additional experiments involved CO_2 continuous bubbling in the solution during the electrolysis. The results show that the CO_2 bubbling is able to hold stable the liquefied biomass emulsion's ionic conductivity for significantly longer times than in the experiments without CO_2 addition.

The authors would like to thank the Portuguese Foundation for Science and Technology (FCT) for contract no. IF/01084/2014/CP1214/CT0003 under IF2014 Programme (D.M.F. Santos) and for PhD grant SFRH/BD/137470/2018 (R.C.P. Oliveira). This work was carried out under the Project Clean4G – "Conversion of CO_2 from cement production process into a clean gaseous fuel for use in the same process - circularity in the process of cement emissions" (POCI-01-0247-FEDER-038323), funded by the Portuguese Ministry of Economy in the frame of "Program Portugal 2020".

Computational Core Level Electron Spectroscopy of Ionic Liquids in Bulk and at Interfaces

Vladislav Ivaništšev,[a] Heigo Ers,[a] Meeri Lembinen,[b] Enn Lust.[a]
[a] Institute of Chemistry, University of Tartu, Ravila 14a, 50411 Tartu, Estonia
[b] Institute of Physics, University of Tartu, Ostwaldi str. 1, Tartu 50411, Estonia
e-mail address: vladislav.ivanistsev@ut.ee

On the example of 40 ion pairs (5 cations times 8 anions), this study demonstrates how the core-level binding energy values can be calculated and used to plot theoretical spectra at low computational cost using density functional theory methods [1]. Three approaches for obtaining the binding energy values are based on delta Kohn–Sham (ΔKS) calculations, 1s KS orbital energies, and atomic charges. The ΔKS results show reasonable agreement with the available experimental X-ray photoelectron data [2–6]. The 1s KS orbital energies correlate well with the ΔKS results. Atomic charge correlation with ΔKS is improved by accounting for the charges of neighboring atoms. The choice between the methods implies a compromise between computational cost and accuracy. For instance, differently from the other methods, the order of ΔKS binding energies is in agreement with the difference spectroscopy used to resolve the order of peaks in pyridinium- and imidazolium-based ILs by comparing the XPS of functionalized and non-functionalized cations [7]. Besides being more accurate, the ΔKS method is also more resource-demanding and less accessible than the other two methods. Thus, the use of the 1s KS orbital energies and atomic charges is justified when qualitative aspects of X-ray photoelectron spectra are of higher interest than the absolute BE values, or when the available computational power is limited. For example, the experimental data taken from [2–4] measured in connection to the electrochemical application in the supercapacitors. On example of graphene–ionic liquid interface, we show that 1s KS orbital energies and atomic charges can be obtained in molecular-level simulations of a supercapacitor model at a relatively low cost.

[*]*silvar.kallip@ut.ee*

The Scanning Vibrating Electrode Technique has been applied to corrosion research for few decades and proved its relevance especially in specific localized corrosion research on carefully designed model-electrode situations. However, due to the technical restrictions several limitations to the sample conditions have to be taken into account, especially the sample size and topography, as the ionic currents under observation are rapidly dependent on the probe to surface distance.

New technical approach of combining the scanning confocal microscopy and 3D resolved SVET will be presented. Several topographically complicated and demanding model electrode systems were explored and the approach of localized electrochemical technics will be discussed and evaluated.

The Different Al alloys (such as aeronautically relevant AA2024 and modern Al-Li alloy AA2198) are given as studied examples for estimation of corrosion localization and it's influence. Also, the different technologically relevant galvanic situations like CFRP + Al alloys or Ti + Al are considered in respect of design of dedicated corrosion inhibiting systems and its relevance of application of new approaches of SVET technique.

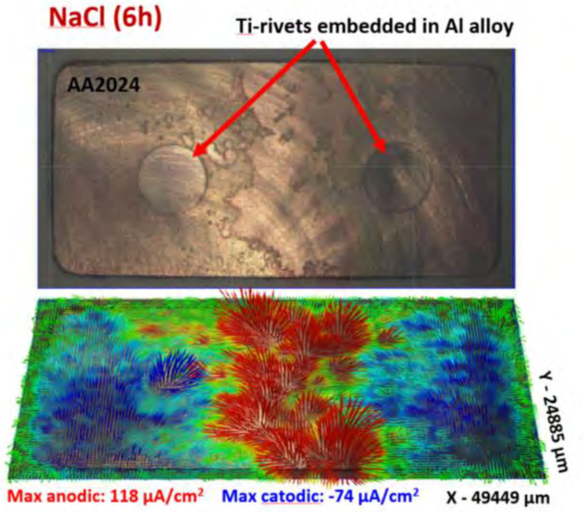

Figure 1. Photograph and 3D SVET map of AA2024 sample with two embedded Ti rivets immersed in 0.05M NaCl for 6h. Localized distribution of galvanic corrosion activities are exposed.

The pressing energy challenges for the coming years call for new materials and new technologies. In the building sector, the need to increase the buildings energy-efficiency must be urgently addressed. The use of low-carbon technologies and renewable sources is essential to implement zero-energy buildings (ZEBs). For instance, efforts to considerably improve the performance of the current photovoltaic (PV) cells and to integrate them into buildings must be made. Luminescent down-shifting (LDS) layers and luminescent solar concentrators (LSCs) are valuable options to tackle this issue. LDS layers are coatings directly applied on the PV cell surface, which absorb the incident radiation complementary to that of the PV cell, and subsequently re-emit it at a specific wavelength that is refracted towards the PV cell. LSCs can be embedded in façades or windows, allowing them to be transformed into energy harvesting units, operating similarly under direct and diffuse sunlight conditions. Another attractive way of increasing energy efficiency in buildings is to incorporate smart electrochromic devices (ECDs) able to modulate sunlight transmittance (visible radiation) and solar heat gain (near-infrared (NIR) radiation) and thus reduce the buildings energy use, increase indoors thermal/visual comfort, and improve outdoors view.

Trivalent lanthanide (Ln^{3+})-based complexes exhibit attractive photoluminescence features, but display poor mechanical properties and low thermal stability. To circumvent these disadvantages these compounds may be added as complex anions of ionic liquids (ILs) whose cations are covalently bonded to the surface of silica to yield luminescent ionosilicas (ISs) [1]. In the light of this approach, we produced optically active coatings for LSCs composed of poly(methyl methacrylate) (PMMA) and imidazolium-based ISs containing Eu^{3+}- and Tb^{3+}-based complex counter anions [2]. Recently IS-PMMA LDS layers were coated on the surface of commercial Si-based PV cells. By controlling the down-shifting layer thickness, the layers also acted as LSCs enabling the collection of the guided radiation by flexible PV cells applied on the borders of the down-shifting layer leading to a marked enhancement of the PV energy conversion. Herein, the electro-optical performance of luminescent ECDs incorporating electrolytes composed of a mixture of Eu^{3+}-doped IS-PMMA and an IL, was tested.

The mechanism of the electrochemical oxidation of kraft black liquor (BL) is extremely complex and, to further understand it, a combination of different techniques is required. Simple voltammetric studies, chronoamperometry, and chronopotentiometry have been employed in the electrochemical characterization of BL [1-4], but the results do not provide enough information to elaborate an oxidation mechanism. To collect more data about this process and help in the construction of a logical mechanism, further studies employing rotating disk electrode (RDE) and rotating ring disk electrode (RRDE) are required.

This study deals with the analysis of the effect of the convection (rotation) in the BL oxidation employing commercial bulk Pt, Au, and Ag RDEs. The effect of temperature under convection is also analyzed and compared with the same effect in diffusion-limited conditions. The number of exchanged electrons is calculated by applying the Koutecky-Levich method and compared with the results obtained by Randles–Sevcik equation (in the absence of convection). The electrochemical behavior of black liquor at the three different electrodes is compared to understand how the electrode material affects the mechanism of the BL oxidation. To the best of our knowledge, this is the first black liquor RDE study to be reported.

Swine wastewater (SW) is a complex wastewater composed of organic and inorganic contaminants. These substances mainly include polysaccharides, proteins, lignin, and short-chain fatty acids, but also pathogens, antibiotics, trace metals (e.g., Zn, Cu), and salts (e.g., NaCl, KCl) [1]. Electrochemical methods have been widely used for the mineralization of a wide range of environmental pollutants from wastewaters containing varying amounts of inorganic ions and organic compounds with a growing interest in SW as a target solution [2].

However, little is known about the fundamental mechanisms that rule the oxidation of pollutants in these wastewaters. In fact, fundamental electrochemical studies dedicated to understanding the electrochemical behavior of these wastewaters as a background electrolyte are very limited. This knowledge is important because low-grade electrolytes can be used in alternative strategies for hydrogen production from water by replacing the challenging oxygen evolution reaction with thermodynamically more favorable organic oxidation reactions that occur at a lower redox potential [3,4].

Based on these premises, this work aims to present voltammetric studies to obtain a better knowledge of the anodic processes (organics oxidation) occurring during the electrolysis of swine-derived solutions. In particular, cyclic voltammetry using a Pt electrode was used to get a preliminary portrait of the electrochemical behavior of two swine solutions: raw wastewater (RW), as collected from a pig farm, and digested wastewater (DW), as the effluent from the anaerobic digestion of the same wastewater. Subsequently, to analyze possible oxidation processes, voltammograms were recorded at different scan rates (5 - 1000 mV s^{-1}) and conclusions were drawn about the nature of the electrochemical process. The electrochemical degradation of raw and anaerobically digested SW samples was also investigated over graphite and nickel electrodes in potentiostatic conditions. The obtained results suggest the development of the concept of a SW electrolyzer that can be installed in future pig farms.

The oxygen reduction reaction (ORR) is one of the most studied in electrochemistry due to its participation in energy conversion devices. Its slow kinetics leads to the inevitable use of catalysts. Within this context, considerable attention was dedicated to electrocatalysis at conducting polymers (CPs) electrodes, its high conductivity and chemical stability makes them very suitable for electrocatalysis purposes [1]. An example of them is CP poly(3-aminobenzylamine-co-aniline) (PABA), copolymer of aniline (ANI), an ORR catalyst, and 3-aminobenzylamine (ABA), which allows the catalysis to occur at neutral pH. One way for increasing the efficiency of these catalysts is the pre-concentration of the O_2 reagent on the surface of the electrode. To achieve that, organometallic networks (MOF) are used as a novel three-dimensional microporous architecture. In particular, the MOF ZIF-8 (Zeolitic Imidazolate Frame), obtained via the polymeric reaction between $Zn(NO_3).6H_2O$ and 2-methyl-imidazole, is widely employed as an O_2 preconcentrator at the electrocatalytic interface.

On the other hand, aniline polymer (PANI) is known to reduce O_2 through the formation of H_2O_2 in a two-electron process [2] but nothing is specifically known about the O_2 reduction mechanism in PABA. Meanwhile, the path of the O_2 molecule through the pores of the ZIF-8 is more turbulent than in solution, being able to modify the kinetics of the conductive polymer.

In this work we will present the development of an electrode composed of the PABA film decorated with ZIF-8 crystals and results from rotating disk electrode (RDE) experiments, performed in order to model the kinetics of the system.

First of all, we will show the electropolymerization of the catalytic copolymer PABA. The obtained nanofilm has been characterized electrochemically and studied by atomic force microscopy (AFM), making possible the elucidation of the surface topography and the determination of its thickness. We will also present the characterization of the ZIF-8 crystals grown onto the PABA-coated electrode, which consist of scanning electron microscopy (SEM) and AFM studies, with the purpose of obtaining details of its microstructure, and X-ray diffraction (XRD) to describe its crystalline nature. Additionally, we will show an ORR linear scan voltammetry (LCV) of the system carried out to demonstrate the effective improvement provided by the ZIF-8 crystals in the catalytic activity of the PABA copolymer for the ORR. Finally, we will provide RDE results that will make possible to establish the kinetic mechanism of the ORR catalysis by PABA and whether or not such mechanism is altered by the presence of the ZIF-8 crystals.

This study investigated the binary PtRu electrocatalyst prepared by modified polyol method for methanol oxidation reaction (MOR)in acidic medium for the synthesized Platinum- Ruthenium metal alloys supported on multi-walled carbon nanotubes (MWCNT) . HR-TEM and XRD techniques were used to determine the particle size and crystalline size of the electrocatalysts, respectively while EDS was used to determine elemental composition. XRD crystalline sizes are from 7.6 to 10.6 nm while from HR-TEM particle sizes are in the range of 9.3 and 11.3 nm. The electroactivity towards the kinetics and stability of the electrocatalysts towards methanol in acidic medium was studied using electrochemical impedance spectrometry (EIS) and chronoamperometry (CA) respectively, while the cyclic voltammetry (CV) was used to determine the electroactive surface area (ECSA) of the electrocatalysts. PtRu electrocatalysts produced by the modified polyol method at pH 11 were the most electrochemically active with value of $11.2X10^5 g/m^2$ compared with a value of $3.2X10^5 g/m^2$ at pH of 3 Electrocatalysts produced at 450^0C showed better activity towards methanol oxidation reaction(MOR)as compared to PtRu nanoparticles produced at 350^OC and 250^OC evident from the highest current density produced. PtRu nanoparticles produced at 350^0C also gave a remarkable kinetics from the electrochemical impedance spectroscopy but at 450°C the electrocatalyst showed best kinetics for the methanol oxidation reaction.

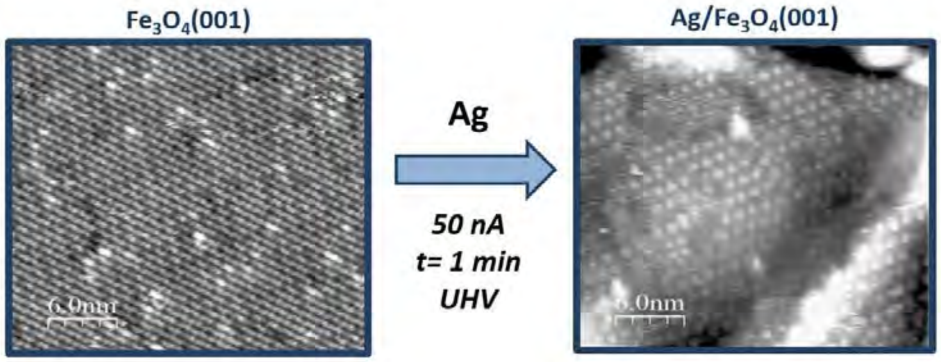
The oxygen evolution reaction (OER) is of great importance in electrochemistry due to its participation in clean energy generation technologies. The main problem with this reaction is its slow kinetics, which leads to the inevitable use of catalysts. The preferred catalysts for this reaction are noble metals, such as Pt or Ag, which have a high cost in the market that is transferred to the technological applications. However, latest efforts are progressively reducing the economic gap with respect to conventional energies, with the single atom catalysis (SAC) as the final limit in minimizing the amount of atoms required to prepare catalysts [1]. Single metal atoms are the best known electrocatalysts for the OER. Nevertheless, their excellent catalytic properties come along with a very high reactivity, making them prone to agglomeration into larger structures with less catalytic power, which in turn impedes the generation of homogeneous coating of individual atoms. To prevent this issue, we propose the use of single crystal surfaces of magnetite (Fe_3O_4) with <001> orientation to act as templates for individual metal atoms. These single crystal <001> Fe_3O_4 surfaces, prepared in ultra high vacuum (UHV) conditions, present a surface reconstruction with nanometric cavities that can act as location sites for individual metal atoms [2]. Recent experiments in our laboratory demonstrated the electrochemical stability of this reconstruction in the range of potentials where the OER occurs [3].



In this work, the adequate preparation of <001> Fe_3O_4 surfaces (under UHV conditions) will be presented, along with first results in the immobilization of individual Pt and Ag atoms; characterization results from scanning tunneling microscopy (STM) and X-ray photoelectron spectroscopy (XPS) techniques will also be available. Furthermore, we will present the electrochemical response of the system to show the catalytic improvement of the OER.

The presented work is dedicated to study of the solvent influence on kinetics of electrochemical reactions. A great impact within the area was made by W.R. Fawcett et al. [1-2]. A theory relating solvent dielectric properties, longintudinal relaxation time and charge transfer rate constant was successfully used by them to predict electrochemical rate constant based on solvent physical properties. The existent theory, though seemed to be advanced for the time, had revealed numerous limitations that subsequently suspended its wide application. One of the gravest limitations is concerned with the case when electrolyte specifically adsorbs on electrode surface.

Chloranil (tetrachloro-1,4-benzoquinone) reversible one-electron reduction was chosen as a test reaction to study effect of the solvent. The electrochemical process was investigated in seven solvents, including dichloromethane, acetonitrile, toluene, N,N-dimethylformamide, propylene-carbonate, dimethyl sulfoxide, tetrahydrofurane and N-methyl-2-pyrrolidone. The experiment was carried out using platinum working electrode and Bu_4NBF_4 as an electrolyte. A set of impedance spectra were obtained and analyzed by deriving an equivalent electrical circuit and determination of its parameters. Charge transfer resistance, double layer capacitance and other parameters were calculated and represented as a function of potential. Combined analysis of charge transfer resistance and diffusion impedance values allowed estimation of the rate constant for chloranil reduction on Pt electrode. The direct application of the known theoretical approach [1-2] was not possible, probably due to inaccuracies in work-term corrections. The challenges and the proposed solutions are to be discussed.

Abstract:

Metal matrix composites containing metal and semiconductor or insulator nanoparticles have been fabricated through different methods, and mechanical and electrochemical behavior studied [1-8]. Electro-codeposition is a metal matrix nanocomposite coating fabrication method that is used widely due to its superior advantages such as homogeneous coatings, low cost, easy set-up and fast deposition rate [9,10]. Several examples of metal matrix composites are reported in the literature. In the case of nickel-based composites, many of the pure, ceramics and oxides nano/micro-sized particles such as Ti [1], TiO_2 [2,3], SiC [4,5], SiO_2 [6,7], and Al_2O_3 [8] are added as the second phase. In this paper, the fabrication of Ni-SiO_2 nanocomposite coatings and the influence of the addition of SiO_2 nanoparticles on composition, microstructure and corrosion properties of electrodeposited Ni-SiO_2 nanocomposite coatings are discussed. A pulse electro-codeposition method was employed to prepare Ni-SiO_2 nanocomposite coating on the surface of AISI 1045 medium carbon steel from a choline chloride (ChCl)/ethylene glycol (EG)-based deep eutectic solvent (DES) with a ChCl to EG molar ratio of 1/2. Nickel chloride [$NiCl_2.6H_2O$] and 15 g/L silicon dioxide (SiO_2) nanopowder, 10-20 nm particle size and 99.5% purity, were then added to the electrolyte. The electro-codeposition process, for pure Ni and Ni-SiO_2 nanocomposite coatings, was carried out at the same conditions of temperature, current density and frequency that were set to 70 °C, 8 mA/cm^2 and 1000 Hz, respectively. Disc-shaped medium carbon steel substrates were mechanically polished and degreased followed by activation before electrocodeposition. Scanning electron microscopy (SEM), Energy-dispersive X-ray spectroscopy (EDS) and X-ray diffraction (XRD), were used to study microstructure, surface morphology, composition, and phase analysis of the Ni-SiO_2 nanocomposite and pure Ni coatings. Corrosion properties of the coatings were evaluated by means of potentiodynamic polarization test in 3.5 wt.% NaCl solution at room temperature. SEM images revealed that the addition of silicon dioxide nanoparticles to the nickel film affects the grain size, microstructure and morphology of the coating surface. The microstructure of the nanocomposite coating is a combination of nano and micro-sized structures on the surface. A granular-like microstructure with a quasi-uniform dispersion of SiO_2 nanoparticles in the coating was observed. Our characterization results confirm the incorporation of SiO_2 nanoparticles into the Ni film. Potentiodynamic polarization results showed that the incorporation of SiO_2 nanoparticles into the Ni film significantly improved the corrosion properties of the coatings compared to the pure nickel. Corrosion potential of Ni-SiO_2 nanocomposite coating increased to a more positive value, and the corrosion current density decreased compared to that of pure Ni. Enhanced corrosion resistance in nanocomposite coating with respect to the pure Ni is explained by the effect of the addition of SiO_2 nanoparticles on both microstructure and composition of the nanocomposite coating. Thus, the electrodeposition method using choline chloride/ethylene glycol-based DES solution can be used to produce Ni-SiO_2 nanocomposite coating with uniformly dispersed SiO_2 nanoparticles in the Ni film that exhibits clearly better corrosion resistance compared to pure Ni coating and suggesting its potential application in industry with the goal of surface corrosion protection.

Oxygen evolution reaction (OER) plays a crucial role in electrochemical energy storage and conversion devices, such as metal-air batteries or unitized regenerative fuel cells, as well as in water electrolyzers [1]. Sluggish reaction kinetics imposes the use of suitable electrocatalysts among which platinum-group metal (PGM) oxides, IrO_2 and RuO_2, have been reported to have the highest activity. Namely, sluggish reaction kinetics results in high overpotential of OER which further results in high energy consumption for water molecule splitting and the overall high price of the process. PGM-based electrocatalysts have high efficiency towards OER, but they also have high price impeding their application in large scale industrial water electrolyzers. Search for lower cost, but highly efficient electrocatalysts for OER is an ongoing quest [2]. Nickel-based electrocatalysts have demonstrated to offer high intrinsic activity along with high stability in alkaline electrolytes [3].

Herein, β-$Ni(OH)_2$ was prepared by hydrothermal method and systematically studied for oxygen evolution reaction in alkaline media (1 M KOH). Material showed activity for OER with low onset potential of ca. 0.55 V and low Tafel slope. Polarization curves were recorded at temperatures up to 85 °C as current industrial electrolyzers commonly operate at temperatures between 65 and 90 °C. Expected reaction kinetics improvement as evidenced by decrease of overpotential and increase of current density reached could be observed for up to 75 °C, while very intense bubbling was observed at 85 °C. Additionally, initial stability test run for 2 h revealed oxidation current density somewhat increasing with time.

Collected results suggest hydrothermally prepared $Ni(OH)_2$ as a good electrocatalyst for OER for application in water electrolyzers and unitized regenerative fuel cells.

The present work reports on the development of a standardless method for the determination of nanometric thicknesses for the morphological characterization of anodes of lithium-ion batteries, in particular for those based on binder-free Si/C binary composites generated by sputtering deposition. The procedure was developed based on the detection of characteristic x rays under electron impact, and although it was specifically designed for nano-stratified samples consisting of a Si film deposited onto a C layer (which in turn is deposited on a Cu substrate), it is also easily applicable to other configurations. Since it is necessary to know the thickness of the surface layer to obtain the thickness of the deepest layer, the calculations involve the application of an iterative strategy based on Monte Carlo simulations. The validation of the method was done on a set of samples whose thicknesses were also determined by Rutherford backscattering spectroscopy (RBS), and the method was applied to another set of anodes, which gave results that coincided with the expected values. The thicknesses of the Si and C layers of the binder-free composite anode obtained by the proposed method were used to calculate the specific capacity. Galvanostatic charge-discharge curves up to 100 cycles were analyzed for three different C/Si ratio anodes, and the experimental results were compared with the theoretical capacity for each binary system.

In Figure 1 a particular application example of the developed method is presented. The analyzed samples were prepared by sputtering deposition of three different thicknesses of C onto Cu foils followed by a deposition of a silicon film. The implementation of the method allowed a thickness estimation of 25 nm for Si, and 92, 156 and 190 nm for C. These values were used to obtain the mass ratio of the anode and a corresponding theoretical specific capacity. Afterward, the anodes were mounted as working electrodes in an electrochemical cell with lithium as a counter electrode and cycled 100 times at a constant current of 20 μA. In Figure 2 it is shown, as an example, the cycling response for the electrode Si25/C92 and the corresponding theoretical capacity, 1098 $mAhg^{-1}$, calculated as a reference. The electrochemical test shows that the experimental specific capacity of the particular anode is 1200 $mAhg^{-1}$, in good agreement with the estimation made by the present method. The nano-stratified Si/C anodes prepared by sputtering deposition showed good cycling performance and great stability regarding the silicon volume expansion during the charge-discharge process.

Colorous porous anodic titanium oxide prepared in ethanol-based electrolyte

Marta Michalska-Domańska, Piotr Nyga, Mateusz Czerwiński
Institute of Optoelectronics, Military University of Technology
Ul. Kaliskiego 2, 00-908 Warsaw, Poland
Marta.michalska@wat.edu.pl

Colorous anodic titanium oxide was produced in ethanol-based electrolyte, which contained 0.3 M ammonium fluoride and 2, 3.5, 5 or 10 wt% of deionized water. The new type of electrolyte was describe elsewhere [1]. The applied anodizing voltage was varied between 20 and 60 V and the anodization temperature was kept constant at 20^{o}C.

Morphological characterization of oxide layer was made using SEM (Fig 1). The optical characterization of fabricated samples was done by measuring diffusion reflectance and calculation of theoretical colors. It was found that depending of anodizing conditions the color of fabricated oxides are significantly changed. Moreover, depending of anodization temperature the fabricated anodic titanium oxide have nanotubular or slightly porous morphology. The thickness of oxide is affected mostly by anodizing voltage not temperature. The colors of anodic oxide could be controlled by changing anodizing conditions.

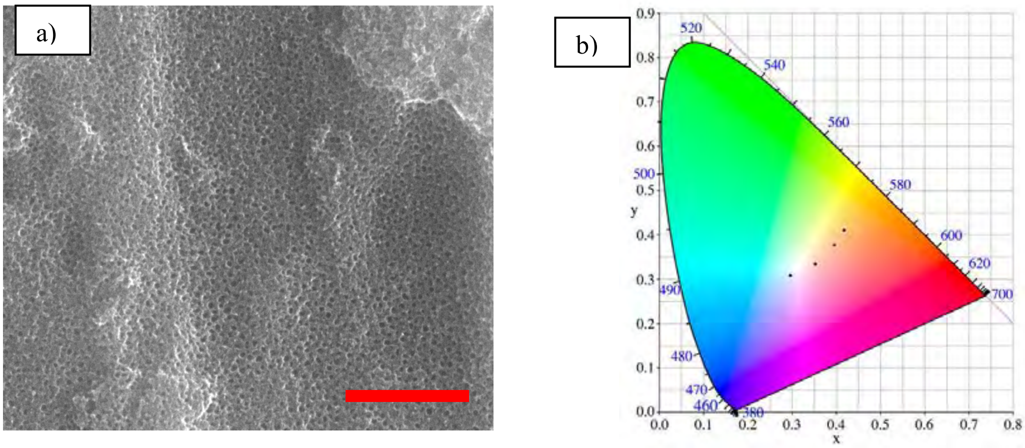

Fig .1. Example of morphology anodic titanium oxide made in ethanol-based electrolyte (a), and theoretical colors of samples made in electrolyte with 3.5 wt% of water (b). The bar is 500µm in real distance.

Electrochemical pH sensor using tape and paper for oral preventative care

Oreoluwa Cherebin, Armelle Metangmo and Frédérique Deiss,
Department of Chemistry & Chemical Biology, Indiana-University Purdue University Indianapolis (IUPUI), IN, USA
402 N Blackford Street, Indianapolis, IN, USA
ochereb@iu.edu

Low oral pH (<5.5) has been shown to play an important role in dental erosion. The measurement of oral pH can be useful in preventative care, particularly in aiding the dental caregiver in determining the likeliness of future dental cavities. The measurement of oral pH has become a more popular area of research in an effort to develop a more quantitative method for the diagnosis of dental caries. We are developing an electrochemical tape-and-paper-based analytical device for pH measurements. These devices are low-cost, easy to fabricate, disposable and portable. These devices rely on the pH-dependent, redox active species, using intrinsic defects of the material that generate oxogroups on the painted graphite electrode. We have optimized a method to carry out these pH measurements using cyclic voltammetry with the use of an ionic adjuster. By measuring the shift in potentials displayed by these species, we can determine the pH of a sample. We have tested the devices in different buffer solutions as well as commercial pH standards. The electrochemical response of the devices has shown good linear correlation in the tested solutions as well as across multiple devices and different users. The devices show promise for pH measurement in artificial saliva and other oral samples.

Obtaining high-added value products from the technical cashew-nut shell liquid using electrochemical oxidation with BDD anodes

carlosmh@quimica.ufrn.br

The electro-organic synthesis is currently experiencing a renaissance due to the tremendous contributions of various electrocatalytic materials as well as the use of electric current as an inexpensive and suitable reagent to drive the electrosynthetic transformations, avoiding conventional chemical oxidizers or reducing agents [1]. Consequently, electrosynthesis has a significant technical impact due to its advantages such as versatility, environmental compatibility (possibility of recovering and recycling non-converted substrates), automation (switching on or off electric current), inherent safety and potential cost effectiveness among others [1]. Although many novel electrode materials have been developed and established in electro-organic synthesis, diamond films (as boron doped diamond (BDD) electrodes) [2] emerge as a novel and sustainable solution in selective electrochemical transformations for value-added organic products. For this reason, in this work, the use of BDD to treat technical cashew-nut shell liquid (t-CNSL) [3] was proposed to favor its conversion on high-added value products such as carboxylic acids [4]. The evolution of five carboxylic acids was followed over time for the experiments of the three different current densities using 0.1% of t-CNSL in 1.00 mol L^{-1} NaOH. At 40 mA cm^{-2}, the most notorious increase in the organic acids concentrations took place during the two last hours achieving electrochemical conversions about of 144, 120, and 75 mg L^{-1} for the acetic, formic and oxalic acids, respectively. The results are discussed in light of the existing literature.

Photoelectrochemical reduction of CO_2 over Ti-Cu alloys: Effect of phases towards multicarbon products

Juliana de Almeida, Ricardo Alexandre Galdino da Silva, Christiane de Arruda Rodrigues
Department of Chemical Engineer – Federal University of São Paulo - UNIFESP
210 São Nicolau Street – Diadema, São Paulo - Brazil
e-mail: juliana.almeida17@unifesp.br

Copper species exhibit favorable positions in the conduction band and high potential for reducing compounds adsorbed on its surface [1], being widely studied in the conversion of CO_2 in multicarbon products. However, when applied in photoelectrocatalytic processes, these are easily oxidized and their stability is a challenge. Copper species can be coupled with other materials, such as TiO_2, a n-type semiconductor with excellent charge transfer properties and chemical stability. These oxides in nanostructured size have properties improved and, consequently, obtain better efficiency of photocatalytic activity [2]. Therefore, the present work evaluated the influence of different species and structures of Cu in Ti-Cu system alloys for converting CO_2 in multi carbon products. The electrodes were manufactured to act as photocathodes from Ti-10at.% Cu alloys. These electrodes were prepared using an arc melting and then, annealed at 900 ° C under argon atmosphere during 120 h. After the heat treatment, the alloy was cooled with controlled temperature at 1 ° C min^{-1}. The identification of the phases presents in the substrate was carried out by optical microscopy, diffraction and X-ray dispersion. The Ti– O – Cu nanostructured films were grown by anodic process using a solution of 0.1 M HF in ethylene glycol + 2.5% (v/v) H_2O and heat treated in different temperature within 350 - 550 ° C. The morphological and compositional properties were investigated by scanning electron microscopy and X-ray diffraction. The quantifications of the phases present in each temperature composition were carried out by the Rietveld method. The photoelectrochemical characterization was examined by linear sweep voltammetry in N_2 bubbled 0.1 mol L^{-1} Na_2SO_4 aqueous solutions (pH 6.6) under irradiation of chopped UV and visible light (a 150 W Hg lamp), with a potential range of onset potential to -1.0 V *vs.* Ag/AgCl/Cl (3M). The photoelectrocatalytic reduction experiments were carried out bubbling CO_2 into 0.1 mol L^{-1} of $NaHCO_3$ aqueous solution and a potential at -0.5 V was applied. The electrode was illuminated for 3 h and then, the samples were taken each 0.5 h to evaluate the product formation at different times. The determination and quantification of compounds, such as methanol, ethanol, and acetone were conducted by gas chromatography by flame ionization. On the substrate, the analyses showed Ti_2Cu and $TiCu_3$ intermetallic phases in its composition. The presence of a significative quantity of Ti_2Cu precursor was essential to defined film composition and its photocatalytic behavior. The Rietveld quantification method for these electrodes revealed binary and ternary oxides on the film nanostructured in different compositions for each temperature. The presence of ternary oxide derives from Ti_2Cu precursor which can provide other properties to the electrode, as more stability and high redox potential. Some characteristic that can be attributed to the Ti_2CuO is oxygen sharing between Ti and Cu species, that did not allow the copper dissolution and change its oxidation state, consequently, it gave new properties for this material that provided significant concentrations of methanol and ethanol as final products.

Shaleme@campus.technion.ac.il

In contemporary redox flow batteries, either static or flowable electrodes are conventionally used. Although the conductivity in static electrodes is several orders of magnitude higher than that of a flowable electrode, the latter offer distinct operational advantages, such as dendrite-less metal deposition.

We here report on a new method utilizing a flowable electrode that can operate in both static and flowable modes, with the user deciding the mode during cell operation. The latter technique utilizes gravitational forces acting on particles to form either a flowable fluidized bed electrode or packed electrode.

We show that such an electrode can repeatedly cycle between modes by adjusting electrode flow velocity, allowing for over four orders of magnitude variation in electric conductivity as seen in Figure 1 .

We further demonstrate the discovery of a novel operational regime, at intermediate velocities where large-scale particle motion through vortex formation occurs, which enables exceptionally high electric conductivity in the flowable state.

We expect this new approach could enable the creation of a more versatile electrodes which can form the basis of future electrochemical systems for energy storage, conversion or water desalination.

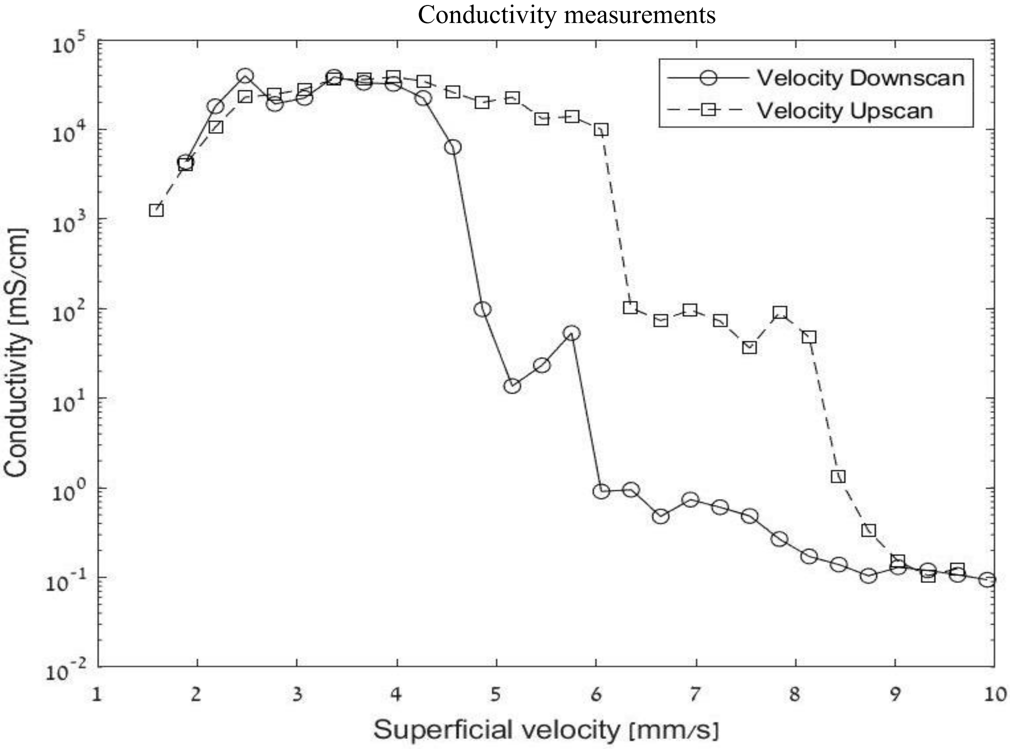

Figure 1 - Electrode Conductivity Vs. Superficial velocity. The electrode changes its state from flowable to static and back exhibiting a change of over 4 orders of magnitude in its conductivity

In the last few years, bioelectrochemical systems (BES) have shown great potential for the conversion of CO2 into C2-C6 volatile fatty acids (VFAs) and alcohols. Despite their versatility, BES present limitations such as the long time associated with the development of biocathodes and the start of bioproduction, even in presence of a pre-enriched inoculum. In this work, we studied the conversion of CO2 via microbial electrosynthesis in BES equipped with carbon based gas diffusion electrodes (GDEs) modified with hydrophilic and conductive polyaniline (PANI) polymer. Reactors were inoculated with a pre-enriched inoculum and operated at -1000 mv vs Ag/AgCl. The utilisation of PANI-modified GDEs significantly reduced the start-up time of bioproduction to only 6 days with an acetate concentration of 1.29 ± 0.36 g L-1 after 17 days of operation, and of 4.01 ± 0.5 g L^{-1} after 24 days with apparition of butyrate. On the other hand, BES reactors equipped with non-modified GDEs showed much slower start-up (17 days) reaching 0.33 ± 0.12 g L^{-1} after 24 days and 1.19 ± 0.73 g L^{-1} after 31 days. Reactors were operated during 60 days and PANI-GDEs led to an acetate concentration of 6.85 ± 0.9 g L-1 and 0.20 ± 0.05 g L-1 butyrate. Electrochemical and physico-chemical analysis revealed that the PANI polymer enhances the interaction between the biofilm and the electrode, thus contributing to the fast start-up and higher bio-production compared to non-modified carbon cloth GDEs.

On the electrochemical behavior of kraft black liquor using BDD electrodes

Black liquor (BL) is a complex solution generated as a by-product of the kraft pulping process and is mainly composed of inorganic salts, such as NaOH, $NaCO_3$, and Na_2SO_4, and lignin [1]. In the last few years, there has been a growing effort of the scientific community to understand the electrochemical behavior of the BL [2–4]. As the electrolysis of BL is being more explored it is being pointed out as a promising process to the treatment and valorization of this by-product. In fact, understanding this electrochemical behavior can bring an important development for the wastewater/environmental processes of pulp and paper industries [5–7].

Therefore, this work aims at analyzing by voltammetric (cyclic voltammetry, CV), amperometric (chronoamperometry, CA), and potentiometric (chronopotentiometry, CP) techniques the behavior of kraft BL solutions utilizing boron-doped diamond (BDD) electrodes. CVs are recorded at several scan rates and the peaks are analyzed using the Randles-Sevcik equation. Then CA and CP techniques are run, and the results analyzed in order to better understand the electrochemical oxidation of lignin in the BL. The obtained results are critically discussed and compared with previous literature studies to comprehend the catalytic effect of BDD electrodes in the electrooxidation process of the lignin present in the kraft BL.

Poly(3-alkylthiophenes) (P3AT´s), due to their double conjugate bonds, are part of the group of conducting polymers, which are of great interest for applications such as battery electrodes, organic light emitting diode (OLED) electronic devices, organic solar cells, low-cost integrated circuits and organic field effect transistors, owing to their good stability, high conductivity and flexibility of preparation[1]. After electrochemical synthesis, these polymers can change from insulators to conductors due to reversible oxidation processes in the p conjugate system, resulting in chains with positive charges, polarons and bipolarons, which are balanced by the incorporation of counterions (anions), referred to as *p*-type doping. Films obtained in this way exhibit properties that make them efficient electron donors at heterojunctions with n-type materials, such as fullerenes and its derivatives, used in organic solar cells.

To study the electrochemical properties of modified polymeric films, the electrochemical impedance (EIS) could be combined with vibrational spectroscopy in order to understand how the positive segments in polymer matrix affect the process of electronic transport in those materials, such as double layer capacitance, charger transfer velocity, charge transfer process[2].

Therefore, in this work, first, a poli(3-hexylthiophene), P3HT, and a blend obtained from two 3-alkylthiophenes monomers, 3-hexylthiophen and 3-octylthiophene, named as CP3(HT-OT), were synthesized by chronoamperometry (in non-aqueous media)[1]. After this, under both films, were deposited, by dropping coating method, a fullerene derivative, [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM). Thus, the blends formed between the P3AT's and PCBM, named as P3HT/PCBM and CP3(HT-OT)/PCBM, were characterized by cyclic voltammetry (CV), EIS, XPS (X-ray Photoelectron Spectroscopy), photoluminescence (PL) and *in situ* and *ex situ* Raman spectroscopy.

The presence of PCBM in P3HT and CP3(HT-OT) blends were confirmed by XPS, which demonstrated a small difference of the fullerene derivative between them. PL spectra showed a *quenching* because of a successful heterojunction formation, being more effective in P3HT/PCBM (indicating that, in this blend, the charge transfer process were more effective). The presence of PCBM did not significantly alter the *band gap* of the blends but was able to change the relative quantity of positive segments, evaluate by in situ Raman spectroscopy, in polymer matrix. The addition of PCBM increased the *bipolaron* segments in P3HT, while in CP3(HT-OT) stabilized the *polaron* segments, considering the submission of the blends to anodic potential (from 0 to +1,4 V). In addition, EIS showed that, despite the reduction in charge resistance transfer (R_{CT}), 9% and 47% for P3HT/PCBM and CP3(HT-OT)/PCBM, respectively, due to the stabilization of positive segments, the non-homogenous phase separation of P3AT's and PCBM prevented this reduction from being even greater.

Because its application on direct methanol fuel cells [1], several works have focused on the synthesis of materials with electrocatalytic activities comparable to that of platinum. Salinas et al. [2] showed that Ni films deposited on Au under galvanostatic control had high electrocatalytic activity. In this work, Ni films were deposited by the galvanostatic method on gold electrodes. Their electrocatalytic activity for methanol electrooxidation was evaluated by cyclic voltammetry (CV) and sampled current voltammetry (SCV). The sampled voltammograms were constructed from individual chronoamperometric measurements so that each measurement was made with a renewed surface, eliminating the effects of the electrode history present in voltage sweep methods [3].

Electrodeposition results of two processes, nucleation and growth, occurring at two different time scales. Nucleation proceeds at the millisecond timescale, and the diffusion field follows the microscopic features of the electrode's surface. The growth of the nuclei takes place at longer timescales when the diffusion field has extended, so the geometric area controls it. Therefore, the applied current relative to the electroactive area dictates nucleation conditions, but leads to different growth kinetics, resulting in variability on the Ni deposits, determining the predominance of $Ni(OH)_2$ polymorph. Figure 1a shows the Ni deposits after cycling in 1 M KOH. The position of the NiOOH peak (Iaf) changed depending on the total applied current. For simplicity, two types of Ni films were identified: Type A with the NiOOH formation peak located below 0.39 V vs. Ag|AgCl, and Type B, which has the NiOOH formation peak above that threshold value. The solid lines in Fig. 1b and 1c represent the CVs for Ni films obtained in the presence of 0.5 M methanol. The anodic peaks, IIaf and IIab, correspond to methanol oxidation during the forward and backward scans. The sum of the current peaks, called Electrocatalytic Intensity, *EI*, can be used to evaluate Ni films' activity. Accordingly, Type B deposits show higher activity for methanol electrooxidation compared to Type A. However, the superimposed SCVs (dotted lines) suggest that although Type B films are suitable catalysts for methanol oxidation, they also exhibit high activity for oxygen evolution, as evidenced by the current increase beyond 0.5 V vs. Ag|AgCl. Conversely, the Type A deposit shows high activity for methanol oxidation without oxygen evolution interference, making it a suitable material for direct alcohol fuel cells. These results demonstrate that SCV is a valuable technique to gain insight into the catalytic behavior of electrocatalytic materials.

Electrochemiluminescence (ECL) is a leading technique in bioanalysis.[1] Since the excited species are produced with an electrochemical stimulus rather than with a light excitation source, ECL displays improved signal-to-noise ratio compared to photoluminescence, with minimized effects due to light scattering and luminescence background.[2]
Chasing ever-increasing sensitivities, ECL can ideally be coupled to nanotechnology and supramolecular chemistry to develop new systems and strategies for analyte determination also in very complex matrices.[3,4]
In particular, dye-doped silica nanoparticles (DDSNs) present many advantages: they can be obtained with accessible synthetic schemes, are intrinsically hydrophilic, and, thanks to silica chemistry, are prone to bioconjugation. With this approach we were able to achieve extremely bright systems and DDSNs assume the photophysical properties of the dye accumulated within the nanoparticle.[5] In DDSNs, light emission is influenced by the combination of several factors that make DDSNs complex multichromophoric structures. However, when ECL comes into play, the scenario is even more complicated due to the coreactant−NP interactions effect.[5] Such complex scenario was approached at the theoretical level by developing suitable mechanistic models for ECL generation[6] while, at the same time, the influence of doping level on ECL efficiency was evaluated. Our results showed that the ECL intensity of a nanosized system cannot be merely incremented acting on doping, since other parameters come into play. These studies provide valuable indications for the design of more efficient ECL nano- and micro-sized labels for ultrasensitive bioanalysis.

The hydroxylation of o-quinone as a kinetic model to the formation of 6-hydroxy-dopamine.

Raphael S. Nakaya, Raphael P. Bacil, Silvia H. P. Serrano

[a]*Instituto de Química, Universidade de São Paulo - Av. Prof. Lineu Prestes, 748 - Butantã - São Paulo – SP, Brazil. CEP: 05508-000*

Nowadays, mental disease diagnosis increases significantly in society in general. [1] The causes of diseases such as Parkinson's disease, Alzheimer's, schizophrenia and depression remain to be unveiled in detail. In this particular scenario, dopamine (DA), is involved in some pathways which are related to synapsis and signalling functions. Most of DA's functions are related to its redox reactivity, which can be electrochemically simulated in an EECEE mechanism.[2] Following-up to the oxidation of DA's catechol moiety to o-quinone, a chemical step occurs as the molecule undergoes an intramolecular Michael addition, a cyclization. [2] On the other hand, the follow-up cyclization reaction competes with the intermolecular Michael addition which would generate the 6-hydroxy-dopamine (6-OHDA). This secondary product (6-OHDA) is used in animal models to generate Parkinson's disease in the subjects. [3] Since DA also presents the cyclization reaction, catechol (CAT) was used as a model to observe the extension of the Michael addition at physiological pH, therefore simulating the *in vivo* DA behaviour in an *in vitro* situation. Cyclic voltammetry was used to obtain the kinetic rate constant (kf) of the chemical step which follows-up the CAT oxidation at physiological pH and other pH values using the number of effective electrons [4] to better comprehend the intermolecular addition mechanism. The Tafel plots were obtained to observe the mechanism as a function of the scan rate, since the charge transfer coefficients (β) values are sensitive to the mechanism change, as already demonstrated. [2] The scan rate values were then restricted in an appropriate window and the kf values to the addition were then obtained. In sequence, to observe the extension of this reaction, the kf values obtained were compared to a recent study of our group in which the cyclization rate constant of DA in pH = 7.4 was obtained. The results show that CAT intermolecular addition occurs with a kf = 0.28 s^{-1}, which is 0.04 s^{-1} superior to the 0.24 s^{-1} previously reported for DA's cyclization. In addition, the chemical step for CAT presented a parabolic behaviour, with a peak at approximately 7.4, which allows two conclusions. Firstly, that the reaction occurs at its optimized situation in physiological media., Secondly, that after CAT oxidation, the further nucleophilic addition occurs in a similar mechanism to a S_NAr, which could also be the case for the 6-OHDA formation. Green synthesis of iron nanoparticles has accumulated an ultimate interest over the last few years due to their distinctive properties and applicability in various fields of science and technology. The use of biological products such as microorganisms, plant extracts or plant biomass is proving to be a better alternative to chemical and physical methods for the engineering of metal oxide nanoparticles through environmentally benign routes. In the present study, the synthesis of iron nanoparticles (Fe_2O_3) was achieved using coffee extracts. The synthesized materials were studied using X-ray diffraction (XRD), UV-visible spectroscopy (UV-vis), Fourier Transform Infrared (FTIR) Spectroscopy, Vibrating Sample Magnetometer (VSM), High Resolution Scanning Electron Microscopy (HRSEM), High Resolution Transmission Electron Microscopy (HRTEM) and Cyclic voltammetry (CV). The average diameter of the Fe_2O_3 nanoparticles was observed to be approximately 35 nm while HRTEM confirmed the cubic nature of the nanoparticles. The FTIR spectrum of the nanoparticles revealed the role of the biomolecules present in the extract in capping the nanoparticles with prominent bands at 3381 cm^{-1}, 1384 cm^{-1} and 691 cm^{-1}. UV-vis studies revealed an absorption band in the ultraviolet region of 289 nm indicating confirming the successful development of the prepared nanoparticles as also indicated by the optical energy band gap determined using Tauc plot. The VSM studies showed the ferromagnetic nature of the synthesized nanoparticles and CV illustrated the electrochemical behaviour of the Fe_2O_3 nanoparticles on glassy carbon electrodes. The modified electrode with showed good electron conductivity when compared to the bare electrode an indication of the potential use of the nanoparticles in the development of sensors or biosensors.

Sensitive and Selective Detection of Low-Level Ammonia Gas Sensor by Reduced-Graphene-Based Nanocomposie

Shih-Han Wang*, Wei-Jie Syu, Bo-Rong Chen

E-mail: wangsh@yuntech.edu.tw

Ammonia is an important indicator for the environment quality and agriculture safety applications. It also has been identified as an important biomarker of breathing gas, and the elevated ammonia levels in exhaled breath could be the results of liver or kidney-related desieases. The exhaled ammonia gas concentration for healthy human is down to 0.02-2 ppm [1], and for the environmental quality evaluation should be lower to 50 ppb. Due to the low concentration and the complicate sample gases, it is important to develop a highly sensitive and selective ammonia sensor. Several materials such as metal oxide, conducting polymer and carbon nanomaterials have been extensively used for ammonia gas sensing. Among those materials, carbon-baed nanosomposite holds great promise for low-concentration ammonia sensing.

We demonstrated a highly sensitive and selective ammonia sensor based on reduced-graphene nanocomposite for detection of ammonia down to the ppb-level at room temperature. Tungsten oxide and polyaniline was incorporated into easily functionalized reduced graphene in supercritical fluid to form a nanocomposite. Metallic nanocatalyst was doped to enhance the sensitivity and selectivity. Ammonia adsorbed on the sensing membrane and then be oxidized at room-temperature. Therefore, the resistance of sensing membrane increased with ammonia concentration. The sensor could detect the ammonia concentration in the range from 0 to 100 ppm at room temperature. The sensitivity was enhanced 4 times by the nanocatalyst, and the lower detection limit was 50 ppb. The effect of interference gases, including nitric oxide (NO), carbon monoxide (CO), carbon dioxide (CO_2), sulfur dioxide (SO_2) has been evaluated as well, and all the cross-talk was less than 10%.

Furthermore, ammonia gas is highly water soluble, the sensing resistance was shift significantly by humidity, especially in higher humid atmosphere. In order to solve the problem, the electrode surface was more hydrophobic. After surface modification, the humidity effect decreased. The sensing mechanism of electrode and effect of humidity was also investigated. The experimental result suggested that the catalyst doped nanocomposite had high sensitivity, stability and selectivity for low concentration ammonia sensing at room temperature, the influence of humidity has been overcome by the surface modification. A room temperature operated low-level ammonia sensor could be potential applied for exhaled gas or environmental quality monitoring.

Ag doped black TiO_2 nanocomposite with enhanced photocatalyst abilities for organic pollution degradation under visible light

Ting Zhang, Wei Gao,*

Department of Chemical and Materials Engineering, the University of Auckland, Private Bag 92019, Auckland 1142, New Zealand

The development of noble metal doped on semiconductor materials has attracted significant attention [1, 2]. Herein, the degradation of Methylene blue over Ag doped black TiO_2 nanocomposite, synthesized using a simple electrochemical doping method, was reported. The Ag nanoparticles doped on black TiO_2 nanotubes exhibits a superior degradation efficiency of methylene blue aqueous solution under visible light irradiation. The efficiency is up to 75%, and around 4 times higher than that of pure TiO_2 nanotube arrays. The enhanced photodegradation performance is attribute to the formation of surface plasmon resonance caused by Ag nanoparticles, as well as the conductivity enhancement caused by Ti^{3+} and Ag doping. This nanocomposite can effectively increase photocurrent under irradiation of visible light and improve the photocatalyst efficiency of TiO_2 nanotube [3].

Tau is a neuronal protein responsible for microtubule formation [1]. It is also the pathological protein active in the Alzheimer's Disease (AD) pathway. When Tau begins to aggregate as a result of misfolding, the neuronal cells die due to the lack of microtubule formation and can take on prion-like properties [2]. Therefore, detection of aggregated Tau can serve as a powerful tool in the early diagnosis of AD and dementia related diseases. As has been previously demonstrated, Tau 441 can be detected with an electrochemical immunoassay based on the electrochemical impedance spectroscopy (EIS) by using gold electrode [3]. The EIS was also used to monitor interactions between Tau protein and Heparin [4]. Due to the sensitive nature of protein molecules, buffers of physiological pH need to be employed to maintain native protein structure. However, not all buffer solutions are appropriately suited for surface studies. Herein, we describe use of EIS and cyclic voltammetry (CV) to monitor and detect surface stability of Tau protein films on gold electrode in two common buffers: MES buffer and Phosphate Buffer (PB). After modifying the surface of the electrode with activated lipoic acid and Tau, a series of further incubation steps were performed to test surface stability under various conditions. The EIS and CV were measured as a function of Tau or Heparin concentrations, and incubation time and temperature. The control experiments included, Tau-free surface, Heparin-free solution, and buffer solutions in order to minimize non-specific interactions. The stability of the surfaces was measured as a signal change in EIS and CV after incubations and it was discovered that certain buffered solution induced large changes in tau protein films on surfaces.

Operando Surface Structure Determination of Pt(111) under Realistic Oxygen Reduction Conditions using High-Energy Surface X-Ray Diffraction

L Jacobse, R Schuster, T Weber, V Vonk, A Stierle
DESY NanoLab, Deutsches Elektronensynchrotron DESY
Notkestrasse 85, D-22607 Hamburg, Germany
leon.jacobse@desy.de

Platinum is the most widely used electrocatalyst driving water-splitting and (the reverse) hydrogen oxidation reactions, which are the processes occurring in electrolysers and fuel cells, respectively. Due to the material costs, it is of crucial importance to maximize the electrode stability. Experiments under static, oxygen-free conditions have provided a detailed description of the degradation of the Pt(111) electrode surface by applying highly oxidizing potentials. In our High-Energy Surface X-Ray Diffraction (HE-SXRD) experiments we have shown that the Pt(111) surfaces change significantly at potentials above 1.1 V vs RHE. These changes depend on the potential, its scan rate and for how long it is applied. Despite extensive oxidation of the electrode, we did not observe any features indication the formation of an ordered (surface) oxide.

However, it is unclear how this degradation changes in case of a high oxygen chemical potential as during the oxygen reduction reaction. We have developed a Rotating Disk Electrode (RDE) setup that can be mounted on the beamline diffractometer, enabling us to perform operando HE-SXRD experiments. This setup has been used to determine the structure of a Pt(111) while a large current density for oxygen reduction is applied. The results are compared to measurements performed under static and oxygen-free conditions.

Reduction of Methane Emissions by Living Electric Cables

Cable bacteria are living electrochemical devices using internal wires to direct electrons from anaerobic decomposition of organic matter to oxygen reduction via a sulfur shunt in sediments. The sulfur shunt involves a continuous cycling between electrogenic sulfide oxidation by cable bacteria und sulfate reducing bacteria, leading to an overall accumulation of sulfate in the porewater.

Here we show that the exclusion of cable bacteria led to the direction of the electron flow to methanogenesis resulting in a more than tenfold higher methane emission from rice-vegetated soil pots to the atmosphere. We also found that cable bacteria do naturally occur in rice fields - although thriving well in some fields, they appear to be absent in others. Moreover, the cable bacteria-induced effects potentially include the protection of rice plants against toxic sulfide. Taken together, we suggest that unraveling the factors controlling cable bacteria blooms in rice fields would allow to tailor mitigation strategies to reduce methane emissions and sulfide toxicity in rice fields.

Ion Exchange Involving Graphene Oxide and Metallic Cations as a Tool for the Electrosynthesis of Advanced Materials

Prussian blue is a hexacyanometallate mixed-valence complex constituted by iron metallic centers in oxidation states two and three, connected by bridges of cyanide ligands. Iron centers can be replaced by other transition metals, generating a class of compounds with the same structure of Prussian blue, the so-called Prussian blue analogues (PBA), with the formula $A_xM_y[M'(CN)_6]_z{\cdot}nH_2O$, wherein M and M' are transition metals and A is a metal cation. These complexes present unique electrochemical properties. At the same time, they show low electrochemical stability, which can be improved through the preparation of composites with carbon nanostructures like graphene or carbon nanotubes. [1,2] This work presents a novel, simple and efficient route to prepare thin films of PBA/graphene nanocomposites, based on ion-exchange reactions. Thin films of graphene oxide (GO) were prepared through the liquid-liquid interfacial route developed in our research group.[3] The GO films were deposited over Fluor-doped tin oxide covered glass (FTO/glass) and immersed in 0.1 mmol L^{-1} aqueous solutions of Fe^{3+} or Cu^{2+} ions for different time intervals, aiming ion-exchange reaction between acidic hydrogens of GO surface and the metallic ions in solution. Further, the films were washed several times with water and reacted with aqueous solution of $NaBH_4$. The reduction process converts graphene oxide into reduced graphene oxide (rGO) and cationic species into their metallic forms. In the following, these films have been used as precursor for both Cupper hexacyanometallates (CuHCF) or iron hexacyanometallates (FeHCF) composites, through heterogeneous electrochemical reactions with $[Fe(CN_6)]^{3-}$ aqueous solution, in a three-electrode electrochemical cell in which the ion-exchanged rGO films act as work electrodes. The cyclic voltammograms of the films during the deposition reactions show redox processes in the region of 0.7 V for Cu^{2+} and 0.8 V for Fe^{3+}, in which the current intensities increase according the number of cycles, indicating the Prussian blue and PBA formation. The occurrence of FeHCF and CuHCF was confirmed by Raman and FT-IR spectroscopy. The morphology of the films visualized by scanning electron microscopy shows the formation of cubes homogeneously distributed over the entire rGO film after electrodeposition, which indicates the formation of hexacyanometallates. The results demonstrate the viability of the electrodeposition processes and represents a new route to prepare PB- and PBA-based composites thin films, opening several possibilities for application in different fields.

Black liquor (BL) is a complex solution generated as a by-product of the kraft pulping process and is mainly composed of inorganic salts (such as NaOH, $NaCO_3$, and Na_2SO_4), and lignin [1]. In the last few years, there has been a growing effort in the scientific community to understand the electrochemical behavior of the BL [2-4]. Currently, there are some well-known processes for the recovery of the lignin, such as the noteworthy LignoBoost and LignoForce commercial processes, a sequence of acidification steps used for the precipitation of the lignin present in the black liquor [5,6]. However, the method used for lignin extraction has a direct impact on the properties of the lignin obtained. As such, it is important to select the appropriate method for the lignin intended applications. As the electrolysis of BL has been more explored in the last few years and can be a promising process to the treatment of this by-product, understanding the properties of the obtained lignin by electrolysis poses an important challenge for its commercial valorization [7].

This work aims to analyze by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) techniques the lignin obtained by electrolysis of kraft BL samples utilizing nickel electrodes. To the best of the authors' knowledge, this is the first time that differences between lignin samples are assessed by electronic microscopy. SEM images, coupled with energy dispersive X-ray analysis, are obtained for several samples of lignin collected from kraft BL by different extraction processes. The morphology of each different sample is critically analyzed. TEM analysis is also performed in the same samples to assess the particle size distribution and understand possible differences in the structure of each lignin sample. The results obtained for the electrodeposited lignin are discussed and compared with those of commercial lignin samples. This will allow us to better comprehend the characteristics of the lignin obtained during the kraft BL electrolysis process.

Preparation and characteristics of a glassy carbon electrode modified with multi-walled carbon nanotubes and palladium

Andrzej Leniart, Barbara Burnat, Mariola Brycht, Sławomira Skrzypek
Department of Inorganic and Analytical Chemistry, Faculty of Chemistry, University of Lodz
Tamka 12, 91-403 Lodz, Poland
andrzej.leniart@chemia.uni.lodz.pl

Glassy carbon due to its unique properties such as high electrical and thermal conductivity, hardness, resistance to high temperatures, chemicals and stability in a wide range of polarization potentials is a widely used electrode material in electrochemistry. In order to improve or obtain new properties of the electrodes surfaces, inter alia, the glassy carbon electrode is subjected to various modifications. Surface modifications can be carried out, for example, as a result of electrochemical processes (electrodeposition of polymers or metallic layers) as well as by applying new materials to the surface (e.g. carbon nanotubes, graphene).

Carbon nanotubes are one-dimensional structures characterized by high electrical conductivity, high chemical stability, high electrical conductivity, high surface area-volume ratio, high adsorption capacity resulting in increased sensitivity of sensors. They are used as a material for modification of electrodes surfaces which are at the same time a substrate for metallic catalysts.

Palladium due to its catalytic properties and hydrogen sorption capacity is used to build fuel cells operating on the basis of oxidation of small organic compounds, such as methanol or formaldehyde.

The type of electrode, surface development and microstructure as well as the size and dispersion of the catalyst on the electrode surface strongly affects the work of such a cell and its efficiency. The combination of the above-mentioned materials, namely: glassy carbon, carbon nanotubes and palladium, results in obtaining an electrode with new properties.

The aim of presenting work was to obtain glassy carbon electrodes (GCE) modified with multi-walled carbon nanotubes (MWCNTs) and palladium (GCE/MWCNTs-Pd), to characterize them in terms of surface morphology and to study their electrochemical properties.

The preparation of GCE/MWCNTs-Pd electrodes consisted of applying multi-walled carbon nanotubes to the prepared glassy carbon electrode surface and electrochemical generation of palladium nanoparticles with programmed charges (-0.005, -0.020, -0.050 and -0.100 C). GCE/MWCNTs-Pd electrodes with different content of palladium nanoparticles were characterized in terms of surface morphology using atomic force microscopy (AFM) and scanning electron microscopy with energy dispersive X-ray spectrometry (SEM-EDS). However, the evaluation of electrochemical properties was carried out with use of cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) in the environment of perchloric acid.

As a result of electrochemical Pd catalyst generation, palladium nanoparticles were obtained in four size ranges: 10-30, 20-40, 50-60 and 70-90 nm. Based on the obtained measurement results, it was observed that the quantity and size of the obtained nanoparticles of deposited palladium on the electrode depends on the charge used during the electrodeposition. The resistance of GCE/MWCNTs-Pd electrodes decreases with increasing amount of palladium.

Many researchers have been studying the ions migration in the activated carbon porous structure to date. One direction of these studies focuses on the examination of dilatometric changes in polarized electrodes. It was found that depending on the current direction, the response of the electrode is different and cathodic polarization causes more pronounced changes. Our recent findings, with application of the electrochemical contact angle measurement, allowed us to observe the direct electrolyte adsorption on the polarized electrode surface. Collected data followed the established trend, where a cathodic polarization induces better wettability and faster absorption.

Now, to further understand the nature of the ion migration in the porous structure of carbon electrode, we applied the dilatometric measurement combined with novel Step Potential Electrochemical Spectroscopy (SPECS). By merging these two techniques, we were able to analyze and identify the current derivatives resulting in specific electrode behavior. Thus, the overall current response has been deconvoluted to individual components.

For this research, two commercial carbons, i.e., Kuraray YP-50F with "closed" and Cabot BP2000 with "open" porosity was chosen. $[EMIm]^+[TFSI]^-$ ionic liquid (IL) was selected as the electrolytic solution. The application of this IL was intentional, as the size of cation and anion are similar. Moreover, the selection of IL electrolyte limits the possibility of parasitic redox processes that may contribute to the final result.

Briefly, it seems that the dilatometric changes depend on the type of the porosity rather than the size of the ions. Moreover, it is assumed that the volume of ions is less important than their mass and mobility during polarization. However, the current deconvolution suggests a non-linear dependence between the 'diffusion' and 'geometric' components.

Finally, the presented results will elucidate the reasons that stay behind the differences in ion diffusion into the carbon porous structure.

roel.bisselink@wur.nl

Maleic acid is an important raw material that finds multiple applications in the chemical industry such as in manufacturing of unsaturated polyester resins, lubricant additives, surface coatings, textile, photographical chemicals, plasticizers, pharmaceutical products and in agricultural chemicals. In our on-going research, Maleic acid is widely being used to synthesize chemicals for different applications, biobased aromatic (bulk) chemicals in particular.[1]

The current industrial process of maleic acid involves hydrolysis of maleic anhydride which in turn is obtained from the vapor phase oxidation of fossil-based benzene or n-butane. Lately, renewable resources have been investigated to circumvent the use of fossil derived feed-stocks. In particular, biomass-derived platform chemicals like butanol, levulinic acid, 5-hydroxymethylfurfural and furfural were investigated as starting materials for the synthesis of maleic acid.[2] Among these platform chemicals, furfural is an interesting substrate since the commercial production is already established starting from carbohydrates.[3]

In the present study, we investigate the two-step synthesis of maleic acid under very mild conditions. In the first step, 5-hydroxy-2(5H)-furanone is synthesized via photochemical oxidation and proposed as an stable intermediate. Subsequent oxidation in the second step, either by an electrochemical or enzymatic process, to produce maleic acid in high yield and selectivity.

In this work different synthetic conditions were analyzed for the preparation of modified ZnO photoelectrodes, in order to prevent the recombination of their photogenerated charge carriers and allow the continuous formation of electrons and holes on photoelectrocatalytic reactions [1,2]. This study aims to prepare in a simple and proficient way photoelectrodes of the ZnO chemically modified with cobalt, $Zn_{1-x}Co_xO$ and superficially with silver Ag-ZnO, both produced from combustion synthesis process and deposited on the indium tin oxide conductive surface by casting method. The influence of different percentages of the metal nitrate precursors (either Co or Ag – 2.0% mol L^{-1}) and thermic treatment (either 500 or 600 ºC) on the photoelectrochemical response of the prepared electrodes were analyzed. The photoelectrodes were used in a photoelectrochemical discoloration reaction of methylene blue (MB) dye. X-ray diffraction (XRD) analysis confirmed chemical modification of ZnO with cobalt and superficial modification with silver for all samples (Fig. 1-a). Scanning electron microscopy indicated that the sample with 2.0% metallic modifying agent and treated at 600 °C produced smaller-sized particles for both materials. Therefore, the electrodes prepared by this condition were the ones that provided better photoelectrochemical and photoelectrocatalytic responses for the MB discoloration, $Zn_{1-x}Co_xO$ (132 μA cm^{-2} and 9.05×10^{-3} min^{-1}) and Ag-ZnO (162 μA cm^{-2} and 15.0×10^{-3} min^{-1}) (Fig. 1-b,c). The surface area related to the particle size and their morphology were determinant factors for the photoelectrodes efficacy. The significant increases in current density, j_N, and photoelectrocatalytic, k_{obs}, efficiencies for Ag-ZnO electrodes are attributed to the synergism between the ability to remove and store electrons by Ag with the applied potential, thus significantly hampering the recombination of ZnO charge carriers under UV light. The superficial modification of ZnO with silver is more efficient for the inhibition of ZnO photogenerated exciton recombination, when compared to the chemical modification with cobalt.

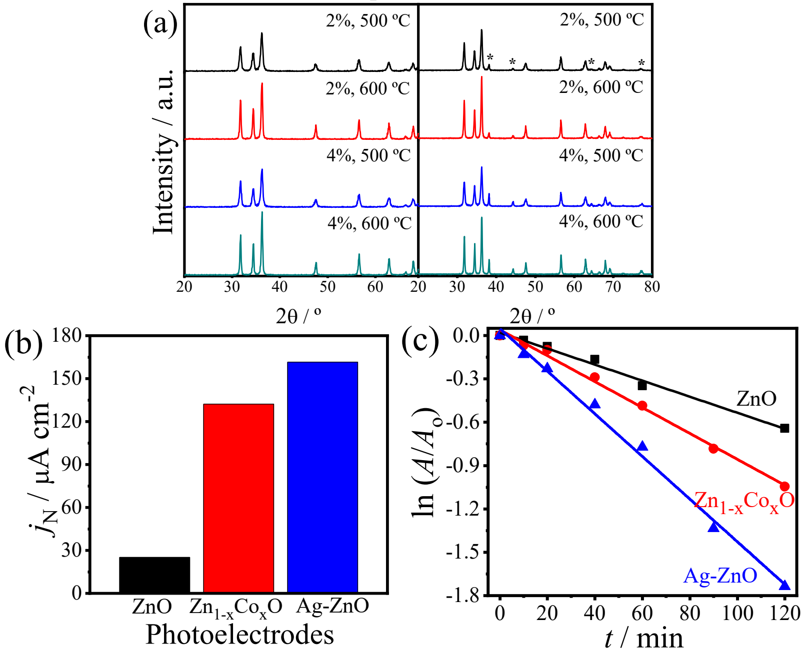

Fig. 1 – (a) X-ray diffraction for $Zn_{1-x}Co_xO$ and Ag-ZnO samples, (b) current density and (c), photoelectrocatalytic responses for the MB discoloration reaction, for ZnO, $Zn_{1-x}Co_xO$ and Ag-ZnO photoelectrodes (E_{app} = +1.0 V, UV light). Electrolyte: 0.1 mol L^{-1} Na_2SO_4 solution.

Fuel cells are one of the most mature technology for green energy, specifically the proton exchanged membrane fuel cell (PEMFC) that depends mostly on the use of expensive platinum group metals (PGMs) [1]. Recently, alkaline exchanged membrane fuel cell (AEMFC) have been received a major attention for advanced and low-cost catalysts. Although there are efficient non-PGM catalysts for alkaline -oxygen reduction reaction (ORR), Pt/C still has the highest performance for alkaline -hydrogen oxidation reaction (HOR) [2]. Beside their cost, the biggest disadvantage of Pt/C and other monometallic PGMs is their drastic degradation in electrochemical surface area and performance at high pH. Several works of Chatenet *et al.* on accelerated stress test (AST) combined with identical location transmission electron microscopy (IL-TEM) showed that Pt assists the local carbon corrosion, leading to CO_2/carbonates formation, and particles detachment [3]. In contrast, bimetallic or bifunction catalysts showed better durability compared to monometallic ones, such as Pd-Pt [4] and Pd-Ni [5] alloy nanoparticles. Bifunction catalyst can also enhance the sluggish kinetic of monometallic PGM in alkaline -HOR, according to the metal-metal oxide theory of Markovic *et al.* [6]. Following this insight, GenCell Energy, Israel patented two compositions of Pd-Pt and Pd-Ni on high surface activated carbon to be used in caustic solution (up to 6.6M KOH in a membraneless alkaline fuel cell set up). In this work, the stable performance of those catalysts was evaluated in 0.1M KOH before and after Ar-AST (150 cycles and 1000 cycles, 0.1 V_{RHE} - 1.2 V_{RHE}, 100 mV/s scan rate). Their physical and chemical properties before and after AST were evaluated by IL-TEM, XRD, XPS and Raman spectroscopy. As expected, both Pd-Pt and Pd-Ni showed better stability compared to monometallic Pt/C and Pd/C (ETEK). Figure 1 presents very little loss of nanoparticles and reasonable agglomeration of Pd-Ni and Pd-Pt catalysts after Ar-AST 150 cycles.

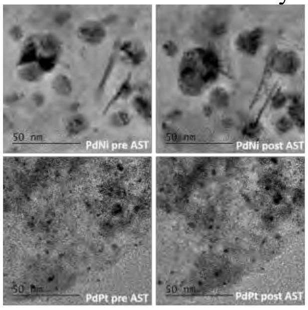

Figure 1: IL-TEM of pre and post Ar-AST 150 cycles (0.1 V_{RHE} -1.2 V_{RHE}, 100 mV/s scan rate).

In this work the electrochemical behavior of some selected rare earth (RRE) was evaluated by cyclic voltammetry (VC) in dicyanamide - based room temperature ionic liquid [1].

The studied elements (yttrium, lanthanum, neodymium and samarium) show an electrochemical response that is dependent both on their reduction electrochemical process (in a single step or in a two consecutive steps) and on their associated oxidation process.

From these results and in account of the voltammetric behavior, it is possible to conclude that the studied REE are reduced and oxidized at very similar processes as in aqueous media, molecular solvents and high temperature molten salts [1-9].

The obtained results of the comparison of the electrochemical behavior of the studied REE allow us to propose the possibility of selectively identifying the studied REE in the context of their differing electrochemical responses.

luanpcamargo@gmail.com

The research and development of new materials with catalytic properties is essential due to the growing industrial development, energy crisis and environmental problems. Vanadates represent a very important class among the commonly used catalytic and photocatalytic materials. For instance, iron vanadates receive attention due to their distinguished properties. The $Fe_2V_4O_{13}$ (n-type) semiconductor stands out due to its low band gap energy, high chemical stability, low cost and ecologically friendly, which makes it promise for use in electrochemical sensors[1], cathode in batteries[2] and photoelectrochemical water oxidation[3]. In this context, the research to materials with better photoelectrocatalytic performances achieves in the SILAR process a way to improve the properties of the $Fe_2V_4O_{13}$. The present work aims to evaluate the electrochemical properties of $Fe_2V_4O_{13}$ film obtained by the SILAR process with 5 layers. The physicochemical film characterization was performed through X-ray diffraction (XRD), Raman spectroscopy, diffuse reflectance and scanning electron microscopy (SEM) techniques, as well as electrochemical characterization through linear sweep voltammetry (LSV) curves, chronoamperometry and electrochemical impedance spectroscopy (EIS) techniques in to the dark and using visible light irradiation (Blue Laser (FA02)). From the XRD and Raman techniques, it was possible to verify the formation of the $Fe_2V_4O_{13}$ monoclinic crystalline structure. By diffuse reflectance spectroscopy results it was observed 1.71 eV band gap energy. The SEM images show that the average particle size was close to 0.08 µm forming a layer of approximately 4.5 µm on the glass substrate (SnO2:F). Regarding the electrochemical characterization the film presented a high current density under the incidence of light (Fig.1). During the anodic scan under the chopped light condition the behavior of n-type semiconductor film was verified. The transient time was also determined using chronoamperometry (+1.0 V *vs.* Ag/AgCl). The observed low transient time, 10.3 seconds, can be associated with the favorable electrochemical properties of the semiconductor, making it difficult to recombine the photo-generated charge carriers (e^-/h^+). The Mott–Schottky plots leads us to estimate the semiconductor flat band potential approximately +1.06 V *vs.* RHE (Fig. 2). This result agrees with the onset potential observed in the LSV curves under irradiation. This work was possible to determine electrochemical properties for $Fe_2V_4O_{13}$ and based on the results it becomes possible to use this material in future in advanced oxidative processes.

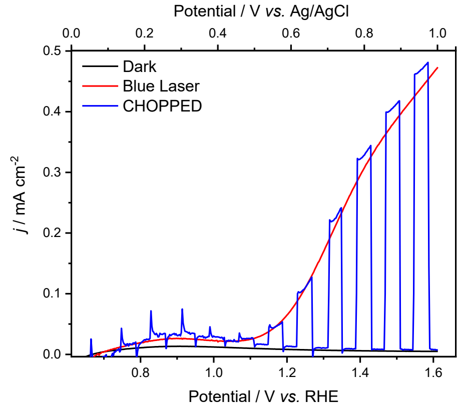

Fig. 1 – Linear sweep voltammetry for FTO/$Fe_2V_4O_{13}$ electrode in 0.1 mol L^{-1} Na_2SO_4 solution, v = 10.0 mV s^{-1}.

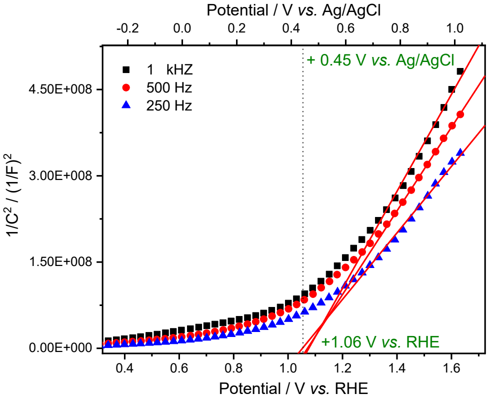

Fig. 2 – Mott–Schottky plots for $Fe_2V_4O_{13}$ collected at a frequency of 1, 0.5 and 0.25 kHz in 0.1 mol L^{-1} Na_2SO_4 solution.

The far-from-equilibrium precipitation reaction of chemical gardens can lead to the formation of biomimetic and complex structures providing a new route for the rational architectural design of functional materials[1].

Inspired by recent developments in the field of chemical gardens[2], we put forward a new scientific question: "Is it possible to create an electrochemical garden?". By implementing state-of-the-art electrochemical techniques and using an otherwise destructive phenomenon, that of metal corrosion, we sculpture self-organized structures on a zinc disc-electrode surface by a mechanism similar to that of chemical gardens. A deeper search in the formation mechanism reveals that ion-selective membranes are the driving force for the growth of an electrochemical garden. At last, electrochemical instabilities, introduced under proper conditions, result in the emergence of current oscillations in the region where electrochemical gardens were discovered. Current oscillations sculpture the electrode surface with a variety of self-organized precipitation structures[3].

Electrochemical sensors have been used in a number of fields such as industry, medicine and agriculture due to their robustness as a sensitive, cost effective and rapid form of molecular detection (Jacobs M, et al., 2013). Electrochemical sensors are devices that change electrochemical information into an analytically signal that is useful. They offer advantages of low detection limits, a wide linear response range as well as good stability and reproducibility. Detection of environmental contaminants using electrochemical methods have advantages of being reliable, fast, portable that can be used for in field analysis to detect environmental pollutants including antibiotic residues (Munteanu FD, et al 2018; Faridbod F, et al., 2011). Norfloxacin is an antibiotic that is usually used to treat complicated urinary tract infection. It has been reported that this antibiotic has been detected in various sources such as surface water, sea water, groundwater and drinking water (Chen, M and Chu, W. 2012). There has been work reported on the detection of norfloxacin (NOR) using electrochemical techniques such as square wave voltammetry (SWV), cyclic voltammetry (CV) and differential pulse voltammetry (DPV). This work reports on the detection of NOR by electrochemical impedance spectroscopy (EIS) in aqueous systems as there is not a lot of work reported on the detection of norfloxacin by EIS. EIS can be used as an analytical tool to measure changes in the electrical properties of the sensor under various analyte concentrations. This electrochemical technique has been extensively utilised for detection of a number of chemical and biological targets in terms of electrochemical change of the electrodes surface (Muñoz J, et al., 2017) EIS have unique advantages compared to CV, SWV and DPV such as ease of signal quantification, ability to separate the surface binding events from the solution and it is also more sensitive compared to the other electrochemical techniques (Chen Z, et al., 2011). This work reports on two different electrochemical detection methods, square wave voltammetry and electrochemical impedance spectroscopy that can be used for detection of norfloxacin in aqueous systems. In this work NOR will be detected by square wave voltammetry and electrochemical impedance at a screen print electrode modified with polyamic acid in 0.1 M pH 7.4 PBS.

luizh@uel.br

The Metal-Organic Frameworks (MOF) is a new class of materials that has had the attention of researchers in the last years. They are structurally based on the presence of a metal ion or clusters linked by an organic ligand in a highly ordered structure, giving rise to materials with pronounced properties [1]. Its main characteristics are its versatility and in its excellent physical-chemical properties, such as a high adsorption capacity, gas storage and catalytic activity and semiconductor behavior[1,2]. MOF 235 stands out among the thousands of different types of MOFs since orange crystals are formed in an octahedral structure and each trivalent iron atom is organized in a network by the organic terephthalic acid ligand[2]. In this study, MOF 235 was easily obtained by the solvothermal method, and its photoelectrochemical properties were investigated by obtaining photoelectrodes by the drop-casting method on conductive ITO glass using different amount of layers (5, 10 and 15). The solid sample was characterized by X-ray diffractometry (XRD), Fourier transform infrared spectroscopy (FTIR) and diffuse reflectance. Regarding electrochemical characterization cyclic voltammetry (CV), chronoamperometry and electrochemical impedance spectroscopy (EIS) techniques were performed. The DRX and FTIR results reveal the formation of MOF 235 by the peaks and bands characteristic of its structure[2]. Based on the diffuse reflectance results the band gap energy was determined 2.0 eV, (Fig. 1-a). The results of CV and chronoamperometry (Fig. 1-b), indicated excellent photoelectrochemical performance with a high current density under irradiation of blue laser. The influence of layers was evaluated by chronoamperometry (Fig. 1-c). The best performance (10.5 µA cm^{-2}) was obtained with 15-layers and its probably related to a large amount of semiconductor deposited. However, impedance measurements demonstrated the lowest charge transference resistance for 5-layers films (246 Ω) (Fig. 1-d). This work demonstrates that a simple and fast route can be used to obtain MOF 235 with excellent photoelectrochemical properties.

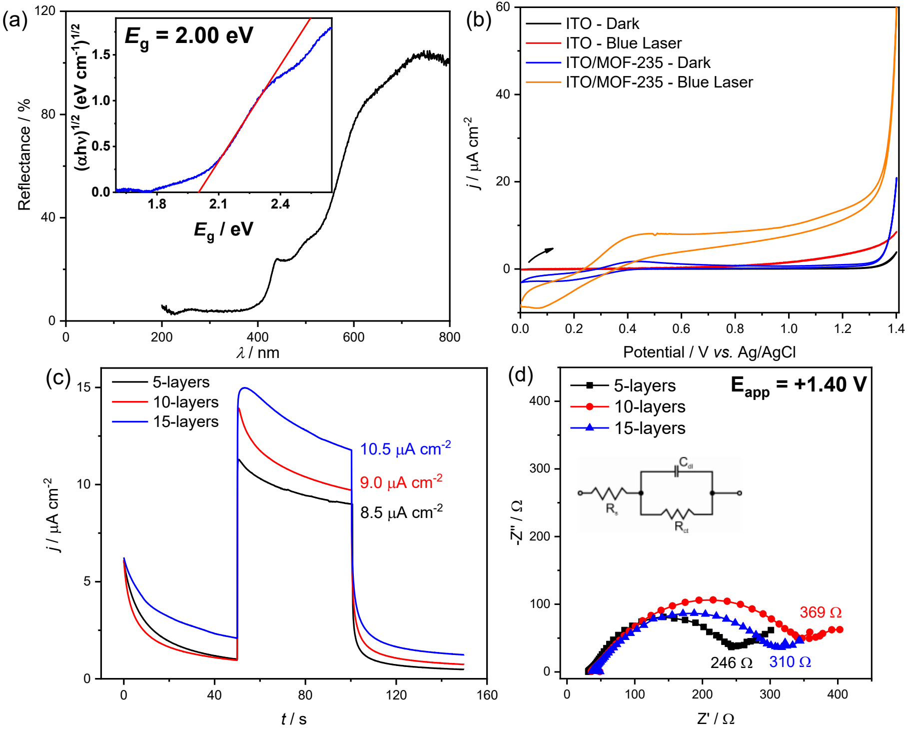

Fig. 1 – (a) – Diffuse reflectance spectra to MOF 235 obtained by solvothermal method, (b) CV for ITO/MOF 235 (5-layers) electrode, (c) chronoamperogram at +1.1 V *vs.* Ag/AgCl with chopped blue laser, and (d) EIS plots for ITO/MOF 235 electrodes. Electrolyte: 0.1 mol L^{-1} Na$_2$SO$_4$ solution.

Tailored Bipolar Membranes Based on Reduced Graphene Oxide/MoS_2 Hybrid Interfaces for Reduced Crossover in CO_2 Reduction Cells

Ramato Ashu Tufa, Qingfeng Li, David Aili

Department of Energy Conversion and Storage, Technical University of Denmark, Building 310, 2800 Kgs. Lyngby, Denmark; emails: rastu@dtu.dk, larda@dtu.dk

The electrochemical CO_2 reduction (CO_2R) using renewable energy is a promising strategy for the conversion of CO_2 into storable fuels and chemicals while keeping a carbon-neutral energy cycle. Recently, the use of bipolar membranes (BPMs) in CO_2 electrolyzers has emerged as a promising solution to achieve the practical ambitions due to its unique advantage in maintaining a constant pH gradient over the membrane and reducing crossover of ionic and molecular specieces[1,2]. Therefore, elucidation of the crossover dependence on membrane structure, among others, is crucial for advancing the selectivity and efficiency of the process[3]. Herein, a series of BPMs are prepared based on a hybrid interface composed of Reduced Graphene Oxide/MoS_2 catalysts for enhanced water splitting. The cation exchange layer, formed from sulfonated poly(ether ether ketone) (SPEEK) based polymer, is tuned in terms of fixed charge density and water uptake, which is suitably combined with Polybenzimidazole (PBI) based membranes as anion exchange layer. The interface layer is optimized by assessing the impact of the composition and loading of the hybrid catalyst on the electrochemical potential difference over the BPMs. The crossover of anionic products (e.g., formate) through the BPMs - evaluated in terms of the ionic flux, permeability or transport number - is investigated at varying electrolyte concentration (pH) and current density. The ultimate goal is to shed light on the interface structure-property-crossover relationships of BPMs under CO_2 reduction conditions.

Bismuth oxychloride (BiOCl) is a p-type semiconductor material with a band gap energy of 3.4 eV. This material has been investigated in recent years due to its unique properties, being the packaging layers of -[Cl-Bi-O-Bi-Cl]- which provides the formation of an internal static electric field that facilitates the separation of photogenerated charge carriers, minimizing the recombination processes of the electron/hole pairs. This inherent property leads this material to be applied as electrode materials in photoelectrochemical systems [1,2]. In this work, the FTO/BiOCl electrode was constructed by simple, fast, low cost and efficient SILAR deposition process. The experimental procedure was carried out by immersion of FTO substrate as follows to form one layer: 1) into Bi^{3+} solution ($Bi(NO_3)_{3(aq)}$ 0.1 mol L^{-1} + acetic acid) for 20 seconds; 2) into deionized water for 20 seconds; 3) into Cl^- solution ($KCl_{(aq)}$ 0.1 mol L^{-1}) and finally, 4) into deionized water for 20 seconds. After ten deposited layers, the electrode was dried at 100 °C for 4 hours. The characterization of the BiOCl sample and the FTO/BiOCl electrode was carried out by x-ray diffraction (XRD). Scanning electron microscopy (SEM) and surface area analysis (BET method), were also used. In Fig. 1-a, it is possible to observe the diffractograms of powder sample and FTO/BiOCl film. All the diffracted peaks are in agreeing to the tetragonal structure (P4/nmm and a=b=0.389 nm, c=0.737 nm) (JCPDS 06-0249 standard). The FTO diffracted peaks (SnO_2:F) are also observed. SEM topographic image of the FTO/BiOCl electrode shows a homogeneous micro-aggregate distribution (Fig. 1-b). Besides, the micro-aggregate with the spherical shape is formed up of small particles with an elongated format. The N_2 physisorption analysis indicates a large specific area of 12.5 m^2 g^{-1}. The electrochemical characterization carried out by linear sweep voltammetry (LSV) and chronoamperometry techniques, showed the photoelectrochemical properties of FTO/BiOCl electrode. LSV curves (Fig. 1c) shows the increase in photocurrent density from the scanning potential of +1.0 V to 0 V *vs*. Ag/AgCl under continuous UV light irradiation. This behavior in the *j vs. E* curve is typical of p-type semiconductor material. In the potential scan with the light chopped condition (light on-light off, 5 seconds), the reproducibility of photocurrent is observed. When the light is off the current back to the current value of the dark condition (black line – Fig. 1-c) and when the light is on the current reaches the value of continuous UV light condition (red line – Fig. 1-c). Chronoamperometric measurements, j *vs*. t curves (inset in Fig. 1c), was carried out by applied potential of 0 V *vs*. Ag/AgCl, obtaining a photocurrent density of -18 µA cm^{-2}. Besides, under the light on condition, it is observed the photocurrent stability, wherein in this case, the recombination of charge carriers process may be being suppressed. Then, from the results obtained in this work, the FTO/BiOCl electrode emerges as an interesting material to be applied as a cathode in photoelectrochemical cells.

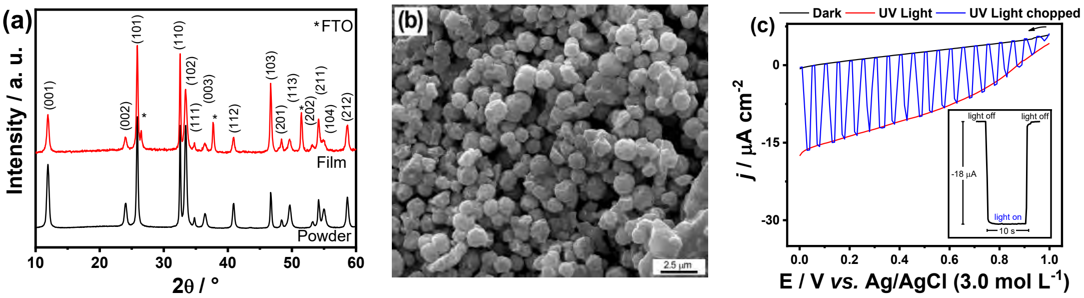

Fig. 1 – (a) X-ray diffractograms of powder and film of BiOCl semiconductor, (b) SEM topographic image of FTO/BiOCl, 12,000× magnification, and (c), LSV of FTO/BiOCl electrode in 0.1 mol L^{-1} KCl solution. Insertion in (c): chronoamperogram under 0 V *vs*. Ag/AgCl in 0.1 mol KCl solution with chopped UV light.

Phase-Field Modeling of Galvanic Corrosion in Magnesium-Aluminum Joints

Kübra Karayağız, Adam Powell, Qingli Ding, Brajendra Mishra
Worcester Polytechnic Institute
Worcester, MA, USA
kkarayagiz@wpi.edu

The future design of light-weight vehicles requires a multi-material design approach in which dissimilar alloys are joined together to form a single structure. Aluminum and magnesium alloys are shown to be amongst the best candidate materials for light-weighting purposes due to their superior properties.

However, the joining of Al and Mg is challenging due to galvanic corrosion, a common issue in dissimilar metal joints. A phase-field model to study the galvanic corrosion in Al-Mg joints is presented in this work. The model accounts for the transport of ions in the electrolyte, the electrochemical reactions at the metal-electrolyte interface, and the formation of hydroxide phases on the metal surface (e.g., $Mg(OH)_2$). Two-dimensional simulations are performed to predict the corrosion microstructure, corrosion rate, and galvanic current density in diffusion bonded Al-Mg couples immersed in an electrolyte solution. Galvanic corrosion experiments are conducted for validation. The predictions obtained from the model are compared with those estimated from the experiments. Overall, good agreement is achieved. The corrosion model formulation presented here is intended for later use with microgalvanic corrosion between pure metal and intermetallic phases in complex friction stir welded magnesium-aluminum joint microstructures.

Localized surface modification with SECCM

E. Oswald, J. Kund, C. Kranz
Institute of Analytical and Bioanalytical Chemistry, Ulm University
Albert-Einstein-Allee 11, 89081 Ulm
eva-1.oswald@uni-ulm.de

During the recent years, scanning electrochemical cell microscopy (SECCM) has mainly been used for studies measuring and mapping local electrochemical processes of electrochemically active materials[1],[2]. For example, SECCM has been used to investigate the heterogeneous electron transfer activity of graphene[3]. Besides, mapping SECCM is also highly suitable for surface patterning[4] and generating nanostructures[5]. Some of the advantages in comparison to the scanning electrochemical microscopy (SECM), are the stable response and the easy fabrication of the SECCM probe. Typically, SECCM experiments are performed with double-barreled nanopipettes with a quasi-reference counter-electrode (QRCE) in both channels, where a thin meniscus droplet at the end of the tip constitutes an electrochemical cell. Since the contact area between the meniscus and the sample surface depends on the tip size, structures possible with nanometer – to micrometer dimensions can be generated.

With this contribution, we present the local modification of carbon-based materials such as graphene or other carbon-based nanomaterials with ruthenium- and cobalt-catalysts. Such catalysts are interesting in molecular-driven photocatalysis. The generated nanostructures are characterized by atomic force microscopy in respect to their structure and size in dependence of the experimental parameter. In addition, TEM analysis will be used. Further investigations will be targeted towards correlated degradation studies for molecular photocatalytic systems.

szabogabor97@gmail.com

The two-dimensional semiconductor crystals, such as nanosheets of transitional-metal dichalcogenides (TMDCs) are promising candidates for applications in energy storage/conversion and sensing, due to their tunable structural, electronic and optical properties. However, over these materials, chalcogenides of post-transition metals also show photoactivity in the spectrum of UV-Visible light, such as tin-disulfide (SnS_2).[1] Due to these characteristics, this formerly neglected layered material could also be a great alternative for applications in light-driven catalysis.

It is crucial to understand the photoelectrochemical (PEC) behavior of these crystals to be able to apply them in energy harvesting applications. The reactivity of TMDCs may change extremely with their surface structure (e.g., basal planes and edges, number of layers and defect density).[2] Since SnS_2 nanosheets have not been studied thoroughly in terms of structure-dependent reactivity, the goal of our group was to determine the effects of different surface domains on microscopic scale and compare those to the performance of macroscopic electrodes, in order to enhance its PEC performance.

The micro-scale electrodes were prepared by micromechanical exfoliation from SnS_2 single crystals and were studied with our custom-designed PEC micro-setup. This setup allows us to deposit and maintain microdroplets on the desired part of a nanosheet, with a micro-injection and manipulator system thus to create a 'microelectrochemical cell'. The deposition happens with the help of a microcapillary giving place to the counter- and reference electrodes. The working electrode is the area of the nanosheet, on which the droplet had been deposited. For the macroscopic measurements, bulk SnS_2 crystals were hydrothermally synthesized and exfoliated in formamide.[3] The resultant dispersion was centrifuged at different speeds to obtain two monodisperse fractions in terms of flake thickness and lateral size. The SnS_2 nanosheets prepared by both mechanical and liquid phase exfoliation were characterized with Raman spectroscopy and microscopy techniques (AFM, TEM, SEM). The as-prepared suspensions were used to fabricate the macroscopic electrodes on ITO-coated glass slides. The (photo)electrochemical activity of the nanosheets will be presented with the help of cyclic voltammetry, photovoltammetry and transient measurements (photocurrent transient analysis), focusing the role of the edges and other structural domains.

As a conclusion, the microscopic measurements allow us to better understand how the surface structure affects the (photo)electrochemical behavior of nanosheets, as well as the behavior of macroscopic electrodes fabricated from them. With the help of this approach we will show that the edges of the nanoflakes do not have such a strong negative effect on the photoactivity in case of SnS_2, compared to other TMDCs like MoS2, or $MoSe_2$.[4] Due to this weaker effect, the photoactivity of SnS_2 electrodes could be enhanced more effectively than that of other TMDC electrodes. The main goal of this work was the development of a methodology to quantify selenium (Se) in the foodstuffs employing silver solid amalgam electrode modified by a thin and stable mercury film (f-AgSAE) coupled to square-wave cathodic adsorptive stripping voltammetry (SWCASV). Preliminary experiments were realized to verify the suitable analytical signal from SWV experiments using AgSAE in acid (0.1 mol L^{-1} HCl) and basic medium (0.1 mol L^{-1} NaOH plus 0.1 mol L^{-1} KCl), where was observed that the signal analytical (I_p) was strongly influenced by pH of the medium. Besides this, the peak potential (E_p) was dislocated to more cathodic values and half-peak width ($\Delta E_{p1/2}$) have value large with the increase of the pH. After experiments of SWV observed a considerable block of the electrode surface by adsorbed products from redox reaction, providing low repeatability and poor reproducibility. Posteriorly, SWCASV experiments were made using AgSAE and *f*-AgSAE in 0.10 mol L^{-1} HCl solution preconcentration steps (-0.2 V by 30 s), where was observed the presence of a well-defined voltammetric peak under AgSAE and *f*-AgSAE at -0.64 V and -0.50 V, respectively. Besides, the *f*-AgSAE showed higher sensibility and selectivity, due to values of the I_p and $\Delta E_{p1/2}$ present values more favorable than AgSAE.

The preconcentration parameters were evaluated using preconcentration potential from +0.10 to -0.50 V *vs.* Ag/AgCl 3.0 mol L^{-1} in accumulation times from 15 to 90 seconds, and was observed that applying 0.0 V during 90 seconds the I_p presented values around fifty times higher than observed to potential preconcentration more cathodic, and without alteration in the E_p and $\Delta E_{p1/2}$ values. Analytical signals are related to a reaction of irreversible reduction of the Se producing HgSe. Voltammetric parameters were individually evaluated, the pulse amplitude (*a*) was varied in 5 at 50 mV, thus, it observed an increase linear of the I_p up until 50 mV, dislodgment in E_p to less cathodic potential direction, but provoked widening in the voltammetric peak baseline, due to 25 mV was selected. Already, the variation of the pulse potential frequency (*f*) was realized from 10 to 300 s^{-1} observing increase linear of I_p with *f* square root, that is typical reaction was controlled by the diffusion rate. Besides this, the Lovric's Equation enabled the calculation of the number of electrons of the reaction of the surface, according to the relationship between the f and E_p, theses reactions that were 4 electrons, and it made possible the verification of the mechanism reduction of selenium. Thus, 90 s^{-1} was chosen to further experiments, and scan potential increment (ΔEs) was chosen value of -2 mV, due to loss of the peak profile.

Parameter	This work
LR (μmol L^{-1})	0.10 - 8.0
r	0.9989
DL (mol L^{-1})	1.0071×10^{-9} 80.53 ng L^{-1}
QL (mol L^{-1})	3.3570×10^{-9} 268.4 ng L^{-1}
Recovery (%)	101.00
Reproducibility (%)	4.90
Repeatability (%)	1.64

Table 1: Analytical parameters for the determination of Se in pure electrolyte on *f*-AgSAE, where LR is the linearity range, r is the correlation coefficient, DL and QL are detection and quantification limit, respectively.

So, analytical curves were built using standar addition method in a linear range from 0.10 to 8.0 μmol L^{-1}, and the analytical parameters were calculated and are shown in Table 1. The correlation coefficient (r) demonstrated excellent linearity. The detection and quantification limits (DL and QL) presented values like obtained using other electrodic surfaces and spectroscopic techniques. The methodology precision was evaluated by repeatability and reproducibility and indicated suitable values that were below 5.0%. While the accuracy was measured according to recovery curves obtained 101.0%. The coconut water, soy juice, soy milk, apple, orange, potato, spinach, and tomato were previously digested using nitric, perchloric, hydrochloric acid, and after this was made recovery curves and obtained recovery values variated from 101.78 to 170.76 %.

The use of the *f*-AgSAE with SWCASV decreased the waste generation and allowed sensitive, selective, reproductive, and yet quick analysis, is a suitable methodology to the determination of Se in foodstuffs samples.

Comparative Corrosion Studies of TiO_2 Coatings Doped with Metal Ions of Biomedical Importance

Barbara Burnat, Andrzej Leniart, Sławomira Skrzypek
Faculty of Chemistry, University of Lodz
12 Tamka St., 91-403 Lodz, Poland
barbara.burnat@chemia.uni.lodz.pl

Biomaterials as materials implanted into a living system must fulfill stringent requirements. Nowadays, studies on biomaterials are focused on enhancing their bioactivity and giving them new properties, e.g. antibacterial properties. One of the methods used for preparation of biomaterials with desirable properties is coating their surfaces with functionalized coatings. For example bioactivity may be enhanced by ion doping procedure – the coating is doped with metal ions e.g. calcium and strontium ions. The antibacterial properties may be also achieved by doping procedure – for that purpose silver, copper, zinc or gallium ions are used as antibacterial agent. Unfortunately, every performed functionalization may cause deterioration of other features of biomaterials. Therefore, it is important to control the impact of carried out modifications on other material features, especially corrosion resistance.

The main goal of this study was to apply the sol-gel method for the preparation of protective ceramic coatings of titanium dioxide and their modification by doping of silver, copper, zinc, and gallium ions, that are of antibacterial importance [1-2].

In this study, TiO_2 sol-gel coatings doped with different metal ions were produced on the surface of M30NW biomedical alloy substrates. The titanium tetrabutoxide was used as a precursor of titanium dioxide. In the doping procedure, the nitrates of silver, copper, zinc, and gallium were used as precursors of particular ions. The content of individual ions in the coating was the same and amounted to 5%. The TiO_2-based coatings were calcined at a temperature of 450°C to obtain anatase structure. The effect of each dopant on microstructural and anticorrosion properties of TiO_2-based coatings was investigated.

The morphology, topography and roughness of TiO_2-based coatings were investigated using scanning electron microscopy (SEM) and atomic force microscopy (AFM). The corrosion measurements were carried out in Phosphate Buffered Saline (PBS) solution using electrochemical methods: linear polarization resistance (LPR), potentiodynamic polarization, and electrochemical impedance spectroscopy. Anticorrosion properties of TiO_2-based coatings were specified on the basis of the results of electrochemical tests.

The sol-gel procedure and annealing temperature of 450°C applied in this study allowed the synthesis of crystalline TiO_2 coating with a thickness of ca. 70 nm. Using the sol-gel procedure the TiO_2 coating was successfully functionalized by doping of silver, copper, zinc, and gallium ions. Depending on doped ion the surface morphology of the coating was different. It was found that the addition of copper and gallium ions does not affect surface roughness, while doping with silver and zinc ions increases surface development. The results of corrosion tests in PBS solution confirmed the anticorrosion properties of all TiO_2-based coatings. However, the anticorrosive nature of titanium dioxide coatings doped with ions of antibacterial activity can be ranked as follows: $Cu\_TiO_2 < TiO_2 < Ag\_TiO_2 < Zn\_TiO_2 < Ga\_TiO_2$.

Ionic liquids (IL) are well-known as candidates for energy storage-and-transformation applications [1]. Herewith, conventional ILs are toxic and harmful to the environment. Biocompatible ILs yield when choline cation is combined with carboxylate anions. Yet, the primary drawback of such ILs is a higher melting point and poor charge transport properties [2]. One way to lower the melting point is to create eutectic mixtures of ILs [3]. The current work demonstrates that molecular dynamics (MD) is a suitable method for predicting properties of possible combinations and compositions of ILs and their mixtures. The solid phases can be obtained by applying Coulombic potential wells to a system of randomly packed ions. Then, the melting points can be determined from a change of slope in the diffusion coefficient *vs.* inverse temperature (Figure 1) during simulated annealing [4]. The presented MD-based method was tested on 13 choline based ILs in work 4 and lately on binary mixtures of ILs for which phase diagrams were predicted (Figure 2).

Biocompatible ILs are possible electrolytes for biomimetic and biomedical applications in smart and soft electroactive polymer actuators. Our recent MD study [5] showed that among other simulated properties, the cation–cation correlation serves as a good predictor of strain difference in such actuators.

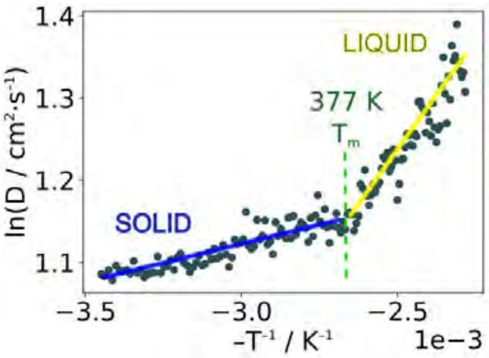

Figure 1: Diffusion coefficient – inverse temperature dependence during simulated annealing.

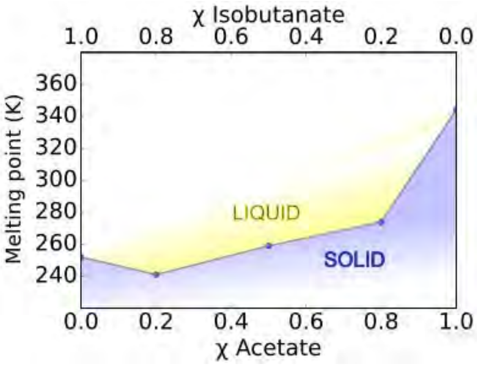

Figure 2: Melting point dependence on anionic molar fraction of mixture (cation is choline).

Transient and Impedance Response of a Rotating Disk Electrode in a Weak Acid

Samuel Jacobs, Chen You, Mark E. Orazem
Department of Chemical Engineering
University of Florida, Gainesville 32611 FL USA
meo@che.ufl.edu

Electrochemical current may be influenced by homogeneous reactions adjacent to the electrode. For example, dissociation of a weak acid may enhance the cathodic current through homogeneous supplementation of hydrogen ions. Enhancement is influenced by dissociation rate, diffusion of the weak acid to the electrode, and applied potential. The objective of this work was to model the impedance response and the transient response under a step in potential. The characteristic time constants of the current response are influenced by the homogeneous dissociation of the weak acid.

In previous work,[1] we modeled impedance of a rotating disk electrode adjacent to a nonlinear homogeneous reaction. Numerical results were fit to a modified Gerischer impedance which included the influence of the convection-diffusion and first-order homogeneous kinetics. Recently, Potoskaya and Gicahn[2] derived an analytic expression for the Gerischer impedance when diffusion coefficients are unequal. Their results show that unequal diffusion coefficients influence the Gerischer impedance at low frequency, but the Warburg response for the diffusion of the electroactive species remains unchanged at high frequencies. The observed influence of the homogeneous reaction disappeared for a sufficiently small rate constant.

The objective of the present work was to develop an impedance model and a transient model to investigate the current response of hydrogen reduction on a rotating disk electrode in a weak acid system. Due to the nonlinear homogeneous kinetics of acid dissociation, a numerical finite-difference method was employed to calculate the response for varied acid dissociation rate constants and applied potential. The relationship between the impedance response to oscillating potential and transient response to step potential was investigated. Time constants extracted from the two methods were found to be in good agreement.

The Effect of the Counter Electrode Material on the Evaluation of Electrocatalysts

Matthew Bird, Sean Goodwin, Darren Walsh
Nottingham Applied Materials and Interfaces Group
GSK Carbon Neutral Laboratory for Sustainable Chemistry
Jubilee Campus, University of Nottingham
Nottingham, NG7 2TU
United Kingdom

Making accurate measurements of electrocatalytic activity is of paramount importance for the development of new earth-abundant electrocatalysts. In a typical three-electrode setup Pt or Au is often used as the counter electrode material. These metals can dissolve during testing and subsequently deposit on the test electrocatalyst surface, artificially increasing the measured activity. A Nafion membrane is sometimes used to separate the counter electrode from the test electrocatalyst to minimise this, though no work has conclusively proved this to be effective. The work presented here uses X-ray photoelectron spectroscopy, energy-dispersive X-ray analysis, mass spectrometry, and voltammetry to demonstrate the issues with using metallic counter electrodes and the ineffectiveness of Nafion to mitigate this during constant-current testing of electrocatalysts for the hydrogen evolution reaction. It is further shown that a carbon counter electrode can deactivate electrocatalyst surfaces, and that a glass frit should be used to separate the test surface from the counter electrode in these cases.

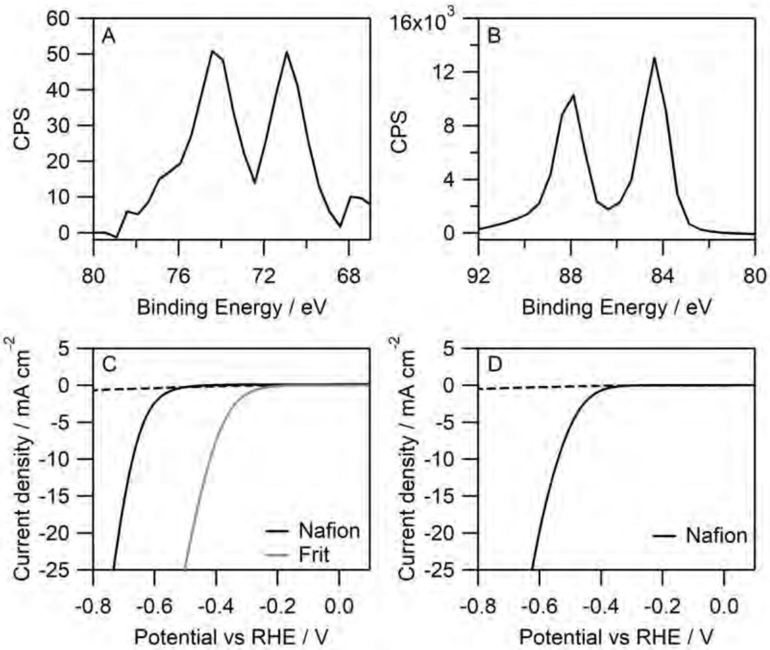

Figure 1: XP spectra of a GC surface after 24 h of HER at –10 mA cm^{-2} in cells containing (A) Pt and (B) Au counter electrodes, with a Nafion membrane separating the counter/reference electrodes from the GC. (C) Voltammograms recorded before (dashed line) and after (solid lines) 24 h of HER at –10 mA cm^{-2} at GC in cells containing a Pt counter electrodes and a Nafion-membrane (black solid line) and glass-frit separator (gray solid line), respectively. (D) Voltammograms recorded before (dashed line) and after (solid line) 24 h of HER at –10 mA cm^{-2} at GC in a cell containing an Au counter electrode and Nafion-membrane separator.

e-mail: david.parra@unesp.br

Abstract: The development of materials to monitor and minimize negative impacts on the environment and human health has been widely studied. In this sense, the aim of this work was the development of a high performance device for the , built by electrospinning the $BiVO_4$/GO, obtaining through the technique, nanofibers with high surface area when compared with other techniques of deposition. The BiVO4 band gap value (2.4 eV) and its absorption in the visible region (520 nm), together with the high conductivity of the GO, a p-n heterojunction was formed, thus increasing the efficiency of the device, provided optimum results [1]. Optical and Scanning Electron Microscopes (SEM) were able to morphologically confirm the efficiency of the electrospinning technique in the preparation of the BiVO4/GO nanofibers, showing excellent fiber uniformity, no coalescence and obtaining fibers with diameters between 60 and 96 nm. The photoelectrovoltaics measurements showed a significant improvement in the photogenerated current, using the nanofibers, confirmed by the increase of the peak current and the decrease in the value of the peak potential when compared to other methods of preparation already described in literature [2]. In this way, the data corroborate that the union of the photoelectrocatalytic effect of $BiVO_4$/GO and electro-spinning process have a high potential for applications in the field of renewable energy generation.

Mathematical Model and Regression Analysis for Electrochemical Impedance Spectroscopy of Continuous Glucose Sensors

Ming Gao,[1] Rui Kong,[2] Mark E. Orazem[1]
[1] *Department of Chemical Engineering, University of Florida, Gainesville, FL 32611*
[2] *Medtronic Inc., Diabetes, 18000 Devonshire St., Northridge, CA 91325*
meo@che.ufl.edu

The Continuous Glucose Monitor (CGM) is a device to help patients with diabetes mellitus monitor the blood sugar level in real time and manage hyperglycemia. It includes an enzyme-based glucose sensor implanted under the skin measuring the glucose level in the subcutaneous fluid.

An advanced one-dimensional mathematical model accounting the physics and chemistry of the continuous glucose monitor has been developed.[2,3] The mechanistic model includes the enzymatic reactions, the anomerization equilibrium of α-D-glucose and β-D-glucose, the pH-dependent enzyme activities and the biological buffers. The coupling between the homogeneous reactions and heterogeneous reactions has been described specifically. The physical properties of the sensor and the transport process are also considered. The mathematical model was solved numerically by using the finite-difference method and Newman's BAND algorithm.[4] A systematic parameter investigation has been explored regarding the steady-state profiles and impedance response. The results showed that oxygen and hydrogen peroxide play a key role in the transport-reaction process. Therefore, the electrochemical impedance response is useful for differentiating fault reading caused by oxygen deficiency and enzyme deactivation. It facilitates the understanding of the transport-reaction process and interpretation of the impedance response of sensor under various working conditions, failure mechanism and different sensor designs.

The approach of analyzing the experimental impedance data is shown in the presented work. The process model that accounts for the reactions and physics has been proposed. Regression analysis for the impedance measurement of continuous glucose sensors has been performed based on the measurement model[5,6] and a proposed process model. The measurement model has been used to confirm the consistency of impedance data with the Kramers-Kronig relations. The data flawed by nonstationary behavior and instrument defects is eliminated. The regression of impedance data can extrapolate fitting parameters that have physical meaning and can be correlated with glucose concentration. The study suggests that more information can be extrapolated from impedance response with measurements taken at lower frequencies and lower applied potentials.

gianina.damian@uab.ro

Waste printed circuit boards (WPCBs) are the most valuable components of the electrical and electronic equipment wastes, which contain different metals with various ranges of concentrations, including hazardous elements (Pb, As, Cd, Hg), base (Cu, Sn, Zn, Ni, Fe) and precious (Au, Ag, Pd) metals [1]. Recovery of metals from WPCBs is of great importance for both environmental protection and resource re-utilization. The traditional hydrometallurgical approaches for metals recovery from WPCBs use leaching systems that cannot always meet the requirements in the environmental, economic and technic aspects. Therefore, much attention should be paid on developing novel leaching methods that use environmental-friendly and easily recycled lixiviant and oxidant [1].

In the present paper, the dissolution and deposition behaviour of base (Zn, Fe, Ni) and metals precious (Au, Ag) was investigated in an acidic bromine-containing electrolyte that could be used as lixiviant in hydrometallurgical route of metals recovery. The experiments were performed in synthetic electrolytes containing known concentrations of metallic ions and in real solutions resulted from WPCBs leaching from which the more noble metals *i.e.* Au, Ag, Cu, Sn and Pb were removed by electroextraction.

Cyclic voltammetry and polarization measurements were performed in order to characterize the metals dissolution and electrodeposition processes. The influence of metals concentrations and/or solution pH on the electrodeposition was also investigated to determine the optimum working conditions.

The present study is part of a complex research project aiming to elaborate an innovative and pollutants-free hydrometallurgical technology for metals recovery from WPCBs.

Deep Eutectic Solvents (DESs), formed from a quaternary ammonium salt and a hydrogen bond donor, have emerged as alternative media to toxic/corrosive aqueous or organic solvents for electrodeposition processes. These solvents are usually ecologically friendly and conductive enough to be used with no further addition of an electrolyte salt. Speciation is an important factor in metal electrodeposition and owing to the large variety of available DES, the deposit characteristics of a given metal can be extremely different between DES.

The present study concerns the electrodeposition of gold from two differents salts (AuCl and $AuCl_3$) dissolved in two different DES, namely choline chloride - oxalic acid (1: 1) (ChCl-Ox) and the choline chloride – urea (1 : 2) (ChCl-U).

On glassy carbon, the voltammetric features associated with the Au(III)/Au(I) and Au(I)/Au(0) couples are clearly identified. Both are associated with slow kinetics, more particularly in the ChCl-U medium where a very large overpotential is required for Au electrodeposition. By contrast, on platinum, the kinetics of the Au(I)/Au(0) couple is much faster, so that only one cathodic wave associated with a 3 e^- reduction is observed while two anodic peaks corresponding to the 1 e^- oxidation to Au(I) followed by the 2 e^- oxidation to Au(III) are obtained in the ChCl-Ox medium.
The electrochemical data are completed by spectrophotometric measurements and a discussion on the speciation of Au is conducted to rationalise the obtained results.

A Preliminary Investigation into the Microscopic Passivation of new Bio High Entropy Alloys

Julia C.Mirza Rosca, Nestor Florido Suarez, Ionelia Voiculescu, Victor Geanta
University of Las Palmas de Gran Canaria, Mech.Eng.Dept.
Campus Universitario Tafira EIIC – 35017
julia.mirza@ulpgc.es

In recent years, due to the great advance of scientific and technological research, new alloys are being explored with a different metallurgical concept: at least three basic components and these alloys are called High Entropy Alloys (HEA). In this way it was created the groundwork for a new concept in alloy design by looking after combinations of metals to work "in team" for an advanced material with unique properties.

At the end of the last century, the progress of science led to the rapid development of biomedical materials and the recent development of high entropy alloys (HEA) provides a new perspective for a new generation of biomaterials.

Two new experimental alloys (with the composition presented in Table 1) were obtained by Vacuum Arc Remelting from high purity chemical elements (99.5%) that exhibit extremely low bio-toxicity for the human body (for this reason we named them BioHEA).

Table 1. Chemical composition of the analyzed BioHEA.

	Wt.%					
	Mo	Ta	Ti	Zr	Nb	Fe
BioHEA 1	20.45	32.45	12.67	18.97		15.46
BioHEA 2	17.32	38.95	13.21	17.45	13.07	

The alloys were microstructurally characterized (dendritic morphology, Fig.1 and Fig.2) and microhardness measurements were performed. Both the compositional analysis performed using the dispersive energy probe and the structural characterization by X-ray diffraction revealed the dendritic separation of compounds in the fine dendritic matrix.

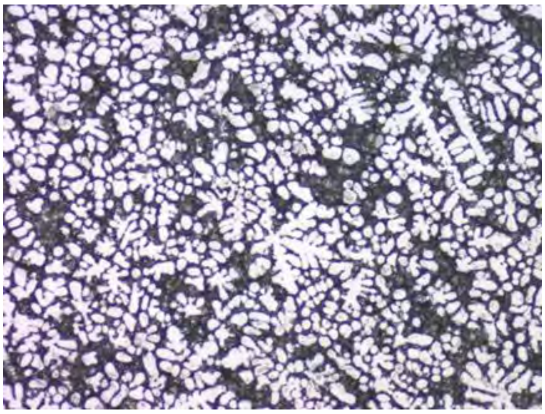

Fig.1. BioHEA 1 microstructure

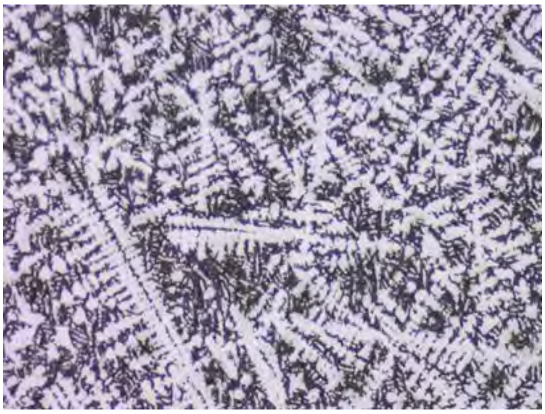

Fig.2. BioHEA 2 microstructure

In order to analyze the passivation process, the electrochemical impedance spectroscopy technique at different potentials was used and the experimental results were compared with those obtained by potentiostatic and potentiodynamic techniques.

The low corrosion rates, low corrosion currents and high polarization resistance attest the good stability of these BioHEA in simulated biological environments.

Influence of the Electrode Substrate (Au, GC, Pt) on the Palladium Electrodeposition in the Choline Chloride-Urea Deep Eutectic Solvent

F. Soma [a, b] *, Q. Rayée [a], M. Bougouma [b], C. Buess-Herman [a], Th. Doneux [a]

Palladium electrodeposition in aqueous media requires potentials close to the decomposition of water, leading to low faradaic yields and embrittlement of electrodeposited palladium. This justifies searching for an alternative electrolyte and the DESs formed from a quaternary ammonium salt and a hydrogen bond donor, have emerged as a judicious choice. These solvents provide relatively large electrochemical potential windows and temperature ranges.

This work reports on the electrodeposition of palladium in the Choline Chloride – Urea (1:2) (ChCl-U) deep eutectic solvent and focuses on the influence of the substrate on the electrochemical behavior of Pd(II).

Curves obtained at a platinum and glassy carbon electrode show two cathodic peaks and two reverse anodic peaks. The first cathodic and anodic responses are linked to the redox reaction of the Pd(II)/Pd(0) couple, while the second cathodic and corresponding anodic waves were attributed to the incorporation and desorption of hydrogen into the deposited palladium.

The overvoltage required for palladium electrodeposition is much higher on glassy carbon than on platinum and associated with a nucleation process.

The gold disc electrode stands out with a different electrochemical behavior signed by the presence of a third cathodic peak which appears long before the two cathodic responses observed on the two previous substrates. No significant overvoltage is required for the deposition of palladium on gold. The most probable explanation of this third response is an under-potential deposition phenomenon of palladium, as observed in an aqueous medium [1]. Rotating disc electrode measurements were performed to obtain more information on these cathodic peaks. Based on these results, the electrochemical behavior of Pd(II) could be separated into four distinct potential zones. In the zone of the most positive potentials the RDE measurements reveal that the intensity corresponding to the first cathodic peak is independent of the rotation rate of the electrode (ω), which indicates a reaction limited by a surface process and confirms our hypothesis of an underpotential deposition in this region.

A portable electroanalytical procedure with unmodified screen-printed carbon electrode to determine paracetamol in urine and struvite used as organic fertilizers

Rafael de Q. Ferreira, Luiz R. G. Silva, Maria de L. S. Vasconcellos
Chemistry Department, Universidade Federal do Espírito Santo, 29075-910, Vitória, ES, Brazil
E-mail address: rafael.q.ferreira@ufes.br

Among organic fertilizers, bovine and human urine are natural substance that can replace chemical fertilizers, since they are rich in potassium and nitrogen, and they have compounds that improve plant resistance in terms of health, pests and diseases[1]. The utilization of urine in agriculture can be made both in liquid or solid form, through the precipitation of struvite[2]. Struvite precipitation has been gaining recognition in the agriculture and industrial sector for being an ecological and economical technique that enables the recovery of macronutrients[3,4]. However, some toxic substances present in the urine can contaminate the soil, such as drugs (e.g. paracetamol), once urine is a direct excretion route. Paracetamol in high dosage and continuous indirect consumption can cause gastrointestinal bleeding, exogenous intoxication, hepatitis and liver necrosis, which can lead to death[5]. The present work developed a fast, sensitive, inexpensive and portable procedure for the determination of paracetamol in urine and struvite used as organic fertilizers. In this study, unmodified screen-printed carbon electrodes (SPCE) were used in conjunction with the square wave voltammetry (SWV) technique, employing a drop of solution (40 µL) for analysis.

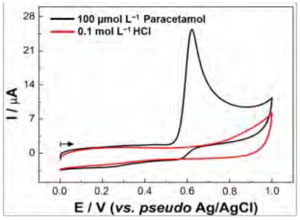

Fig. 1. Cyclic voltamogram of (—) 0.1 mol L^{-1} HCl and (—) 100 µmol L^{-1} paracetamol in 0.1 mol L^{-1} HCl. Potential range applied 0 to 1 V, scan rate 50 mV s^{-1}.

Initially, the voltammetric profile of paracetamol was obtained by cyclic voltammetry (CV), to identify the redox potentials and possible coupled chemical reactions. Fig. 1 represents the cyclic voltammogram of 100 µmol L^{-1} paracetamol in 0.1 mol L^{-1} HCl (pH 1.0). The response obtained for the supporting electrolyte (0.1 mol L^{-1} HCl) indicates that there are no significant background currents, interfering processes or any adjacent reactions in the applied potential range. The pH effect on the voltammetric response of paracetamol was evaluated by CV, in the pH range of 1.0 to 12.0, using HCl, KCl and BR buffers in the presence of 100 µmol L^{-1} of the analyte (Fig. 2). The results demonstrate that 0.1 mol L^{-1} HCl (pH 1.0) was the best support electrolyte.

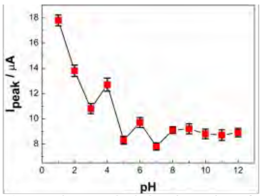

Fig. 2. Peak Current (I_{peak}) dependece with pH for determination of 100 µmol L^{-1} paracetamol in 0.1 mol L^{-1} HCl (pH 1.0), 0.1 mol L^{-1} BR buffer (pH 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 9.0, 10.0, 11.0 and 12.0) and 0.05 mol L^{-1} KCl (pH 7.0).

The operational parameters of the SWV were optimized by univariate experiments. The optimal values found were: 10 mV (step potential); 40 mV (modulation amplitude) and 15 Hz (frequency). In addition, a SPEC stability study was carried out by application of 50 successive SWV scans. The results indicated that after 25 scans, the SPCE loses the ability to generate reliable responses due to erosion from continuous use of the electrode.

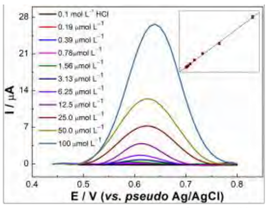

Fig. 3. Square wave voltamograms for the addition of ten solutions of paracetamol (0.19 to 100 µmol L^{-1}) in 0.1 mol L^{-1} HCl.

The analytical curve was constructed in a linear range of 0.19 to 100.0 µmol L^{-1} (Fig. 3). The procedure presented a limit of detection (LOD) and quantification of 0.046 and 0.156 µmol L^{-1}, respectively, and R^2 of 0.998. The determination of paracetamol in struvite and urine samples indicated that the concentration of the drug is below of LOD in both. The recovery tests in different matrices showed values between 92 and 106%, indicating that there is no matrix effect. Based on all of these results, the proposed procedure proved to be effective, simple, fast and a sustainable alternative to promote green chemistry in the determination of paracetamol in urine and struvite.

Electrochemical processes are a promising alternative to convert electricity into chemical energy, thereby contributing to the development of an economy propelled by sustainable energy. The rational improvement of such processes requires in-depth, atomic-scale understanding of the reaction mechanisms and the factors influencing the reaction performance [1], which can be obtained with the help of DFT studies. However, countless electrocatalytic reactions occur in aqueous media where adsorbates and water molecules interact through hydrogen bonds, which are not fully captured by calculations in vacuum. Explicit inclusion of the solvent, in terms of accuracy, is probably the best way to incorporate solvation effects, but its high computational cost makes it unsuitable for mechanistic studies of complex reactions [1, 2]. Conversely, implicit solvation models are practical, and generally inexpensive, however their description of hydrogen bonding is still insufficient in general [3]. Therefore, an alternative approximation is the addition of ad hoc solvation corrections, computed as the difference between the adsorption energies with and without the solvent. In previous DFT-based studies, ad hoc corrections were reported for R-OH adsorbates, either on Cu(111) or Pt(111), with magnitudes from −0.1 to −0.6 eV [4, 5]. Nevertheless, recent works have shown that these corrections may significantly change from one material to the next, introducing errors in the predictions of adsorption energies, reaction pathways, and overpotentials obtained from simulations in vacuum [6].

Here we will introduce a simple and affordable micro-solvation method to estimate the solvation contributions to the adsorption energies [2]. Within this method, an adsorbate-water hydrogen bond occurs when it leads to a more stable energetic state, so that water-adsorbate and water-water interactions are weighed. The method determines the number of water molecules in the first solvation shell of each adsorbate, and the energetic stabilization granted by adsorbate-water hydrogen bonds. The CO_2RR on Cu in aqueous media was used to develop and test the method, and the analysis was extended to Ag, Au and Zn electrodes. Applying the calculated solvation corrections, we find good agreement with experiments in the calculated pathways and onset potentials, with an average error of only 0.07 V. The results obtained on (111) surfaces can be used as ad hoc corrections on other facets of the same metal.

Formation of Singlet Oxygen in the Oxygen Reduction Reaction in LiTFSI-DMSO in Lithium Oxygen Battery Cathodes

D. Córdoba, H.B. Rodríguez, E.J. Calvo
INQUIMAE. Universidad de Buenos Aires, Pabellón 2, Ciudad Universitaria,
Bueos Aires, Argentina
calvo@qi.fcen.uba.ar

The formation of singlet oxygen, $^1O_2$, during the O_2 electroreduction reaction on carbon electrodes in lithium bis-(trifluorometilsulfonyl) imide (LiTFSI) in dimetilsulfoxide (DMSO) has been detected “in-operando” by 9,10-dimetil anthracene, (DMA) fluorescence quenching.

The formation of $^1O_2$ during the oxygen electroreduction (ORR) requires Li^+ ions while in the presence of sodium azide, a specific physical quencher of $^1O_2$, the flurescence quenching of DMA is negligible. The addition of Li^+ ions to a superoxide solution in DMSO stabilized by tetrabutylammonium bis-(tri-fluorometilsulfonyl) imide increases the fluorescence decay of DMA, which is a proof of $^1O_2$ formation during superoxide radical anion bimolecular disproportionation:[1]

$$LiO_2^{\cdot} + LiO_2^{\cdot} \rightarrow Li_2O_2 + {}^1O_2$$

The discharge and charge of Li-O_2 batteries under long term operation to deep discharge in repetitive cycles, in the presence of sodium azide in the electrolyte resulted in full charge recovery below 4.3 V vs. Li^+(DMSO) and increased capacity, unlike batteries cycled under similar conditions but in the absence of azide in the electrolyte, where the charge is not recovered. Note that 4.3 V is the stability anodic limit of the solvent DMSO.[2]

Kraft black liquor (BL) is a complex solution mainly composed by inorganic salts used in the pulp cooking process (e.g., NaOH, $NaCO_3$, Na_2SO_4, Na_2S), sugars, hemicellulose, and lignin [1]. Due to its complexity, BL electrochemical behavior is still misunderstood despite the efforts of the scientific community [2–4]. Understanding BL electrochemical processes can be an important advance in the topic of industrial wastewater/environmental electrochemistry. As a result, the electrolysis of this by-product has been significantly explored in the last 5 years and is becoming a promising alternative to process the excess of produced BL [5–7].

Considering that, this work aims to analyze by voltammetric techniques (i.e., by cyclic voltammetry, CV, and linear scan voltammetry, LSV) the behavior of artificial solutions containing the main components of the BL. The initial solution is composed exclusively by KOH + NaOH, being the other inorganic salts gradually added according to the following order: Na_2CO_3 + K_2CO_3, K_2SO_4 + Na_2SO_4, Na_2S. After each addition, CVs and LSVs of this BL artificial solution are recorded using a commercial Pt electrode. Then, lignin is finally added (considering its original concentration in real BL) to the final solution containing all the inorganic salts and the electrochemical behavior of this artificial BL is analyzed. The study is done using acid precipitated lignin and LignoBoost lignin, in order to identify electrochemical differences between them. Finally, the effect of lignin concentration in the voltammetric behavior of the artificial BL is analyzed. All results are critically discussed and compared with the literature to clarify the most important BL electrochemical processes.

The main goal of this work was the development of an electroanalytical procedure for the determination of folic acid in bread samples using dental amalgam electrode (DAE) and square wave voltammetric (SWV) technique. Preliminary, electronegativity tests were performed in Britton-Robinson (BR) with pH values around to ionization constants of folic acid (pK_a), pH 2.50 and 8.00, which indicated that in the acid medium the redox reaction is more favourable. So, BR and oxalic acid/oxalate buffer in pH 2.50 were individually evaluated and voltammetric responses indicated that in oxalic acid/oxalate buffer the peak potential (E_p) and current intensity (I_p) presented more favourable values, and for this, the pH values of acid/oxalate buffer were changed to 2.00 from 5.00. The voltammetric responses indicated that I_p increased up until the pH 3.00 without loss in voltammetric profile and E_p presented none relationship with the pH, indicating that the protonation is not the step determinant in reaction kinetics. This way, the pH 3.00 were chosen, presenting two well-defined voltammetric peaks, in -0.50 V and -0.84 V *vs* Ag/AgCl 3.0 mol L^{-1}.

SWV parameters were evaluated using pulse amplitude (*a*) from 5 to 50 mV, pulse potential frequency (*f*) from 10 to 250 s^{-1} and scan potential increment (ΔE_s) from 2 to 10 mV. Voltammetric responses indicated that best voltammetric signals were observed using a = 50 mV, f = 250 s^{-1} and ΔE_s = 2 mV. Besides, analysis of E_p and I_p using different *f* values indicated that the electrons transfer occur quickly and following a redox reaction controlled by diffusion rate. Thus, the relationships between E_p and logarithm of *f* values, called as Lovric's Equation, enabled the calculous of electrons number and offers a possible redox mechanism that probably involves the reduction of the group C=N in the main heterocyclic ring, that was previously protonated, following a fast electron transfer with coupled reactions involving an intermediary chemical specie.

Analytical parameters (linear range, linearity coefficient, detection and quantification limits, precision, accuracy and robustness) were evaluated using analytical and recovery curves built using 70 and 250 s^{-1} as *f* parameter, as shown in Table 1. The linearity coefficient (r) value demonstrated good linearity, detection and quantification limits (DL and QL, respectively) were lower than the concentration expected in the bread samples. The precision of methodology was evaluated by repeatability and reproducibility and indicated suitable values, coupled to an adequate recovery efficiency values, indicating that the proposed methodology using DAE and SWV is proper for folic acid determination. All analytical parameters were compared to similar data obtained using the high-performance liquid chromatography with diode array detection (HPLC-DAD), using a precolumn and a column C18, a mobile phase constituted by 0.1 mol L^{-1} of the acetic acid solution and acetonitrile that had a flow rate of 0.6 mL/minute at a temperature of 40°C and an elution gradient with organic phase changing from of the 10 to 24%.

Parameters	***f*** **= 70 s^{-1}**	***f*** **= 250 s^{-1}**	**HPLC-DAD**
LR (μmol L^{-1})	0.1000 – 10.00	0.01000 – 5.000	0.5000 – 5.000
r	0.9955	0.9965	0.9978
DL (mol L^{-1})	$1.202 x 10^{-06}$	$1.726 x 10^{-08}$	$20.299 x 10^{-6}$
QL (mol L^{-1})	$3.641 x 10^{-06}$	$5.2291 x 10^{-08}$	$61.512 x 10^{-6}$
Repeatability (%)	4.73	4.49	-
Reproducibility (%)	5.96	5.07	-
Recovery (%)	93	103	-

Table 1: Analytical parameters for the determination of folic acid in pure electrolyte on DAE, where LR is the linearity range, r is the correlation coefficient, DL and QL are detection and quantification limit, respectively.

The proposed methodology using DAE and SWV was applied in 27 bread samples, which were previously pretreated according to literature reports. The voltammetric data permitted the folic acid quantification in bread samples prepared using different baking temperature and various steam during the process of bread production, permitting the evaluation of the availability of folic acid in commercial bread. So, the proposed methodology presented as an alternative environmentally friendly to the folic acid determination.

Electrodeposition of Germanium Antimony Telluride Microarrays from a Weakly Coordinating, Non-aqueous Electrolyte

L. Meng[1], Y. J. Noori[2], G. P. Kissling[1], R Huang[2], W. Zhang[1], C.H. (Kees) de Groot[2], G. Reid[1], A. Hector[1], D. Smith[3], P.N. Bartlett[1]

L.meng@soton.ac.uk

Electrodeposition provides a bottom-up technique compared to conventional coating methods, such as physical vapor deposition (PVD). It is of advantage in the efficient use of the starting material and can be used to plate curved surfaces and even inside of topologically demanding surfaces.

Aqueous electryolytes are commonly used solvent in electrochemical deposition, however, it suffers from narrow deposition potential window which makes water reduction a competing process vs high potential metal reduction/deposition, adding major complexities to experiments. Here we employ an electrolyte system based on tetrabutylammonium chlorometallate metal sources with compatible tetraalkyl halide supporting electrolytes in non-aqueous, weakly coordinating solvents, which provides the ability to deposit alloys with desired structures and properties at high potentials [1, 2].

In this work we report the deposition of germanium antimony telluride (GST) into microstructured TiN arrays from dichloromethane. We present how adjusting the concentrations of the chlorometallates allows control over the composition and also the morphology of the deposits (Figure 1). We also highlight the composition variation of GST deposits in the microarray structures and the design of experiment to minimize the convection effect causing the composition variation.

This work is conducted as part of the ADEPT project funded by EPSRC (EP/N035437/1).

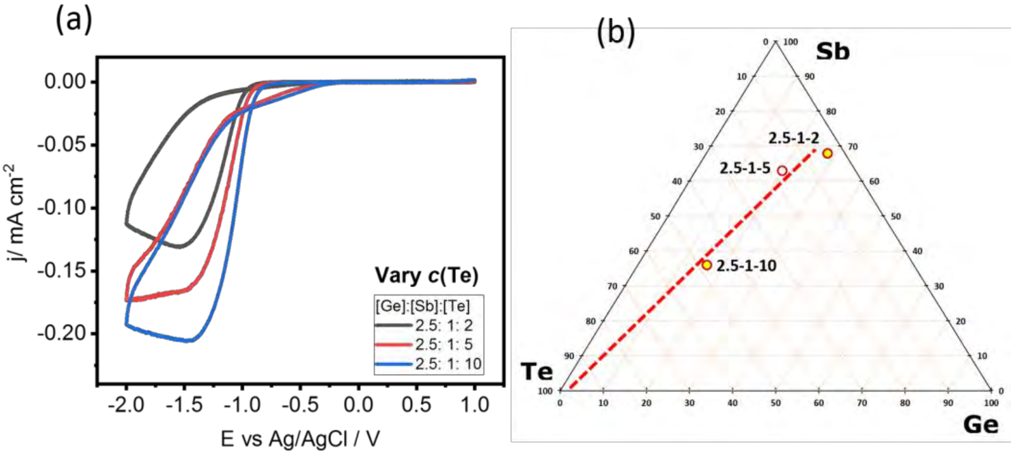

Figure 1: (a) Cyclic voltammetry of 2.5 mM $[NBu^n_4][GeCl_5]$, 1 mM $[NBu^n_4][SbCl_4]$ and a range of $[NBu^n_4]_2[TeCl_6]$ conventrations (black: 2 mM, red: 5 mM and blue: 10 mM) in 0.1 M $[NBu^n_4]Cl$ in CH_2Cl_2 measured at a scan rate of 50 mV s^{-1}. (b) Change in the composition of electrodeposited GST microarrays as a function of the precursor concentration in the plating bath represented as composition triangles.

Understanding the complex mechanism of the electrochemical oxidation of kraft black liquor (BL) is something that requires the combination of different techniques. Conventional electrochemical techniques, such as voltammetry, chronoamperometry, and chronopotentiometry have been already employed in the electrochemical characterization of BL [1-4]. These results allowed the collection of relevant kinetic parameters but do not provide enough information to elaborate a more detailed oxidation mechanism. In order to get additional data on the BL oxidation mechanism, this work involves rotating ring disk electrode (RRDE) studies in real industrial weak BL samples.

The employed RRDE system (Pt ring/Pt disk and Pt ring/Au disk) was used to identify the presence of intermediates and to verify the reversibility of the electrochemical reaction. For that, the Pt ring electrode was maintained at a fixed potential (ranging from 200 mV below OCP to 500 mV above the OCP) while linear scan voltammetry (LSV) was run at the disk. A potential scan rate of 10 mV s^{-1} and rotation of 1200 rpm were applied for all the experiments. The effect of the temperature (25 – 65 ºC) in the electrochemical response was also analyzed. To the best of our knowledge, this is the first black liquor RRDE study that has been reported so far.

Lithium ion-batteries (LIBs) are a widely employed option in the energy storage field for mobile devices (cellphones, electric vehicles, etc.) due to their capacity and power characteristics, and above all their stable cycling. Apart from all the knowledge in the cathode and anode material and electrolyte composition, other important aspect for an optimal operation is the charging protocol. A broad list of charging techniques has been reported[1], but the standard one is a Constant Current-Constant Voltage (CC-CV) protocol.

In this work a new charging methodology is presented. This consist on two steps, firstly a pulsed current period, followed by a pulsed voltage period. Pulsed parameters have the advantage that allows the system to change the diffusional stress in the interface[2]. As innovation, the proposed method applies current and voltage values that oscillate according to a square pulse around a central value without reaching null values.

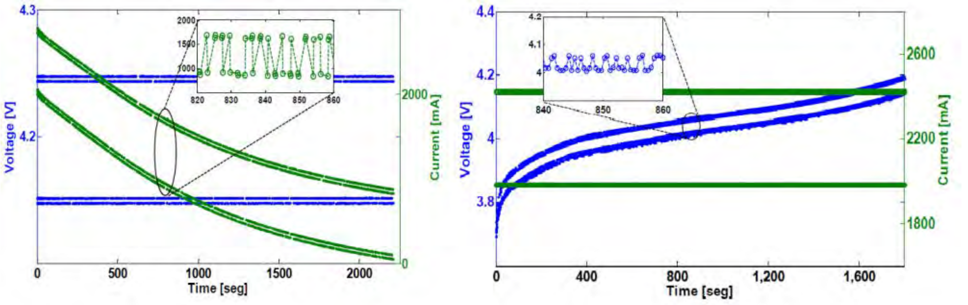

Figure 1: Current (left) and voltage (right) response of a 18650 LIB under voltage pulsed and current pulsed respectively.

The experiments were carried on 18650 LIBs and the protocol was repeated several times to exhibit its impact on the cell capacity over its cycling. The pulse amplitude and frequency of both section was varied to see its impact on the learning curves.

Host-Guest inclusion systems have aroused widespread interest, since they play important roles in molecular recognition, particularly in sensor devices. A class of host molecules that has often been used in sensing applications is that of the cyclodextrins, cyclic oligosaccharides that consist of six (α-cyclodextrin), seven (β-cyclodextrin, β-CD), or eight (γ-cyclodextrin) glucose moieties [1]. Depending on the cavity size, cyclodextrins have shown a selective affinity to a wide variety of molecules. For instance, in a previous work, we succeeded to demonstrate the affinity of cyclodextrins for o-toluidine, a toxic water pollutant [2].

Various functional composites based on β-CD have been developed in the Literature. Particularly, Organic-Metal oxides nanocomposites have emerged as an outstanding surface modifier for sensors construction. However, the composite concept can even go beyond this approach by combining electroactive and fluorescent nanomaterials for the creation of a dual-mode sensing device.

Based on this, a novel system based on Graphene Quantum Dots GQDs@Benzoquinone@β-cyclodextrin as a host guest capturing probe was proposed. In this approach, EDC/NHS chemistry was used to covalently immobilize benzoquinone, the electroactive probe, via a cysteamine spacer on graphene quantum dots. Finally, β-cyclodextrin was added via a reductive amination. The optical properties of the synthesized GQDs were studied using UV-vis and PL spectroscopy. Structural and morphological characterizations were examined by the Transmission Electron Microscopy and Fourier-Transform InfraRed spectroscopy. Cyclic voltammetry, differential pulse voltammetry and electrochemical impedance spectroscopy were performed to investigate the surface modification at each step.

The system was firstly immobilized directly on glassy carbon electrode, then on fluorine tin oxide glass, bare or covered with a thin layer of Titania film, to test the possibility of a dual mode sensing. In fact, the capturing of the target molecule will be accompanied by a simultaneous substantial variation in the benzoquinone electrochemical signal and an evident fluorescence quenching of GQDs.

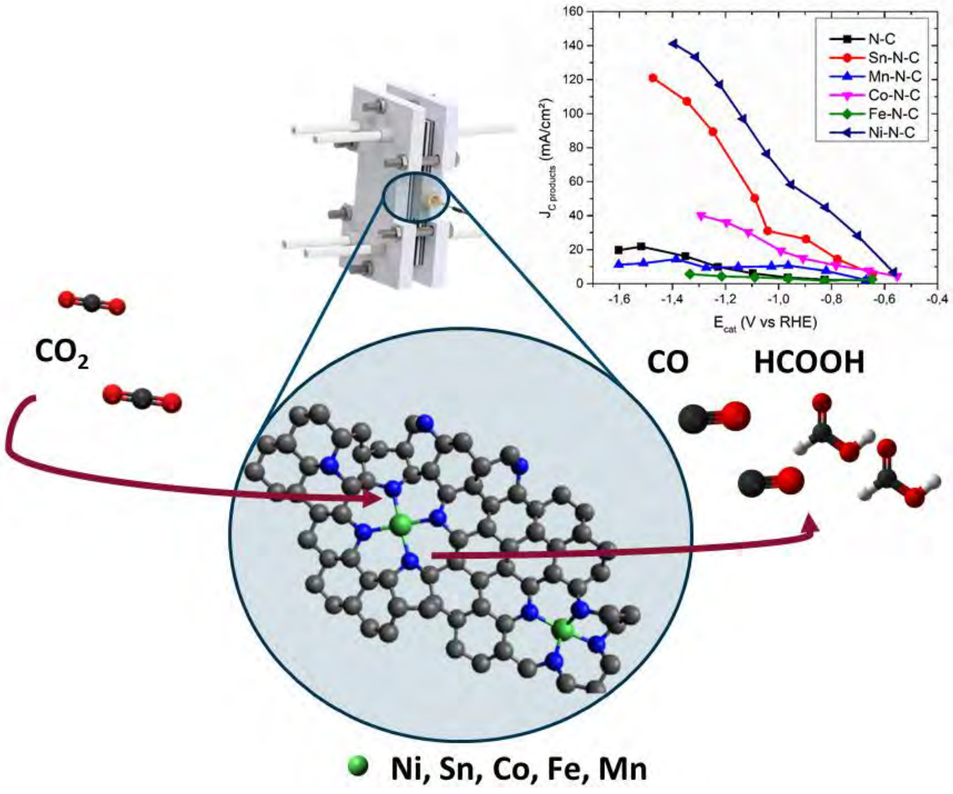
We report the synthesis and operation of various metal-nitrogen-doped carbons for the electrochemical reduction of carbon dioxide to carbon monoxide and/or formic acid as part of a mitigation and adaptation approach to increasing CO_2 atmospheric concentrations. For the first time different transition metals (i.e. Sn, Co, Fe, Mn and Ni) were embedded in nitrogen-doped carbons through an easily up-scalable and tunable method and its performance characterized in a continuous flow reactor at industrially relevant current densities up to 200 mA cm^{-2}. Moreover, changing the embedded transition metal allowed tuning the selectivity towards the desired product. A complete potential-productivity profile was established for CO and/or formic acid yielding better insights into the overall performance of all electrocatalysts. Mn-N-C and Fe-N-C performance was compromised by its high CO* binding energy, while Co-N-C gave way mostly to HER. Ni-N-C and Sn-N-C revealed to be competitive electrocatalysts, being the latter for the first time tested in a flow reactor at high current densities. A productivity of 589 L CO $m^{-2}h^{-1}$ at -1.39 V vs RHE with Ni-N-C and 456 L HCOOH $m^{-2}h^{-1}$ at -1.47 V vs RHE with Sn-N-C was achieved and no signs of degradation were detected after 24 hours of operation at industrially relevant current densities (100 mA cm^{-2}). Stable operation at 200 mA cm^{-2} led to turnover frequencies for the production of carbon products up to 5176 h^{-1}. This unprecedented analysis constitutes an essential step towards the scalability and ultimately towards the economical valorization of CO_2 electrolyzers using metal-containing nitrogen-doped catalysts.



Dental amalgam electrode as a voltammetric tool for triazine-based pesticides determination: application in natural water samples

Fernanda C. O. L.Martins[1] and Djenaine De Souza[2]

fernandacolm@hotmail.com and djenaine@gmail.com

The main goal of this work was the use of the dental amalgam electrode (DAE) allied to square wave voltammetry (SWV) in the analytical determination of the ametrine, atrazine and simazine in natural water. The experimental and voltammetric parameters were optimized in Brinton-Robinson buffer at pH 2.5, with a pulse amplitude of 50 mV, pulse frequency of 100 s^{-1}, and scan increment of -2 mV, and consequently, it was presented irreversible well-defined voltammetric peaks at -1.05 V, -0.97 V and -0.99 V *vs* Ag/AgCl 3.0 mol L^{-1} for ametrine, atrazine, and simazine respectively. Additionally, the SWV parameters evaluation indicated the redox reaction of the ametrine and simazine were controlled by diffusion rate, while, the atrazine was controlled by adsorption kinetic. Furthermore, Lovric's Equation enabled the calculation of the number of electrons of these reactions that were 2 electrons, and it made possible the verification of the mechanism of the three triazines, being that the ametrine was the reduction of bond carbon-SCH_3, already, the atrazine reduction of the bond carbon-chloride and the simazine was supposed that occurred atrazine like a mechanism, reducing of the bond of the carbon-chloride bond in the pyridinic ring.

Analytical curves were built for each triazine separately using the standard addition method in a linear range from 0.7500 to 10.00 µmol L^{-1}. All analytical parameters (linear range, determination coefficient, detection and quantification limits, precision and accuracy) were calculations, and are shown in Table 1. The data indicated a suitable linearity and adequate detection and quantification limits, which presented values lower than the maximum limits of residues permitted in natural water by Brazilian Environmental Agency, 100 µg L^{-1} (100 ppb) and near values obtained using the chromatographic techniques and other electrodic surfaces. The methodology precision was evaluated by repeatability and reproducibility experiments producing adequate values, while the accuracy was measured using recovery curves producing recovery values of 100.5, 100.2, 99.6 % to ametrine, atrazine and simazine, respectively.

Parameter	Ametrine	Atrazine	Simazine
LR (µmol L^{-1})	0.7500 – 10.00	0.7500 – 10.00	0.7500 – 10.00
r	0.9989	0.9952	0.9963
DL (mol L^{-1})	1.200×10^{-7} (27.28 µg L^{-1})	1.241×10^{-7} (26.77 µg L^{-1})	1.624×10^{-7} (32.75 µg L^{-1})
QL (mol L^{-1})	3.636×10^{-7} (82.66 µg L^{-1})	3.759×10^{-7} (81.07 µg L^{-1})	4.921×10^{-7} (99.24 µg L^{-1})
Repeatability (%)	2.13	4.25	4.75
Reproducibility (%)	2.58	3.56	2.62
Recovery (%)	100.5	100.2	99.6

Table 1: Analytical parameters for the determination of triazines in pure electrolyte on DAE, where LR is the linearity range, r is the correlation coefficient, S_b is the blank standard from reduction potential values of triazines, DL and QL are detection and quantification limit, respectively.

The proposed methodology was applied in the natural water from Paranaíba River, considering samples characterized by biochemical oxygen demand analysis, that indicated the presence of the 10.8 mg L^{-1}, 11.6 mg L^{-1} and 15.4 mg L^{-1} of total organic compounds considering the sample 1, sample 2 and sample 3, respectively, which are directly related to different levels of organic matter, including wastes from agricultural, industrial and urban activities.

1.0 mL of each sample was mixture with 9.0 mL of BR buffer pH 2.5 in an electrochemical cell and analytical curves and recovery curves were obtained by SWV experiments on the DAE. The inclination of the curves was influenced according to the organic composition, so, the increase of BOD values provided a proportional increase in the slope of the analytical curves, indicating that components interact with the triazines promoting an improvement in the analytical signals. The recovery curves also evaluate the interference of organic and inorganic compounds in the natural water sample, which presented values around to ones obtained in pure electrolyte showing that the sample did not interfere in the voltammetric signals. The methodology proposed was applied in the natural water sample without sample preparation step, showing its robustness. Furthermore, the DAE presented an alternative environmentally friendly to determination of triazines based pesticides.

Correlation between the electrochemical behavior and mechanical properties of Ti-20Zr as a candidate for orthopedic material

Nestor R. Florido Suarez, Pedro P. Socorro Perdomo, Amparo Verdú Vazquez, Julia C. Mirza Rosca
Processing Engineering Department, University of Las Palmas de Gran Canaria
Campus Universitario de Tafira, EIIC, 35017
nestor.florido@ulpgc.es

A combination of titanium with zirconium was evaluated because it has been suggested as a candidate for human body implant material and was primarily developed in response to concerns of potential cytotoxicity and adverse tissue reactions caused by vanadium and aluminum in the actually used biomaterial Ti6Al4V.

From all the metallic alloys used in prosthesis, probably the most used one is Ti-6Al-4V alloy. Titanium has poor mechanical strength [1] and when aluminium or vanadium are added to titanium in small quantities, the strength of the alloy is much increased over that of titanium [2]. Therefore, the Ti-6Al-4V alloy achieves considerably higher tensile properties than of pure titanium and this alloy is used in high stress-bearing situations. But Ti-6Al-4V has a potential cytotoxicity and adverse tissue reactions caused by vanadium [3].

Further studies have shown the release of both V and Al ions from the alloy might cause long-term health problems, such as peripheral neuropathy, osteomalacia and Alzheimer diseases.

The microstructure and microhardness were determinate; the tensile strength and electrochemical behavior were evaluated. Titanium is an allotropic element and this mean that exists in more than one crystallographic form. At room temperature has a hexagonal close-packed (hcp) crystal structure, which is referred to as 'alpha' phase. At 883ºC (1621 ºF) this structure transforms to a body-centred cubic (bcc) called 'beta' phase.

The Ti-20Zr alloy, composed of 80% Titanium and 20% Zirconium, (from R&D CS Bucharest, Romania – Research &Development Consulting and Services) was obtained by vacuum melting.

From metallographical images can be observed that the sample has an alpha-beta structure. The microhardness measurements concluded that the alloy formed a hard layer on its surface which greatly improves the wear resistance. The obtained tensile strength can be considered good in relation with other similar implant materials.

The impedance spectra were fitted with two time constants equivalent circuit and the fitting parameters indicate long-term stability of the passive layers in surgical implant conditions.

The results were confirmed by mechanical approach, in terms of two-layer model of the oxide film, consisting of a thin barrier type inner layer and a porous outer layer. The pronounced porous outer layer is expected to facilitate the incorporation of mineral ions and to improve the resistance to electrochemical corrosion over the potential of relevance for human body conditions.

The hardness of Ti-20Zr alloy is 20% higher than that of commercially pure Ti, confirming the alloy's superior mechanical strength.

Post-lithium metal-ion battery technologies based on Na^+, K^+, Mg^{2+} and Ca^{2+} – ions are attracting more and more attention from the battery community. Recently, the possibility of employing proton-intercalating materials for energy storage applications has been investigated due to the low cost of the materials, environmental friendliness of aqueous solutions and exceedingly high transport rates of protons.[1] Prussian Blue Analogues (PBAs) have been acknowledged as prospective electrode materials for both sodium-ion and potassium-ion batteries due to high diffusivities of Na^+ and K^+ cations, which are achieved due to the presence of large 3d-channels in PBA structures.[2] PBAs can also be considered as suitable materials for proton-intercalation batteries due to the hydrogen bond networks in the structures of hydrated PBAs, which could provide exceptionally high proton transport rates via Grotthuss-type mechanisms. Yet, PBAs exhibit different structures and different phase-transformation patterns[3] depending on the amount of water and intercalated alkali ions in the as-synthesized materials, which calls for the investigation of the effect of the PBA structure type and hydration level on the mobilities of charge-compensating species.

In this work, we focus on comparing potassium-ion and hydroxonium diffusivities in nickel hexacyanoferrate structures. The electrochemical behavior of the PBA cathode materials with the compositions $Ni_{1.5}[Fe(CN)_6]\cdot 6.9H_2O$ and $K_2Ni[Fe(CN)_6]\cdot 1.6H_2O$ was investigated with respect to their charge storage properties in aqueous solutions containing K^+ and H_3O^+ as charge compensating cations. The diffusion coefficients and charge transfer resistances were estimated based on chronoamperometry and electrochemical impedance spectroscopy data. Complementary information on the mechanism of redox transformations of PBA materials in aqueous solutions was obtained based on IR spectroscopy and electrochemical quartz crystal microbalance measurements. Our results indicate that the rates of diffusional transport of cations in nickel hexacyanoferrate structures are strongly dependent on the PBA water content. The presence of a hydrogen bond network in the PBA structure leads to an increase in the proton transport rates and slows down the transport of potassium cations.

Iron porphyrins FeP are of high interest in electrocatalysts developing for the oxygen reduction reaction (ORR) in replacement to Pt, which is the best catalyst for ORR but too expensive and ambiently scarce[1,2]. The technological applications require immobilizing FeP on the surface. Many alternatives have been explored to bring FeP to substrate surfaces resulting in different orientations[2,3,4], interaction with the substrate (Van der Walls or covalent bounding), and chemical nature, etc. All these final structures of the FeP on a substrate would affect the ORR performance and this should be taken into account [5].

In this work, we will present the influence on the ORR of the final orientation of 5,10,15,20-Tetrakis(4-phenyl) iron(III) porphyrin (FeTPP) on Au surfaces achieved by immobilization of FeTPP to the surface by two different preparation methods. One method uses *physical vapor deposition* of FeTPP on ultra-high vacuum (UHV) conditions which creates self-assembly monolayers of FeTPP lying flat on the surface (Figure 1.a). A second method consists in *electrografting* of the diazonium salt of the FeTPP in presence of an excess of the radical scavenger, 2,2-diphenyl-1-picrylhydrazil (DPPP) in order to favor monolayer grown, followed by metalation in solution. This second method creates monolayers of FeTPP orientated quasi perpendicular to the surfaces (figure 1.b). Both parallel and perpendicular configurations have been characterized by atomic force microscopy (AFM), scanning tunnel microscopy (STM), X-ray photoelectron spectroscopy (XPS) and electrochemical quartz crystal microbalance (EQCM). Finally, the influence of the orientation and chemical nature of the FeTPP monolayer on the ORR performance has been evaluated by lineal scan voltammetry (LSV) in alkaline solution.

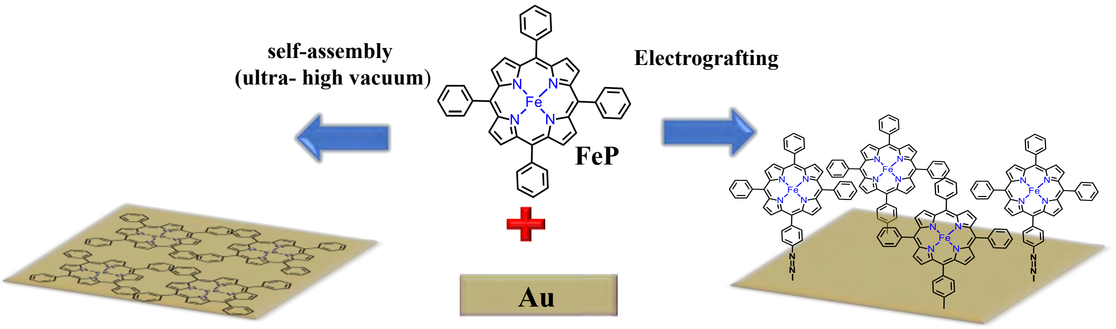

Figure 1. Monolayers of FeTPP obtained on gold surfaces by (a) physical vapor deposition on ultra-high vacuum and (b) electrografting via radical scavenger technique followed by metallization in solution.

The oscillatory electrodissolution of nickel is one among several reactions utilized as a model-system to study the emergence of oscillations and pattern formation in electrochemical interfaces, in addition to frequently providing experimental proofs for theoretical predictions in synchronization engineering. The reaction was modeled in 1992 by Haim and co-workers[1] and since then the model has been used with great success. Although some numerical studies have been done in this regard, there is still no detailed investigation of the effect of control parameters on the complex dynamics of nickel dissolution. Here, we provide a well-detailed and rigorous analysis of the effect of the external resistance and applied potential by simulating high-resolution phase diagrams based on the calculation of Lyapunov exponents and morphological periods (also known as isospikes[2]) of the time-series. Our findings clearly indicate a strong dependence of the self-similar periodic islands, the so-called "shrimps",[3] with the control parameters. Overall, we observed a low shrimp density in the phase diagrams being completely suppressed in large values of resistance and potential. The shrimp-like structures become gradually elongated with an increase of the control parameters to the point where only diagonally aligned periodic bands intertwined with chaotic domains are present. Interestingly, period-doubling cascades were observed not only on the shrimps but also on the periodic bands. Some of these particularities found in the oscillatory electrodissolution of nickel may be attributed to the exponential dependence of Butler-Volmer kinetics on differential equations.

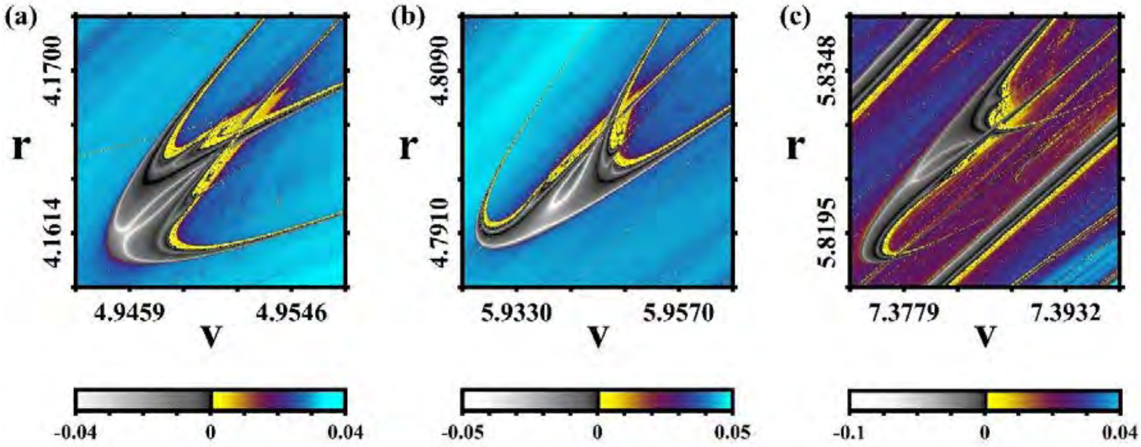

Figure 1 – Lyapunov diagram in the (r, v) control space indicating chaotic and periodic regions for three different ranges of resistance and potential: (a) low, (b) intermediate and (c) high values. Chaos is marked by yellow-cyan scale and periodicity is denoted by white-black one.

Probing Speciation and its Applicability to Concentrated Electrolyte Transport Modelling

Andrew A. Wang, Charles W. Monroe
Department of Engineering Science, University of Oxford
Oxford, United Kingdom
andrew.wang@eng.ox.ac.uk

Speciation in concentrated electrolytes has been demonstrated to occur due to coordination between solvents, cations, and anions [1]. Interactions between species such as ion pairs impact the transport laws governing diffusion, migration, and convection. To model how composition and potential gradients develop across a concentrated electrolyte, one may need to account for the equilibria between different molecular structures.

The dynamics of ion-pair formation and salt association/dissociation kinetics both can impact the availability of charge-carrying species in an electrolyte. Experimentally, transport and thermodynamic measurements present indicators for ion-pairing, while spectroscopic techniques can further quantify extent of dissociation. Transport phenomena relating to solute and solvent structure, such as Faradaic convection and the excluded-volume effect, can also become dominant in the super-concentrated regime [2]. In very concentrated electrolytes convection can be important because when the salt occupies a large volume fraction of the solution, salt flux across the boundary of a solution drives a bulk solution velocity through overall mass continuity. Faradaic convection can be quantified by combining densitometry with electrochemical measurements.

Newman's application of Onsager–Stefan–Maxwell theory to electrochemical transport considers solute/solute interactions neglected in Nernst–Planck dilute solution theory [3]. The distinction between higher-order species in models may be necessitated by the timescales relevant to bulk transport and ion-pairing dynamics. We will discuss how solute-volume effects and ion-association equilibria influence apparent flux-explicit transport properties such as conductivity, diffusivity and transference number [4].

The most commonly used titanium alloy is Ti6Al4V but further studies have shown that the release of both V and Al ions might cause long-term health problems [1,2]. In response to these health problems, new Ti alloys have been developed and among them, titanium-tantalum alloys are expected to become promising candidates for medical applications due firstly to tantalum which is a non-toxic element and secondly due to their better compatibility with bone tissue compared with Ti and Ti6Al4V [3].

The aim of this study is to investigate the influence of tantalum concentration on the behaviour of different bioactive Ti-Ta alloys as biomaterials for medical applications. Three kinds of binary Ti-Ta alloys with 5%,15% and 25% mass tantalum with a surface modification treatment consisting of immersing the samples in hot concentrated NaOH followed by washing with distilled water and dried at 40ºC during 24 hours.

The microstructure of the Ti-Ta alloys was observed by metallographic technique and by scanning tunnelling microscopy (STM).

Were analysed using various roughness parameters such as: arithmetic mean roughness (Ra), maximum height (Ry) and 10-point mean roughness (Rz).

Ti25Ta alloy with lower surface roughness experienced less corrosion when compared to the specimens with higher surface roughness values.

The differences in the hardness and depth of passive layer concerned mostly with bioactive treatment and the concentration of tantalum in the alloy.

Analysis of the impedance spectra was done by fitting these data to the equivalent circuit proposed in Fig.1. The components of the circuit take into account the electrolytic resistance, the resistance and the capacitance of the passive layer, the double layer capacitance and the charge transfer resistance (the model of the surface is presented in Fig.2).

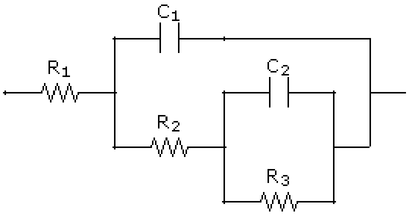

Fig. 1. Equivalent circuit used for fitting the experimental data of EIS

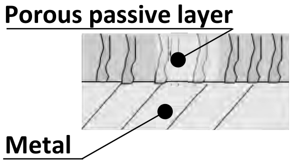

Fig. 2. The model proposed for passive layer formed on the surface of bioactive alloys.

Among studied Ti-Ta alloys, the Ti-25Ta exhibits after chemical treatment, superior properties of the passive film and corrosion behaviour, therefore it appears to be a promising candidate for novel biomaterials. Further experiments are needed to quantify the influence of tantalum content on biocompatibility and cell growth on nanostructurated bioactive Ti-Ta alloys.

Nanostructurated bioactive surface of Ti-Ta alloys for medical devices

Increasing the Osseoinduction of Ti6Al7Nb Tibia Implant by Surface Treatment and “in vivo” Application

Julia C. Mirza Rosca[1], Nestor R. Florido Suarez[2], Pedro P.Socorro Perdomo[1] , Tomas Gil López[3]
[1]Mechanical Eng.Dept., University of Las Palmas de Gran Canaria,35017, SPAIN
julia.mirza@ulpgc.es

Animals such as rats, guinea pigs, rabbits, dogs, sheep, goats, pigs and others with a relatively long life expectancy are suitable for long-term testing of subcutaneous tissues, bones and muscles. Pigs are one of the preferred species as they have organs and osseointegration times similar to humans and this is one of the main reasons why the minipig has been chosen as an experimental animal in our study, mainly focused on analyzing the behavior "in vivo" of a titanium alloy plate Ti6Al7Nb with nanostructured surface, from the point of view of its osseointegration and its toxicity.

A micro-nanocrystalline hydroxyapatite coating on the bioactivated surface has been deposited in two steps: immersion in NaOH solution plus heat treatment and immersion in SBF solution with additional biovitroceramic PAW1 content

.

The importance of the mechanical stability of the implant is evaluated by analyzing the quality of the osseointegration at the bone-implant interface through the analysis of the amount of neoformed bone in direct contact with the implant, able to mechanically fix the implant and the type of bone tissue that is formed.

In this study, the implant was designed so that implantation is simple and as minimally invasive as possible, in the tibia (Fig.1), ensuring optimal bone-implant contact as well as load transmission (bone growth induction).

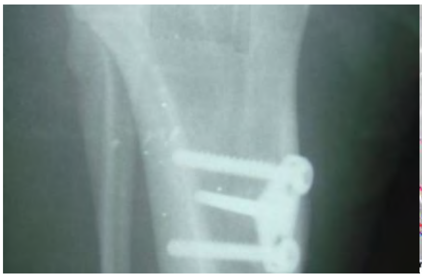

Fig.1. Radiography of the implant

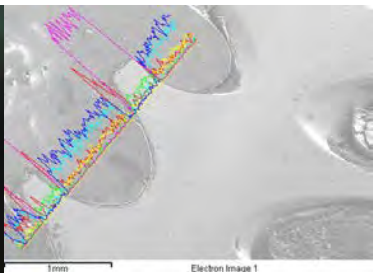

Fig.2. Metal-implant interface analysis

The implantation period has been 6 months and during the healing period the contact between the bone and the implant of each operated pig has been guaranteed, no signs of inflammation have been observed. The toxicity of the implanted metal plate was evaluated by determining the concentration of aluminium by atomic absorption in the different organs of the experimental animals.

Analysis by scanning electron microscope and EDX analyzer of the bone-implant interface of the samples indicates that there is no presence of potentially toxic elements (aluminum) belonging to the implant, results confirmed by electrochemical tests obtained in vitro before implantation.

The study of the bone-implant interface (Fig.2) of the samples from the experimental animals shows that elements belonging to the mineral part of the bone tissue (calcium, phosphorus) have been found. The average of the results obtained from the Ca/P ratio that have been analyzed for each animal allow us to confirm that there is bone growth.

Studies using the atomic absorption spectropy technique indicate that the proportion of aluminium that can affect humans due to the diffusion of this element when wearing an implant is insignificant and cannot be considered harmful compared to daily consumption through food intake or other factors.

Bioenergy generation from glycerol in an MFC using a mixed culture of microorganisms

Gisele Giovanna Halfeld[a], Erica Janaina Rodrigues de Almeida[a], Valeria Reginatto Spiller[a], Adalgisa Rodrigues de Andrade[a,b]

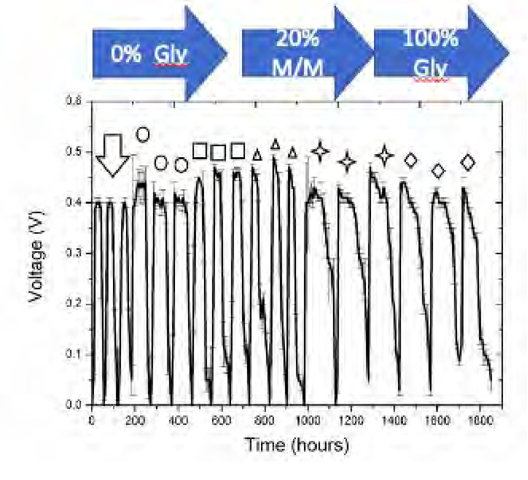
gihalfeld@usp.br

The use of microorganisms immobilized onto the surface of electrodes in MFC devises can be employed to generate efficient electrical energy. In addition, the low environmental impact and variety of fuels and oxidants must be considerate. Recently, we have concentrated our goal to the develop anaerobic degradation of glycerol to produce energy. This may be important to alternative glycerol treatment plus product valorization to overcome the surplus of this fuel. We will report the energy generation of energy employing pure glycerol in an air-breathing MFC with an anaerobic anode compartment (30 mL). The anode (carbon fiber brush - Research Laboratory Shop/China) with 3 x 2 cm was connected with cathode ((HT1400W, ELAT® GDL–BASF) across the external resistance of 1 KU. A mixture culture of microorganisms from a lagoon of Mina Gerais state/Brazil was Inoculated (10 days) in a proper medium [1]. In order to obtain a stable microorganism's films continuous acclimation of glycerol was done by replacement gradually acetate from glycerol (fractions of 20% w/w). We started initially with1.0 g L-1 of acetate until the total replacement of the carbon source for glycerol (1.0 g/L). As can be seen in the figure replacement of acetate for glycerol increases more than 2 times (144 h) the operational cycle of the MFC plus furnishing an increase in the power output (440 mV ± 0.1 or 12.57 mA m-2). These results are higher compared with the ones found in the literature. A good stability of glycerol MFC was obtained in the different feeding cycles investigated. The maximum power density obtained for MFC was 7.7 mW m^{-2} and the maximum current was 25.8 mA m-2. HPLC data showed that the fuel is fast metabolized by the microorganism and the main product at the end of the feeding cycle is propanediol.



Our results showed that glycerol is a suitable and promising substrate for power generation, using a simple two-chamber MFC even at high glycerol concentrations. SEM images showed the formation of the biofilm, predominantly with the rod-shaped. The formation of nanowires was also detected in a large extend.

Lithium-sulfur batteries are considered as the optimal second-generation commercial battery due to their high theoretical energy density of 2600 Wh kg $^{-1}$ and ~~a high specific~~ a high theoretical specific capacity of 1675 mAh g $^{-1}$, the natural abundance of sulfur~~its natural abundance~~, it's low cost and environmental friendliness [1]. However, Li-S batteries suffer from different problems, such as the insulating nature of sulfur, the change of volume of the active material and the loss of active sulfur material during repeated charge/discharge cycling. Upon lithiation of sulfur, higher-order lithium polysulfides ($Li_2 S_x$ (x =4, 6, and 8)) are generated that are highly soluble in the liquid electrolytes and shuttle across the separator causing low charge/discharge efficiency and corrosion of the lithium anode. This effect produces low utilization of the active material and capacity fades. Another fact that makes Li-S batteries non-~~-~~commerciable until today is the uncontrollable electrodeposition of insulating Li_2S_2 /Li_2S that blocks ion/electron diffusion and decreases the utilization of sulfur [2].~~-~~ To ~~-~~overcome ~~-~~these ~~-~~issues, there ~~are differen t~~are ~~approaches~~different approaches, ~~such~~, ~~as~~such as, ~~incorporation,~~ incorporation of conductive matrices and adsorbent agents in the cathode, optimization of new electrolytes, modification of the separator to reduce the shuttle effect, protection of lithium anode with polymers, among others. ~~But~~However, despite the obtained advances in inhibiting the shuttle effect, ~~it's~~it is worth noting that the nucleation and growth of Li_2S_2/Li_2S is still uncontrolled during the discharge process, which leads to large insoluble Li_2S_2 /Li_2S aggregates.~~-~~ Considering this fact, catalyzing the reduction of long-chain polysulfides to Li_2S_2 /Li_2S and enhancing the reaction kinetics have proven to be valid ways to solve the shuttle effect and improve the rate performance of Li-S batteries. Recently, a series of functional composite interlayers have been systematically investigated to identify the key parameters that determine their role in improving the performance of Li/S batteries. It is well known that trialkyl phosphines have the property of selectively reducing~~e~~ disulfide bonds. Recent~~ly~~ experimental works use the commercially available organophosphorus tris(2- carboxyethyl)phosphine hydrochloride (TCEP) taking advantage of its effect in disrupting disulfide bonds in various proteins [3] to catalyze the cleavage of –S–S– in polysulfides. In the present work, we perform density functional calculations using SIESTA [4] ~~with the aim of understanding~~to understand the specific working principle of TCEP in lithium-sulfur batteries. In this regard, we have performed studies of the interaction of long-~~-~~chain polysulfides with TCEP and studied the TCEP-assisted polysulfide reduction reaction by Nudged elastic band calculations [5]. The reaction steps for TCEP to reduce the polysulfide chains, including the intermediate product of each reduction step (i.e. cleavage site of polysulfides) are elucidated in this work.

The electrocatalytic reduction of CO_2 is a captivating strategy for the conversion of CO_2 into fuels, to realize a close loop for carbon footprinting. The research has focused on the development of new materials and technology capable of capturing and converting CO_2 into useful products.[1] Among all reduction products, formic acid is particularly attractive for its high volumetric hydrogen density, low toxicity and liquid state, that make it a valuable hydrogen storage vector.

The design of new electrocatalysts that reduce CO_2 in a selective and efficient fashion is a key step for future exploitation of this technology.

Here we present how the combination of different building blocks in a single nanostructure might be a good strategy to achieve a good selectivity in the CO_2 reduction process.

Combining the unique physico-chemical properties of functionalized nanomaterials (such as carbon nanotubes and carbon nanohorns) and nanocrystalline cerium dioxide (CeO_2) we revealed faradaic efficiency for formic acid production as high as 55% at an overpotential as low as 0.02V in acid solutions. These performances have been possible by the formation of partially reduced ceria ($Ce^{4+/3+}O_{2-x}$) responsible of an increased CO_2 adsorption and a more efficient electron transfer at the surface.[2] In the nanocomposite, the carbon nanostructures don't just act as a support, but they counteract the insulating effect of oxide nanoparticles and promote the generation of Ce^{3+} sites. Their elevated surface area and high electrical conductivity guarantee a greater process efficiency.[3] In particular, the nanohorns have a unique conical geometric, where the nano-tips terminals act as "electron collector", increasing the charge mobility.[4]

The interconnection of the various components has been shown to be fundamental for the efficient CO_2 reduction to formic acid with this new metal-free nanocomposite and opens new possibilities in the design of optimized electrocatalytic materials.

Reduced Graphene Oxide Fibre Electrodes for Drug Sensing

Sutthima Sriprasertsuk, John Varcoe and Carol Crean
Department of Chemistry, University of Surrey, Guildford, Surrey GU2 7XH, UK.
s.sriprasertsuk@surrey.ac.uk

Reduced graphene oxide (rGO) functionalized carbon fibre electrodes and their ability to sense paracetamol (as model drug) in addition to interferents such as ascorbic acid and dopamine were studied. rGO was electrodeposited onto carbon fibre via 2 techniques: potentiostatic deposition and cyclic voltammetry (CV). In CV, the number of CV scans (3 to 20) was varied to study the effect on sensing. rGO-coated on carbon fibres could sense paracetamol at an oxidation peak at 0.62 V (vs Ag/AgCl). The limit of detection for paracetamol, using a carbon fibre coated with rGO using 3 CV cycles, was 10.8 µM (S/N = 3) with a linear range of 0 – 100 µM of paracetamol ($R^2 = 0.9904$). The performance of this sensor with respect to interferents such as ascorbic acid and dopamine, commonly found in blood, was also tested. Increasing the number of CV scans for rGO deposition improved the sensing ability due to an increased electrochemical surface area. The morphology of rGO fibre electrodes was characterised by scanning electron microscopy (SEM) and the presence of rGO on the carbon fibre surface was confirmed by Raman spectroscopic analysis. Further work is underway to sense a range of drug molecules.

For fast charging and speeding up an electric vehicle, the high power of supercapacitors is needed. Driving a long distance can be realized by the high capacity of a battery. A combination of the advantages of supercapacitors and batteries in one material can bring novel possibilities for electric mobility in the future. Therefore, hybrid materials have attracted much attention in recent years, since they can simultaneously deliver high power and high energy density [1]. Polyoxometalates (POMs), for example, the α-Kegging type: y $H^+\cdot[XM_{12}O_{40}]^{-y}$, are well known as very stable towards oxidation and reduction. These materials show fast and reversible multi-electron transfer reactions [2], and can, therefore, be considered as a promising candidate. In previous experiments, the properties of the POM were optimized for the use in an organic electrolyte by temperature treatment, and the cycling stability of the material improved by 20-times [3].

In this work, activated carbon (AC) was used to prepare POM@AC hybrid material. Due to the absorption properties of the activated carbon, the maximum POM amount was 45 %-wt. The high-temperature optimization of the POM was achieved in one step together with the activated carbon. The combination and optimization of the two materials enables increased cycling stability, as well as a higher capacity with respect to the two single materials (Fig.1). SEM revealed a smaller POM particle size. Therefore the increased capacity can be related to a higher surface of the active material. Further, the hybrid material was characterized by XRD, TGA-DSC, and electrochemically.

Future experiments will focus on increasing the amount of POM on the activated carbon. A higher percentage of POM in the hybrid material, as well as a better distribution of the particles on the surface, can lead to an increase in capacity.

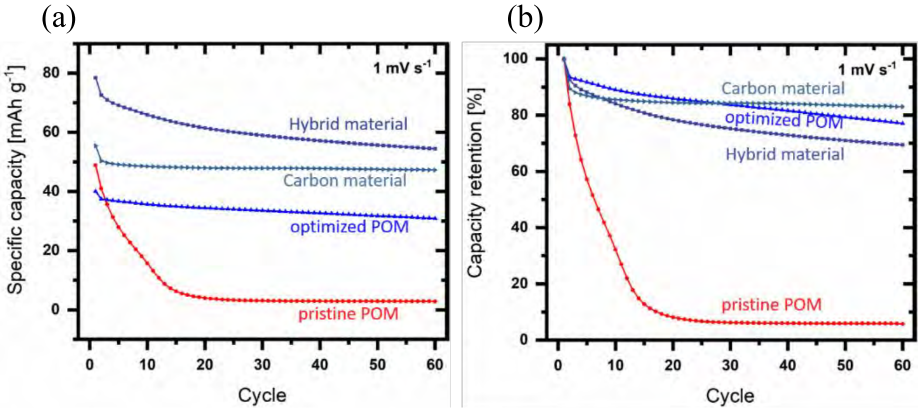

Figure 1: *Comparison of (a) specific capacity and (b) capacity retention of the POM with and without optimized properties, the carbon material, and the carbon-POM-hybrid material. (Measurement was done in LP30 in the potential range 1.4-3.5 V vs. Li/Li$^+$.)*

Developing Machine Learning Algorithms Able To Identify The Tool-Electrode Dipping Depth During Glass Micro-Machining By Spark Assisted Chemical Engraving

Soheila Kabirghadim [a], Rolf Wuthrich[a,b]

Rolf.wuthrich@concordia.ca

Spark Assisted Chemical Engraving (SACE) is a method for micro-machining glass which utilizes glow discharge electrolysis in alkaline solutions such as sodium or potassium hydroxide [1]. A micro-sized cathode is used as tool-electrode in a two electrode setup. Under high enough cell terminal voltages (typically 25-35V, depending the size of the tool-electrode) glow discharge electrolysis phenomena happens. The electrical discharges happening between the tool and electrolyte trough a gas film surrounding the tool-electrode increase the local temperature to 500-600°C. Bringing the tool-electrode near the workpiece controlled machining by etching of the glass happens.

Controlling of this process requires adequate electrical signals (typically pulses which altering glow discharge electrolysis with regular electrolysis in order to gain a better control over the local temperature) and appropriate tool-electrode motion (combining rotation and relative positioning of the tool to the workpiece). Recently SACE process was commercialized and industrial machines are now available [2]. Even if very high precision micro-parts can be manufactured by SACE (typical surface roughness are well below 1 μm and geometrical accuracy is below typically 5 μm) research is ongoing to enhance further the precision of SACE micro-machining. A major challenge that limits machining precision is the uncontrolled surface *S* that the tool-electrode is in contact with the surrounding electrolyte during the process. This difficulty results from the turbulent nature of glow discharge electrolysis and the motion of the tool-electrode during machining process. A solution would be to adjust the machining parameters (potential and tool motion) in function of the actual surface *S*. This requires a way to measure the dipping depth of the tool-electrode in-line while machining is proceeding. This measurement must be fast as the typical time scale of glow discharge phenomena is a hundred few milliseconds.

In this communication we present the development of machine learning algorithms which are able to identify the dipping depth of the tool during machining within a few milliseconds. The algorithms, based on logistic regression with regularisation using the current signal as input features, are trained on data where the tool electrode is dipped with a known depth into the electrolyte. The algorithms are not only able to identify the dipping depth but can potentially as well give valuable information on the local temperature surrounding the electrode.

Array Microcell Method (AMCM) for Serial Electroanalysis

Sasha E. Alden, Natasha P. Siepser, Jacqueline A. Patterson, Gargi S. Jagdale, Myunghoon Choi, and Lane A. Baker
Indiana University
800 E Kirkwood Ave, Bloomington IN
sealden@iu.edu

Here we describe a method for electrochemical measurement and synthesis based on the combination of a mobile micropipette and a microelectrode array, which we term the Array MicroCell Method (AMCM) as illustrated by Figure 1. AMCM has the ability to address single electrodes within a microelectrode array (MEA) and provides a simple, low cost format to enable versatile electrochemical measurements. In AMCM a droplet at the tip of a movable micropipette (inner diameter of 50 µm) functions as an electrochemical cell in which the electrode area is defined by a microelectrode of the array. We also report carbon MEAs that are well suited for AMCM and are fabricated from pyrolyzed photoresist films (PPFs). PPF-MEAs with nominal electrode diameters of 5.5 µm are characterized by AMCM, standard macroscale electrochemical methods and finite element modeling. The versatility of AMCM is demonstrated by shape-controlled metal particle electrodepositions, single particle measurements and molecule detection within single cells.

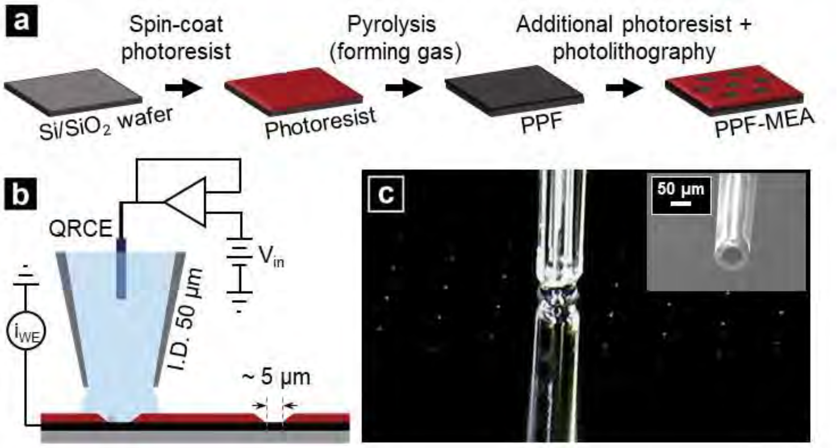

Figure 1. (a) Scheme of pyrolyzed photoresist film-microelectrode array (PPF-MEA) fabrication. (b) AMCM electrochemical measurement setup. (c) Optical image of AMCM, where bright spots are microelectodes 150 µm apart. The inset shows an electron micrograph of a typical pipette used.

Ionic fluxes within porous carbon electrodes operating in aqueous lithium sulphate solution at different pH

Paulina Bujewska, Krzysztof Fic
Institute of Chemistry and Technical Electrochemistry, Poznan University of Technology
Berdychowo 4, 60-965 Poznan, Poland
Paulina.Bujewska@put.poznan.pl

Electrochemical capacitors (ECs) are devices for energy storage and conversion. During EC operation, charge is accumulated at an electrode surface when it is polarized and an electrical double-layer is formed [1]. Because of solely physical interactions between ions and the electrode, ECs are able to deliver energy in a very short time. Processes occurring at the electrode/electrolyte interface seem to be simple – an electrode polarized negatively attracts cations, while an electrode polarized positively attracts anions causing volumetric changes of the electrode [2-4]. To date, ionic fluxes have not been described in detail and it is still an open question how the ions move near the electrode surface, how many of them are attracted to the surface and how the ion exchange proceeds during charge and discharge of the ECs.

In this work, we report on the volumetric changes of microporous carbon electrodes caused by ions adsorption/desorption in aqueous electrolyte – 1 mol L^{-1} Li_2SO_4, measured during in-situ electrochemical dilatometry experiments at different pH values. The results of the preliminary studies are presented in Fig. 1.

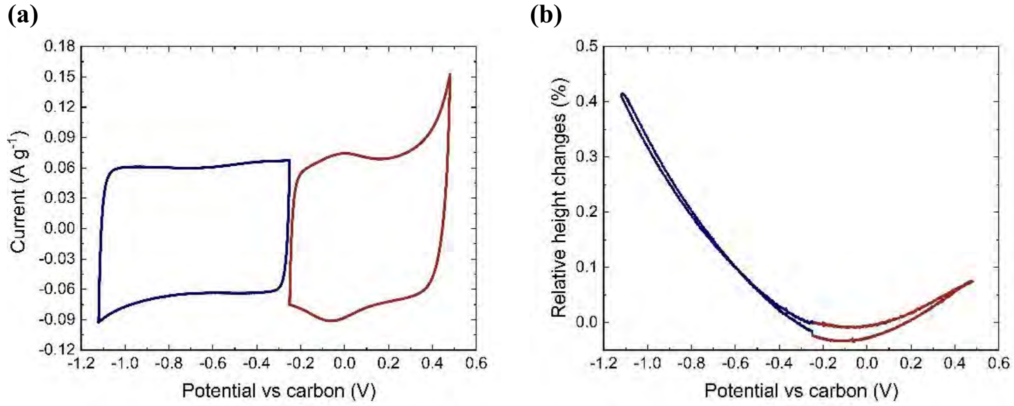

Fig. 1. Cyclic voltammograms (a) and dilatometry curves (b) recorded for the cell operating in 1 mol L^{-1} Li_2SO_4 electrolyte at microporous carbon material (Kuraray YP-80 F) at room temperature

Furthermore, in the case of aqueous electrolytes, pH is a very important parameter because it influences hydrogen and oxygen evolution reaction potentials and, consequently, has an impact on the operating voltage of EC and possible reduction/oxidation reactions of sulphate anion. Moreover, pH may change the hydration energy of ions, thus simplify or hinder a desolvation process. In this context, the paper will bring the insights into composition of the electrolyte at various pH and its impact on the dilatometric response of the polarized electrode.

Influence of electrolyte CO_2 saturation on aqueous electrochemical capacitor characteristics and long-term performance

Adam Slesinski, Justyna Piwek, Elzbieta Frackowiak, Krzysztof Fic
Institute of Chemistry and Technical Electrochemistry, Poznan University of Technology
Berdychowo 4, 60-965 Poznan, Poland
adam.slesinski@put.poznan.pl

Electrochemical double-layer capacitors (EDLC) operate owing to the physical interactions of electrolyte ions present in the liquid medium with the electrodes. To obtain satisfactory energy output, it is necessary to apply high cell voltage. In the case of exceeding the stability voltage of the electrolyte, the decomposition of the electrolytic medium occurs and the side products are released. In the simplest case of aqueous electrolyte, it is hydrogen at the negative electrode and oxygen at the positive one, as depicted by Pourbaix diagram. At the positive electrode, which is considered to be the limiting one in the system, the material itself can undergo oxidation. It leads to the formation of carbon oxides (most often carbon dioxide). Taking the advantage of Le Chatelier's principle, the foregoing electrolyte saturation with carbon dioxide shifts the equilibrium, thus restrains the destructive electrode oxidation.

$$\text{carbon positive electrode: } 2\ H_2O + C \leftrightarrow CO_2 + 4H^+ + 4e^-$$

The current research focuses on the validation of the above concept. For that purpose, we select the neutral aqueous electrolyte 1 mol L^{-1} $LiNO_3$ and binder-free carbon cloth Kynol 507-20. The electrodes and soaked separator (Whatman Glass fiber A) are placed in a tight electrochemical vessel of ca. 0.5 mL dead volume. Three setups are used:

1. a cell containing the atmospheric air (percentage of CO_2 being 0.4 mbar);
2. a cell with the air being displaced by CO_2 (percentage of CO_2 being 1 bar);
3. a pressurized cell with 3.5 bar CO_2.

The above setups are tested at 1.5 V and 1.8 V to elaborate the CO_2 influence at the sub-boundary conditions and at overexposed voltage, respectively. The electrochemical experimental matrix includes the basic testing and long-term floating. Moreover, the carbon electrodes are physicochemically tested in *post-mortem* mode, for the assessment of their elemental composition, with the special attention to the oxygen content before and after the ageing process (floating experiment). Moreover, the reaction mechanisms will be proposed and discussed.

The initial floating data shows that the CO_2 addition does influence the cell potentials during the test at 1.5 V, what confirms that the reaction equilibria are shifted. The E_0 potentials of the electrodes (i.e. at the discharged state) are presented in Figure 1.

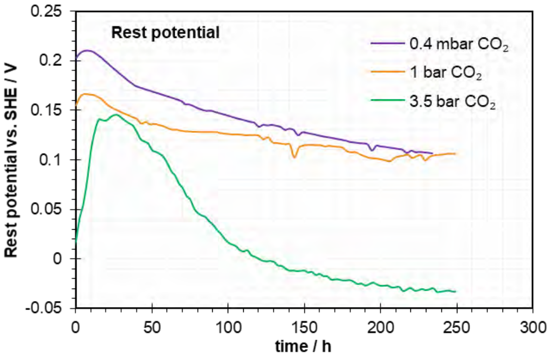

Figure 1. Rest (E_0) potentials of the electrodes during floating experiment at 1.5 V

Fresh water scarcity will arise as one of the major environmental issues in the coming years. Low-energy desalination technologies such as Microbial Desalination Cell (MDC) are needed. Briefly, an MDC consists in a three-chamber electrochemical reactor: an anode and a cathode chambers separated by ionic exchange membranes from a middle chamber (containing saltwater). At the anode, organic matter is oxidized by electroactive bacteria, while at the cathode, reduction processes take place. The redox reaction becomes the driving force for ions removal from the saline chamber by charges compensation. In MIDES project, MDC key components have been studied to increase overall desalination performance.
Carbonous materials (>20), including uni/bidirectional carbon fibers and carbon felts, have been employed as anode materials. Best results, in terms of biofilm formation time (<7days) and current density (>0.3mA/cm^2), were achieved with carbon felt. Besides, electroactive biofilm population differs depending on anode material despite using identical inoculum.

Air-cathodes, based on carbon nanofibers (CNFs) doped with metal nanoparticles (Fe and Co), were developed using electrospinning technique as an alternative to costly and non-regenerative catalysts. Electrochemical tests were performed to evaluate the Oxygen Reduction Reaction (ORR) catalytic activity. CNFs demonstrated suitable ORR performance. CNFs incorporating Fe further enhanced ORR kinetics.

Anionic exchange membranes with low electrical resistance, high permselectivity and anti(bio)fouling properties coatings were developed for MDC application. Their performance was benchmarked with standard membranes, in terms of membrane properties and desalination capacity. Also, their performance over time under MDC operation was studied.

Best performing materials were assembled in MDC for assessing the performance in seawater and brackish water scenarios. Best desalination rates were reached in brackish water, accounting for 2.2 gNaCl/m^2·h, with a 60% salt removal in 72 hours.

Results regarding materials development in MIDES project are likely to be transferrable to other bioelectrochemical systems. Research leading to these results has received funding from EU-Horizon 2020 programme, GA Nº685793 (MIDES project).

On the Development of a Computationally Efficient Model to Predict the Performance of Porous Carbons as Electrode Materials for Electrochemical Capacitors

Progress in the development of novel energy storage systems is hampered by our lack of understanding of the microscopic mechanisms that determine their performance. The key issue is that phenomena on the atomistic scale have consequences on macroscopic length and timescales. In particular, the effects of ionic confinement and diffusion are crucial for device performance, yet experiments that probe properties related to local structure and diffusion are challenging and difficult to interpret without a parallel modelling approach. In this talk, I will focus on carbon-carbon supercapacitors in which the energy is stored by ion adsorption at the electrode surface. In order to understand fundamentally the macroscopic properties of such systems, it is essential to characterise finely the porous materials used and the structural and dynamic properties of the fluid adsorbed. But, in order to screen materials for energy storage applications, it is necessary to develop computationally efficient methods.

Molecular Dynamics simulations is a very useful tool in the context of energy storage systems as it allows one to get a microscopic picture of the phenomena at play. Here, we focus on concentrated electrolytes in contact with various porous carbons (ordered and disordered) and use molecular dynamics simulations to investigate the structural and dynamic properties of the adsorbed liquid. The concentrated electrolyte is represented using a simple coarse-grained model which allows us to tune its characteristics (e.g. ion size, ion charge) and analyse the effect of such variations on the properties of the system [1]. We then report on the development of a lattice model, to predict quantities of adsorbed ions and capacitances 10,000 times faster than with Molecular Dynamics simulations. While the lattice model is still in a primitive form, it shows some promising results as it is able to reproduce the effects of solvation and pore size observed experimentally [2].

Cetyltrimethylammonium bromide (CTAB) is a common organic surfactants employed in seed-mediated synthesis of nanomaterials.[1] Au nanocrystals grown by seed-mediated growth provide an interesting model system to understand nanoscale nucleation and growth, and are also promising technological materials, having found utility as catalysts for energy conversion.[2,3] In some cases, notably catalysis, CTAB ligands adsorbed to the Au surface can prove deleterious to catalytic activity or selectivity.4 In a recent report from our groups, we found that the residual CTAB on Au NCs complicated quantitation by electrochemical imaging.[5]

Methods to remove adsorbed CTAB via chemical treatments have been reported. In particular, thiols containing carboxylic acids,[6] have been explored, with CTAB removal efficiency evaluated by optical spectroscopy such as FT-IR or UV-Vis spectroscopy. Bulk spectroscopic characterization of ligands on three dimensional nanomaterials can prove challenging, however, as monolayer or sub-monolayer quantities can be difficult to detect reliably. Here we demonstrate characterization of CTAB ligands adsorption on Au nanocubes (Au NCs) with a combination of in situ atomic force microscopy and electron microscopy. Highly disperse Au nanocubes (NCs) were utilized as a model system, enabling quantitative comparison of height and width measurement. Force-distance (FD) curves and correlative in situ AFM topography of CTAB adsorbed at Au NCs, compared to SEM measurements provides compelling evidence of the effects of surface cleaning on CTAB adsorbed on the Au NCs.

Brownem6@tcd.ie

Currently, the state-of-the-art materials for the Oxygen Evolution Reaction (OER) and the Oxygen Reduction Rection (ORR), the energy intensive reactions in water electrolysis and fuel cells respectively, stem from the expensive and rare Platinum Group Metals (PGMs). However, major problems remain when using these PGMs for these reactions. For the OER and ORR, most state-of-the-art PGM catalysts exhibit large overpotentials and this value needs to be significantly decreased for electrolysis and fuel cell technologies to become economical.

In general, few layer and 2D-materials exhibit higher surface area and are more conductive than their bulk counterparts therefore hold great promise as next generation materials for the OER and ORR.[1] Hence, as Transition Metal Oxide (TMO) based materials are currently the best performing catalysts for the OER and ORR, it is logical that few layer and 2D TMO materials are likely candidates to emerge as alternative low cost and active catalysts for these electrochemical energy conversion applications.[2] In this work we explore layered and 2D TMO based materials as potential catalysts for these technologies, as we try to create materials with increased active sites, surface areas and conductivity compared to bulk TMO materials.[3]

e-mail: hilmar.guzman@polito.it

Electrochemical Reduction of CO_2 (ER-CO_2) is a very attractive alternative to tackle Global Warming[1]. Cu-based materials have shown increased yields of hydrocarbon and oxygenate products, while its selectivity towards CO is low[2]. Inspired by the thermocatalytic process, a traditional co-precipitation method was employed to synthesize CuZnAl-based oxide catalysts with a mesoporous structure. This CuZnAl catalyst was tested for the first time for the ER-CO_2 under ambient conditions. The chemical-physical properties of the catalysts were studied by several characterization techniques (e.g. XRD, XPS, BET, SEM, TEM) and electrochemical impedance spectroscopy at different applied-potentials to understand the role of the modification of the catalyst components during operation in the final selectivity and activity. Results revealed that by adding amphoteric metal oxides like ZnO and Al_2O_3 to the CuO-based catalyst contributed to promote CO formation over H_2. XPS measurements on the fresh samples revealed that the ternary CuZnAl catalyst presented a lower percentage (5%) of $Cu^0 + Cu^{1+}$ mixture on the surface than the other catalysts, being mainly constituted by Cu^{+2}. This material reached a Faradaic efficiency towards syngas of almost 95% at -0.89 V vs RHE. Nevertheless, the highest production rate of syngas was obtained at the most negative applied potential (~ 17 µmol h^{-1} cm^{-2} at -1.14 V vs RHE).). A tunable H_2/CO ratio was achieved by applying different potentials, reaching lower values by increasing applied negative potential (CO current density increased). In fact, a syngas with a H_2/CO ratio of ~ 2 was obtained at -0.89 V vs RHE, which is a suitable raw material for further methanol synthesis[3]. The enhanced performance for syngas production of the developed CuZnAl catalyst is demonstrated to be attributed to its surface properties (i.e. alkalinity and the oxidation state on the surface, its lowest diffusional mass transfer resistance, its highest total pore volume and the lowest Cu crystals size among the prepared catalysts.

The energy conversion of light energy into electricity is one of the most interesting studies to be explored. Light energy as an alternative energy source is utilized for energy conversion devices such as solar cells. Solar cells convert light energy into electrical energy. However, both of the light and electrical energies cannot be stored in their form; thus, it requires the energy conversion from the electrical to the chemical energy using rechargeable batteries. Two steps of energy conversion in the basic solar cell drive the low efficiency of energy converted during device-to-device transfer. The efficient establishment of solar cell technology on a global scale requires an efficient improvement concerning materials and devices to increase the power conversion efficiency. The integration of light-harvesting solar energy with the battery system was expected to drastically improve the energy efficiency.

The photo-electrochemical reaction of lithium-ion insertion and deinsertion has been reported by employing dye-sensitized battery material driven by light irradiation [1]. The light energy generated electron-hole pairs with the holes aiding to the chemical conversion. Nevertheless, energy efficiency and reaction kinetics should be improved by investigating the appropriate anode material for the system. By utilizing the photo-intercalation and photo-deintercalation concept that has been proposed by H. Tributsch in 1983 [2], the light energy can induce the transfer of ions between the electrode and electrolyte when there is a difference of fermi level energy between electrolyte and electrodes in semiconductor materials. Hence, to investigate the basic fundamental studies of the photo-intercalation reaction, active battery materials and semiconductors were utilized in the photochemical cell. A photo-sensitized $LiFePO_4$ has been prepared to be applied as the working electrode, while a silicon p-type semiconductor has a role as the counter electrode in three electrodes battery system. The electrochemical transparent cell was utilized in order to observe the electrical current response from the energy produced by the reaction that takes place under the light irradiation.

The experiment of photo-lithiation was conducted by observing the currents response of the $LiFePO_4$/Si and the potential changes of $LiFePO_4$ vs. Li^+/Li full cell system under light irradiation. There was no electrochemical activation involved in the system. When there was no light irradiation, there was no currents response observed. Meanwhile, there was a distinct current change from 0 mA to ±0.6 mA once the light irradiates the photochemical cell. In order to further analyze the chemical state changes of the electrode materials in the photo-electrochemical system, an experiment was conducted by using X-ray absorption spectroscopy measurement. The experiment was established after the irradiation of light towards the materials. The intense absorption in the near-edge area broadened, and the edge energy was shifted towards lower energy. This trend corresponds with the spectrum change during the electrochemical lithium insertion of the silicon electrode [3]. By this result, we acquired the possibility of advancing the design principles for photo-assisted rechargeable batteries.

System identification of PEMFCs through EIS and cFRA: a comparative study

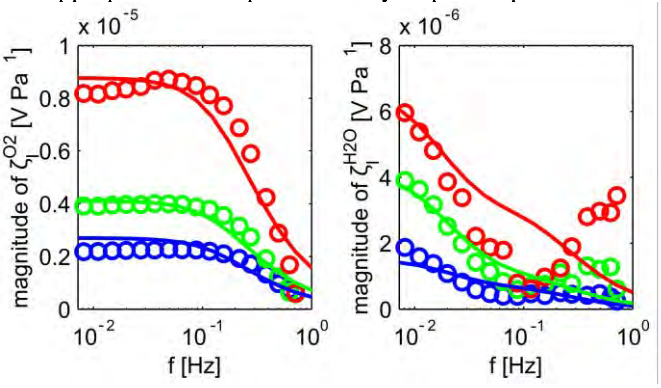
A. Sorrentino[1]*, K. Sundmacher[1,2], T. Vidakovic-Koch[1]

[1]Max Planck Institute for Dynamics of Complex Technical Systems,
Sandtorstraße 1, D-39106 Magdeburg, Germany
[2]Otto-von-Guericke University Magdeburg, Process Systems Engineering, Universitätsplatz 2, D-39106
Magdeburg, Germany

Due to its capability to separate power losses related to different mass transport and kinetic phenomena, electrochemical impedance spectroscopy (EIS) is commonly applied as fault identification tool for polymer electrolyte fuel cells (PEMFCs). However, this is not always the case especially in the lower frequency region of the EIS spectra (< 1 Hz), where the contributions of the gas transport of oxygen and liquid water, water sorption in the Nafion membrane, and adsorption/desorption kinetic steps of the HOR and ORR overlap, becoming practically indistinguishable. In this frequent scenario, the efficacy of EIS as PEMFCs diagnosis tool and its capabilities to estimate key parameters related to the fuel cell performance are inadequate.

Recently, our group has developed a novel frequency response methodology based on the use of periodic concentration as input which aims to overcome the limitations of the EIS at low frequencies [1,2]. The new technique, named concentration-alternating frequency response analysis (cFRA), applies periodic input of oxygen or water at the cathode side of PEMFCs and detects electric responses under galvanostatic or voltastatic conditions, cell potential and current respectively.

In this contribution, an experimental facility capable to produce an input flow with periodic concentration of oxygen or water at different frequencies is presented, and a procedure to measure cFRA spectra is described. Then, by the support of a mathematical model of a PEMFC, the capability of the cFRA to separate the dynamics of gas transport and water sorption in Nafion membrane depending on the kind of concentration input and output is demonstrated (please see the figure below). Finally, the identifiability and estimation of some key PEMFC performance parameters using EIS and cFRA transfer functions have been compared by considering sensitivity and collinearity of the different parameters. Criteria to choose a most appropriate technique to identify a specific parameter are discussed.



$$\zeta_I^{O_2}(\omega)=\frac{\Delta V(\omega)}{\Delta P_{O_2}(\omega)}$$

$$\zeta_I^{H_2O}(\omega)=\frac{\Delta V(\omega)}{\Delta P_{H_2O}(\omega)}$$

Left: cFRA transfer function obtained by periodic oxygen concentration change under galvanostatic conditions. Only dynamics of gas transport in the channel is detected. **Right:** cFRA transfer function obtained by periodic water concentration change under galvanostatic conditions. Only dynamics of water sorption in Nafion is detected.

We examined the effect of the carboxyl group (–COOH) functionalization at the edges of graphene nanoplatelets (GNPs) for the electrochemical sensing of dopamine (DA) in the presence of ascorbic acid (AA) and uric acid (UA). The –COOH functionalized GNP at the edges (ECG) was prepared by a ball mill method with a high percentage of functional groups (26.40%). For comparison, GNPs with a low percentage of –COOH (2.35%) functionalization was also prepared by the heat treatment of ECG (HECG). Both ECG and HECG dispersions in 2-propanol were used to modify the fluorine-doped tin-oxide electrodes (FTO) by the e-spray method. The ECG/FTO sensor displayed high catalytic activity and sensitivity with the signal separation of DA, AA, and UA, while the HECG/FTO sensor completely suppresses the oxidation signals of AA and UA with a low sensitivity of DA oxidation. This can be ascribed to the varying interaction mechanism of AA^-, DA^+, and UA^- at pH 7.0 with the –COOH groups of ECG and HECG. The differential pulse voltammetry (DPV) signals for the oxidation of DA revealed the detection limits (S/N = 3) of 0.26 and 1.0 μM, respectively, at the ECG/FTO and H-ECG/FTO sensor with the sensitivity of 2.11 and 0.55 $\mu A/cm^2/\mu M$, respectively.

The Li-ion battery is one of the most important devices involved in the change towards a new energetic paradigm, being graphite the most used material as anode due to its high specific capacity, low cost, and low volume expansion, to name a few properties. Li-ion (de)intercalation (from)into graphite involves a series of stable compounds denoted as stages.

Understanding how external variables, such as pressure or temperature, affect batteries is important to improve their operation since they have demonstrated to play a role in several processes, such as changes in the interphase resistance. Several studies have tackled temperature effects on Li-ion intercalation into graphite but, until now, none has addressed a detailed atomistic study.

In this presentation, we introduce our most recent results regarding the kinetics of Li-ion (de)intercalation (from)into graphite from a theoretical-computational perspective, using the kinetic Monte Carlo (kMC) method. We have extended our previous work[1] to cover a complete set of properties at different temperatures, which can be contrasted with experimental results. In this respect, we have simulated cyclic voltammograms and potentiostatic steps, and calculated diffusion coefficients and exchange current densities for different states of charge at different temperatures. Some of these results are shown below.

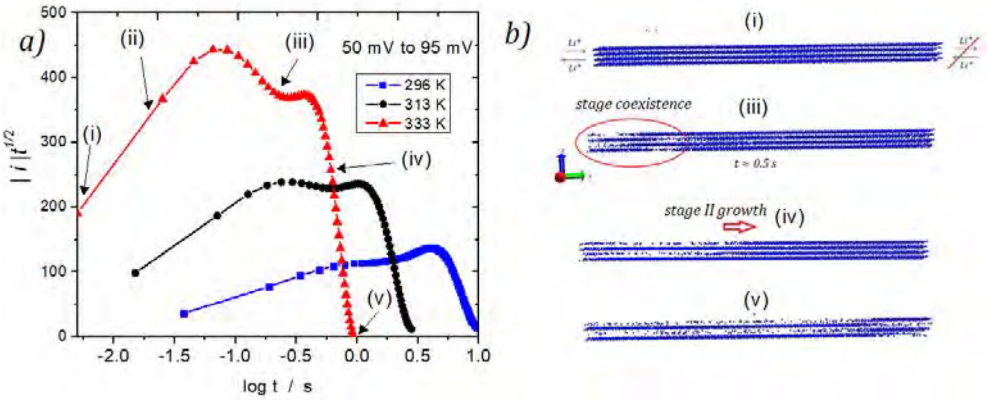

Figure: a) kMC chronoamperometric simulation results for a potentiostatic step from a potential where stage I is stable (50 mV), up to a potential where stage II is formed (95 mV) for three different temperatures. The principal events are indicated in the Figure form (i) to (v) for T=333 K. b) Snapshots showing some of the features labeled in Figure a.

Towards Increasing the Operating Potential Window of Aqueous Supercapacitors through the Passivation of Carbon-based Electrodes by Electrodeposition of Poly(phenylene oxide)

Baptista, J. M.*(1,2), Gaspar, G.(1), Santos, D. R.(1,3), Sagu, J.S.(2), Correia, J. P.(3), Wijayantha, U. K.G.(2), Lobato, K.(1).

The main drawback of supercapacitors is their low energy density, which is mostly limited by the breakdown voltage of the electrolyte. Commercial devices typically use organic solvents, which can withstand up to 2.7 V, but are toxic and expensive[1]. Aqueous electrolytes would be a cheaper and environmentally friendly alternative if their electrochemically stable potential window ($\Delta V \approx 1V$) could be extended.

A conceivable way to achieve this is by electrodepositing an insulating material on the surface of the carbon-based electrode. Poly(phenylene oxide) was identified as a suitable candidate[2]. For a successful passivation, the deposited material must be thick enough to prevent electron transfer between the electrode and the electrolyte (>2 nm)[3] whilst simultaneously thin enough (<30 nm) to preserve the electrode's high surface area, indispensable for a high capacitance.

Preliminary results suggest a trade-off between capacitance and degree of passivation: a decrease in both oxidation and reduction leakage currents (measured at constant potentials and respectively associated to the oxygen and hydrogen evolution reactions) comes at the expense of a capacitance loss. This work will present results comparing differing polymer electrodeposition conditions and how these correlate both to the passivation of the electrode and to its performance metrics.

Polymeric matrices as cathodes for Sodium-ion batteries - Electrochemical and pseudocationic doping behaviour characterization

Daniel R. Santos[a], Carlos Ferreira[a], Upul Wijayantha KG[b], Killian Lobato[c], Jorge P. Correia[a]

drcsantos@fc.ul.pt

Sodium-ion batteries appear as an alternative more abundant, in terms of resource, and less expensive than the conventional Lithium-ion batteries, being used for applications where the weight and the specific energy are less determinant [1]. Their delay in commercialization is related to the delayed development of cathodes with capacities and performance similar to those achieved by commonly used materials in Lithium-ion batteries, since they must be designed for a larger size ion exchange [2]. The cathodic structure must be sufficiently flexible and stable, and extremely light [3] to compensate the total mass of the storage unit. An electronically conducting polymer with pseudocationic doping may fulfil this requirement. Here cations are exchanged during the polymer redox conversion.

Poly(3,4-ethylenedioxythiophene) doped with poly(styrene-4-sulfonate) (PEDOT:PSS) is a stable material that exhibits, in some extent, pseudocationic doping character, making it an attractive choice for cathodes in Sodium-ion batteries. Other doping polyanions such as Poly(2-acrylamido-2-methyl-1-propanesulfonic acid) (PAMPSA) and Sodium dodecyl sulphate (SDS), may also impart, theoretically, a pseudocationic behaviour to the polymeric matrix.

Electrochemical techniques can provide information about the thermodynamics and kinetics of electroactive systems, but they do not resolve the structural and chemical modifications imparted by the mass transfer processes. So, the coupling of electrochemical methods with techniques sensitive to the structural and chemical changes caused by charge transfer phenomena on the electrode surface, will grant more information about the nature of the mass flow.

In this work PEDOT:PSS, PEDOT:PAMPSA, PEDOT:SDS, films were potentiostatically, galvanostatically and potentiodynamically synthesized onto platinum electrodes from aqueous solutions containing the monomer and the polyanion. The electroactivity and redox reversibility of these films was characterized by cyclic voltammetry in acetonitrile medium containing $NaClO_4$. Wettability was monitored by contact angle goniometry. The mass transfer phenomena taking place during the redox conversion of PEDOT:PSS films deposited with different thicknesses and at different temperatures, were investigated by coupling electrochemical methods with microgravimetry (EQCM) and Probe Beam Deflection (PBD). These techniques are well suited for measuring the mass flow, since they transduce both the ionic flow (probed by EQCM and PBD), and solvent molecules associated to the mechanical changes that occur during the redox conversion on the polymeric matrices (only probed by EQCM). By cooperatively using PBD and EQCM data, the ionic and the solvent mass flows were separately distinguished.

It is particularly challenging to find a bifunctional catalyst capable of accelerating both O_2 evolution and reduction in aqueous solutions. The discovery of such a material would bring reversible fuel cells and metal air batteries much closer to technological fruition. Researchers have shown that both doped carbon and oxides show appreciable activity in short term tests, lasting hours. However, in a real device, such a catalyst will need to retain its activity over several years. Even the best bifunctional catalysts reported, thus far, would need to withstand an enormous potential window of at least 1 V. Nonetheless, to the best of our knowledge, little is known about the factors controlling the stability of bifunctional catalysts.

In the current contribution, we investigate $NiCo_2O_4$ and Co_3O_4 under both oxygen evolution and reduction conditions in 0.1 M KOH. When these materials undergo accelerated degradation test in a rotating disk electrode (RDE) configuration, rapid deactivation of the oxygen reduction is observed, as shown in figure 1. At the same time, this is accompanied by a significant increase in oxygen evolution activity and a shift in pre-catalytic redox peak. Herein, we employ a range of post-mortem techniques including inductively coupled plasma mass spectrometry (ICP-MS), transmission electron microscopy (TEM), and x-ray photoelectron spectroscopy (XPS), to understand the causes of the deactivation of $NiCo_2O_4$. Additionally, oxygen-electrode prototypes were manufactured and characterized in a half-cell configuration.

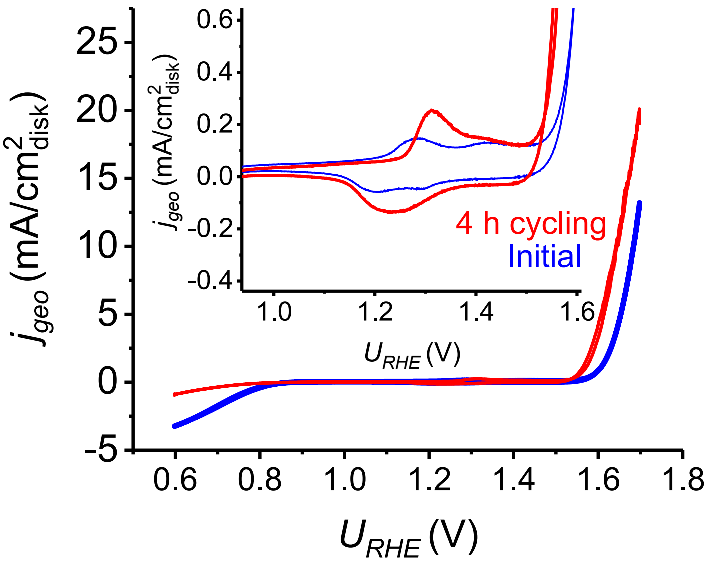

Figure 1 Cyclic voltammogram of $NiCo_2O_4$ in O_2 saturated 0.1 M KOH recorded at 10 mV/s, 1600 RPM and 25 $\mu g_{catalyst}/cm^2$. Blue line corresponds to the third scan and green line corresponds to the scan after cycling for 4 hours between 0.6 V_{RHE} and 1.7 V_{RHE} under the aforementioned conditions. Figure inset corresponds to a magnification of the cyclic voltammogram.

Interprotein electron transport (ET) is a key process for living organisms, playing a fundamental role in respiration and photosynthesis. ET processes between photosynthetic complexes and electron carrier partner proteins have been widely studied with bulk spectroscopic techniques[1], however the characterization of ET at the level of single molecules is limited. This is due in part to the lack of a well-defined experimental setup for protein orientation and current measurement. In this work, a peptide[2] that binds selectively to plant Photosynthetic Complex I (PSI) in is used to functionalize atomically flat gold monocrystal electrodes and to evaluate photocurrents by bulk photo-electrochemical experiments and ET by scanning probe techniques, atomic force microscopy (AFM) and electrochemical scanning tunneling microscopy (ECSTM). ECSTM-based spectroscopic measurements allow investigating the current decay distance[3] (β [nm^{-1}]) of PSI functionalized electrodes under electrochemical control. Mapping β over sample and probe potentials reveals enhanced charge exchange distance as probe potential is aligned with PSI's electron acceptor cofactor redox potential.

Tetraglyme - $Ca(TFSI)_2$, a non-monotonic liquid electrolyte

Tanguy Gogny Picard, Nicolas Sergent, Cristina Iojoiu, Fannie Alloin
Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, Grenoble INP, LEPMI, 38000 Grenoble, France
tanguy.picard@grenoble-inp.fr

Ca-ion batteries are considered among the most suitable candidate for post-lithium batteries as they present similar charge density and a large theoretical energy density 2.06 Ah/cm^3 [1]. Calcium, considering its reactivity and metal properties, is a safer element than lithium as it is less prone to burst in flame in contact with air and Ca platting-stripping reported so far did not show any dendrites growth demonstrating the safety of such technology to a moderate cost on electrolyte resistance [2]. In addition, Ca is the 5th most available element and evenly distributed on Earth compared to Li, 25th, making it a very promising alternative to Li [3].

Polymer electrolytes as compared to liquid electrolytes are easier to handle and shape on an industrial scale and tackle dendrite growth issues. Here we propose to pave the way to safe and efficient Ca-Polymer batteries avoiding the usage of organic based electrolyte. We investigated the most commonly reported polymer in the literature, PEO. A tetraglyme electrolyte coupled to a calcium salt ($Ca(TFSI)_2$) is used as preliminary study. This approach helps us to investigate the interaction between PEO polymer with calcium salt by means of ionic conductivity measurement carried out by Electrochemical Impedance Spectroscopy (EIS) and complementary techniques based on Raman and FT-IR spectroscopies. As can be seen in Figure 1, the conductivity response with respect to temperature is non-monotonic as normally expected from the Vögel-Tammann–Fulcher model. Several parameters could influence this behaviour among them, the viscosity of the electrolyte, the salt dissociation process, the crystallinity of the polymer etc. Such behaviour deserves a proper investigation to elucidate the process behind. We employed here *operando* Raman spectroscopy technique at specific temperatures to get insights into molecular structure of the species in solution (aggregates, solvated-Ca...). This method allows us quantifying the amount of Ca-diffusing species in the electrolyte and to correct Vögel-Tammann–Fulcher model, proposing then a new model better featuring the obtained conductivity measurements.

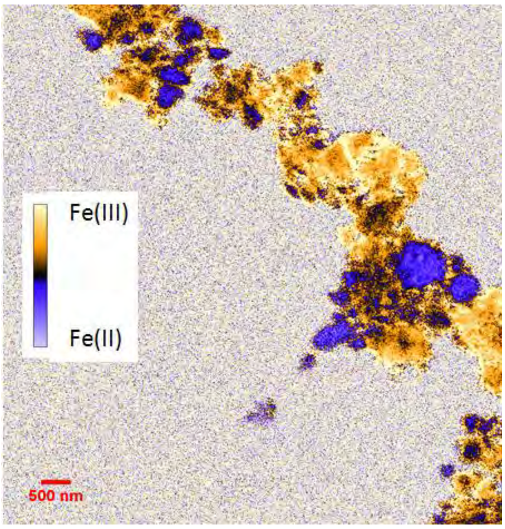
A very interesting, durable and cheap class of active intercalation cathode materials is represented by open-framework structures such as Prussian blue analogues (PBAs). Manganese hexacyanoferrate (MnHCF) with nominal formula $Na_2Mn[Fe(CN)_6]\bullet zH_2O$, only includes abundant elements and is safely and easily synthesized. The material features high specific capacities at high potentials when compared to other PBAs [1]. A combined XAS and XRD study has demonstrated that both Fe and Mn sites are involved in the electrochemical process but a capacity fading is observed during the charge and discharge steps, due to a Jahn-Teller (J-T) effect [2].

Using energy-dependent soft x-ray microscopy [3,4] in this study we reveal and visualize the spatial distribution of the oxidation state of Mn, Fe and N at different electrode composition and after 50 cycles in a Li and in a Na battery. The high-resolution access to the metal L edge provided complementary details on the metal-ligand characteristic to the one already available by hard x-ray absorption, while the images demonstrate particles at different state of charge, likely caused by J-T-related passivations, in particular in the cycled lithiated samples. This confirms the superior stability to sodiation and provides an important support for strategies aimed to the suppression of fading.



An example of data extracted from energy-dependent images at the Fe-L edge of a fully charged MnHCF electrode material in a Li battery after 50 charge-discharge cycles: maps of ratio between main spectral components highlighting distribution of different prevalent Fe oxidation states.

Proton exchange membrane (PEM) electrolysis of water is a green procedure for hydrogen production, but to become competitive the cost of stack components, in particular bipolar plates (BPP) need to be reduced. This can be achieved by using coated low-cost materials as alternative to titanium. In this work, we report on the development of a highly corrosion-resistant coating deposited by vacuum plasma spraying (VPS) of niobium powder on copper substrate. Copper substrate has been used as a cost-effective replacement of titanium, commonly used to manufacture BPPs. The influence of the Nb coating thickness, given by the number of deposited layers (32, 16 and respectively 8 layers of Nb coating), on the corrosion resistance properties is investigated by electrochemical methods. Corrosion parameters of Nb coated samples have been determined from the Tafel plots shown in Fig. 1 and compared to those of pure metallic Nb, both before and after an accelerated stress test (AST) consisting in polarization at 2 V for 6 hours. Appropriate conditions for the corrosion and stress tests have been chosen to simulate the anode side environment of PEM electrolyzer under operating conditions and the degradation of the proton exchange membrane by fluoride release.

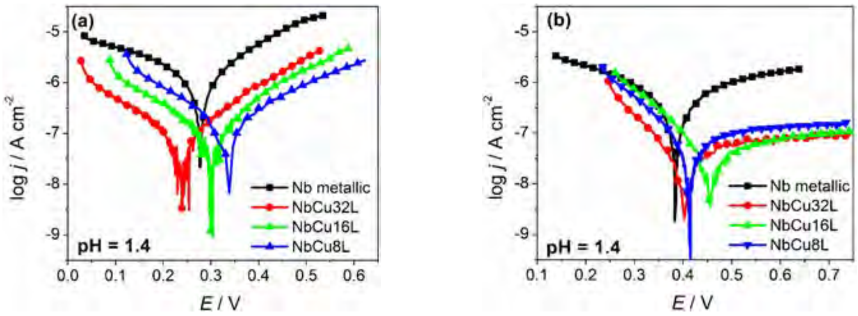

Figure 1. Potentiodynamic polarization curves (v = 1 mV s^{-1}) of metallic Nb and VPS Nb-coatings on copper in 0.05 M H_2SO_4 + 0.1 ppm F^- (pH = 1.4) (a) before and (b) after polarization at 2 V for 6 h, measured in O_2 saturated solution at 90°C.

Electrochemical impedance spectroscopy (EIS) is used to estimate the polarization resistance and thickness of Nb coatings. Interfacial contact resistance at different compaction forces is evaluated both before and after the AST. Post-test analytic is carried out by X-ray photoemission spectroscopy (XPS) and atomic force microscopy (AFM) measurements.

The results showed that even with a reduction of coating thickness from 130 to 30 µm, the highly corrosion resistance properties of Nb coatings are preserved, as proven by corrosion currents bellow 0.1 µA cm^{-2}. The AST at 2 V induces the formation of a passive oxide layer. Both EIS and XPS analysis gave a similar estimate of the protective oxide layer thickness of about 10 nm. The chemical composition determined by XPS shows the predominance of Nb_2O_5 in the outermost layer. These results demonstrate the possibility to reduce production cost of BPPs in PEM water electrolyzers by using alternative low-cost materials such as copper and substituting precious metals coatings with highly corrosion resistant coatings based on niobium.

npalacios@cidmeju.unju.edu.ar

In a context in which it is urgent to change the energy matrix dependent on fossil fuels for a more sustainable one, the reference to energy accumulation, electromobility and lithium is undeniable. Continental brines as present in a small region in South America (the Lithium Triangle), are the most abundant and the easiest to exploit with an evaporitic method [1]. Current practice is highly water and chemical intensive, and delivers besides lithium only waste to be landfilled [2,3]. Concerns about processing practices are growing, particularly with the local native population. As an alternative to the current extraction process, it is proposed an integrated membrane electrolysis process with three stages, each based on a water electrolyser with a side crystallizer. Lithium is present in diluted concentrations together with different ions, and it is imperative to fully remove both magnesium and calcium before lithium carbonate can be precipitated. In the stage I of this approach, hydroxyl groups are generated in situ in a two chamber electrochemical cell with a side crystallizer, omitting the need for chemical addition and not leading to substantial loss of lithium rich brine. The native brine is introduced into the cathodic compartment of a 2-chamber electrolyzer (AEM) like the one show in the figure. As the pH increases, $Mg(OH)_2$ and $Ca(OH)_2$ will quantitatively precipitate. The objective is to obtain these two salts with commercial value, avoiding that they remain as waste in the salar and minimize the amount of brine adsorbed on solids. Batch electrolysis experiments were performed and showed that for a native south american brine containing 3090 mg L^{-1} of Mg^{2+} and 685 mg L^{-1} of Ca^{2+}, 62 kWh m^{-3} are needed for the full removal of both cations when a current density of 223 A m^{-2}. It is necessary to remark that the Li^+ concentration in the brine is not affected. The first stage of this alternative process to the evaporitic method, not only performs the necessary removal of the divalent cations from the brine, but also allows obtaining magnesium and calcium compounds simultaneously, minimizing the production of waste.

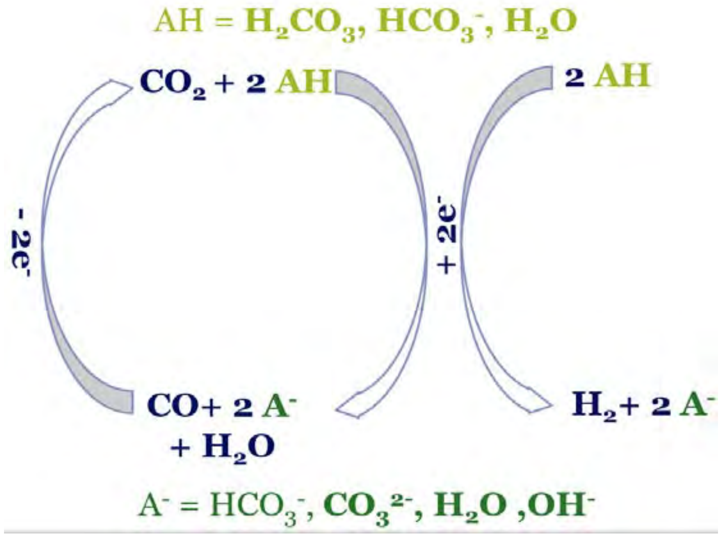
The Importance of the Electrolyte in Energy-Related Electrocatalytic Reactions: the Case of Bicarbonate

Giulia Marcandalli, Marc T. M. Koper
Leiden Institute of Chemistry, Leiden University
P.O. Box 9502, 2300 RA Leiden, The Netherlands
g.marcandalli@lic.leidenuniv.nl

The nature of the electrolyte (pH, identity of buffer and its concentration) has proven to crucially affect electrocatalytic behaviour in a way that goes beyond simple water related equilibria. Herein, we expand the understanding of the effect of the widely employed bicarbonate electrolytes on hydrogen evolution reaction (HER), CO_2 electrochemical reduction (CO2RR) to CO and, viceversa, CO electroxidation to CO_2 (COOR).

We performed voltammetry measurements under well-defined mass transport conditions using a gold rotating disk electrode and rotating-ring disk electrode assembly changing the concentration of the bicarbonate electrolyte. Importantly, this systematic investigation reveals that carbonic acid and bicarbonate are viable proton donors for HER and CO2RR and that carbonate is an oxygen donor for COOR.

Additionally, probing the catalytic surface by in situ IR spectroscopy, we gain insights into the mechanism regulating the participation of bicarbonate-related species in the mechanism of HER, CO2RR and COOR.



Preparation of Co Single-Atom Nanozyme Based on Graphyne and Its Efficient Detection of H_2O_2

Lihua Shen[1], Yuan Xu[1], Cong Chen[1], Daixin Ye[1,*], Hongbin Zhao[1,*]
[1]Department of Chemistry, College of Sciences, Shanghai University, 200444

E-mail: hongbinzhao@shu.edu.cn, daixinye@shu.edu.cn

Single-Atom Nanozyme (SAN) inherits the advantages of heterogeneous catalysts and homogeneous catalysts, not only has excellent activity and selectivity, but also achieves the maximum utilization efficiency of atoms [1]. Meanwhile, nanozymes with oxidoreductase-like activity, such as peroxidase, oxidase and catalase, have been extensively applied in biosensors, immunoassay, and therapy. Graphyne as a novel and unique two-dimensional planar carbon nanomaterial has excellent properties such as high electrical conductivity, high specific surface area, and stable structure, and can be used as an ideal biosensing platform [2]. Reactive oxygen species (ROS) such as superoxide ($O_2^{\cdot-}$) hydroxyl radical ($\cdot$OH) as well as H_2O_2 are present in numerous biological processes. However, the excessive generation of ROS would cause tissue injury and associated inflammation. Therefore, it is necessary to develop an ultra-sensitive and selective method to detect H_2O_2 in living cells.

In this work, graphyne was prepared by the mechanical milling method. First, the mixture composed of benzene and CaC_2 was put it into the ball milling chamber and ball milled for a certain period of time under certain ball milling conditions. Then, the product was calcined at 260°C and N_2 for 2 hours, and further washed by acid and dried to obtain graphyne. Next, Co-MOF@graphyne precursor solution was prepared by mixing $Zn(NO_3)_2\cdot 6H_2O$, $Co(NO_3)_2\cdot 6H_2O$, 2-methylimidazole and methanol. The mixture solution mildly stirred at room temperature for 24 hours, then the solution was transferred into a Teflon-lined stainless-steel autoclave, sealed, and heated to 120 ℃ for 6 h. The Co-MOF@graphyne was obtained by centrifugation, washed and dried in a vacuum oven at 60 ℃ overnight eventually. Scanning electron microscopy, transmission electron microscopy, and X-ray diffraction can be used to prove that the folded sheets of the catalyst are stacked. At last, Co SAN was successfully synthesized by high-temperature pyrolysis of Co-MOF@graphyne. After calcined at 900°C for 2h, Co single-atom nanozyme was obtained. At the same time, electrochemical tests also showed that the catalyst has oxygen reduction catalytic activity. For further research, the catalyst was tested for peroxidase-like enzymes to optimize pH, temperature, and incubation time for TMB substrate catalysis conditions.

The microbial corrosion of metals induced by sulfate reducing bacteria

Guan fang[1,2], Zhai xiaofan[1,2], Duan Jizhou[1,2*], Hou Baorong[1,2]

e-mail address duanjz@qdio.ac.cn

Microbiologically influenced corrosion (MIC) is one of the main reasons for the failure of engineering materials immersed in seawater. Sulfate-reducing bacteria (SRB) could induce corrosion on almost all metals, causing severe corrosion in almost all metals immersing in sea water. The corrosion of metal is closely related to the metabolic activity of SRB [1].

T. Gu [2] divided SRB induced metal corrosion into two forms: metabolite MIC (M-MIC) and extracellular electron transfer MIC (EET-MIC). M-MIC refers to the process in which the organic acids and other metabolites produced by SRB attack metals indirectly and accelerate corrosion by chemical reaction. Whereas EET-MIC refers to the process of direct corrosion of the metal by the SRB with the ability of extracellular electron transfer to obtain electrons directly from the metal surface and accelerate the corrosion of the metal. It is proved that the biocorrosion mechanism of metal is related to metal composition, environmental and bacteria. The corrosion mechanism of the same SRB strain is different for different metals. The corrosion of carbon steel caused by *Desulfovibrio vulgaris* strain SRB is mainly EET-MIC [3], while for copper alloy, the corrosion of *Desulfovibrio vulgaris* on copper alloy is mainly M-MIC [4].

To verify the MIC difference of 5052 and Al-Zn-In-Cd aluminum alloys by SRB strain *Desulfovibrio caledoniensis*, and the interaction between the aluminum alloys and *D. caledoniensis* metabolic activity. SRB growth curve and sulfate variation with and without aluminum were performed to find the effect of two aluminum alloys on SRB metabolic activity. Corrosion of 5052 aluminum alloy and Al-Zn-In-Cd aluminum alloy with and without SRB were performed. The results showed that both the presence of 5052 and Al-Zn-In-Cd aluminum alloy promoted SRB metabolic activity, with more significant effect was found on the 5052 aluminum alloy. The electrochemical results suggested that the corrosion of the Al-Zn-In-Cd aluminum alloy was accelerated substantially by SRB. EET-MIC is the most possible corrosion mechanism of Al-Zn-In-Cd aluminum alloy in SRB was EET-MIC, while M-MIC for 5052 aluminum alloy.

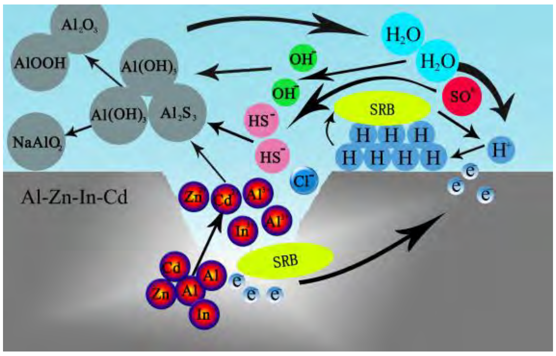

Fig.1 Schematic of the corrosion mechanism for the Al-Zn-In-Cd aluminum in SRB medium.

Institute of Chemistry, University of Tartu, Ravila 14a, Tartu 50411, Estonia
E-mail: heigoers@ut.ee

Supercapacitors are electrochemical energy storage devices, where energy is accumulated at the double layer. To achieve better energy and power density, the electrolyte used in supercapacitors should have high electrochemical stability and ion conductivity. Room-temperature ionic liquids (RTIL) are novel compounds, which are considered as possible electrolytes due to their stability and low vapor pressure. As RTILs consist only of ions, the electrode-RTIL interfacial structure differs noticeably from other electrode-electrolyte interfaces. To study RTILs structure, molecular dynamics (MD) simulations are indispensable, as they allow modeling and investigating the interface on the atomic-scale without any undesirable impurities, which could alter the RTIL structure.

In this study, MD simulations have been used to evaluate the capacitance of an interface between model graphene electrode and 1-ethyl-3-methylimidazolium tetrafluoroborate ionic liquid and to investigate its structural response to changes in temperature and potential. The aim of this study is to relate trends in interfacial capacitance dependencies to changes in ionic liquid's interfacial structure. This work shows that near the potential of zero charge, the increase in temperature decreases the capacitance due to increased thermal motion, which hinders the ordered packing of ions. Furthermore, characteristic saddle points in the capacitance-potential curve were related to the restructuring of the ionic liquid.

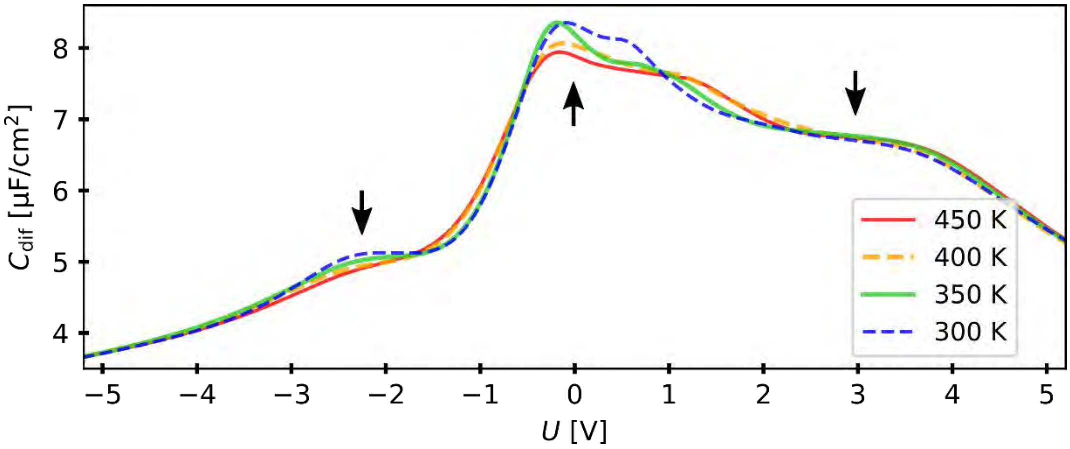

Figure 1. Capacitance-potential dependencies of studied temperatures in the range from −5 to 5 V. The potential axis (U) is shifted by the potential of zero charge of each temperature.

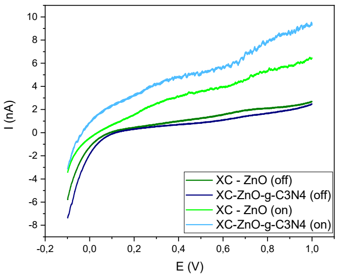
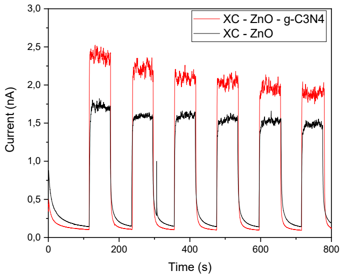
In the photocatalytic process for persistent organic pollutant degradation, the main aim is the increasing of the quantum efficiency diminishing charge recombination. The present study evaluates the effect of hybrids g-C_3N_4/ZnO/carbon xerogel and ZnO/carbon xerogel on heterogeneous photocatalysis in the degradation of 4-Chlorophenol. For the synthesis, 4.5 g of $ZnCl_2$ and 0.0689 g of g-C_3N_4 were solubilized in ethyl alcohol. Then, 1.5 ml of formaldehyde and 1.5 g of tannin were added and mixed with another solution with 4 g of KOH and the same solvent. The product was washed, dried in an oven (24 hours at 100 ºC), ground and sieved (325 mesh). The materials were calcined at 300 ºC for 30 min, under N_2 atmosphere. The XC/ZnO synthesis followed the same procedure. However, the g-C_3N_4 mass was not added. Electrochemical experiments were performed with linear linear voltammetry from -0.1 to 1.0 V on porous microlayers prepared with each material, deposited on a rotating ring electrode glass carbon. The electrochemical measurements were obtained with electrolyte K_2SO_4 0.05 mol L^{-1} (pH 2) using a potentiostat PGSTAT-bi-204N (Autolab/Metrohm) and RRDE (Pine Research).





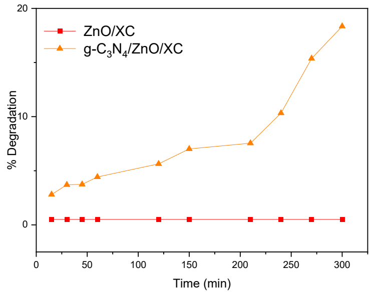


Figure 1: Linear voltammetry comparing under visible light and dark (on/off)
Figure 2: Photocurrent generation under pulsed irradiation for the materials prepared.
Figure 3: Degradation under visible radiation

According to Figure 1, the g-C_3N_4/ZnO/XC material shows higher current under visible light, implying in better charge separation and higher photocatalytic activity. Lower recombination rates result in higher photocurrent generations, and the g-C_3N_4/ZnO/XC shows superior photocurrent generation and high sensibility to light irradiation (Figure 2), which agrees with the photocatalytic efficiency shown in Figure 3, that exhibits 17% of photodegradation of 4-Chlorophenol. Therefore, this test proves the improvement of the efficiency of the catalyst under visible radiation with the presence of carbon xerogel and g-C_3N_4.

A Metallic Copper Based Catalyst For The CO_2 Reduction To Formic And Acetic Acid

martina.serafini6@unibo.it

Starting from the industrial revolution, the majority of the human activities have been tied to the use of fossil fuels. Electricity and heat production, intensive agriculture, industries and transportation are the main causes for the increase of gaseous CO_2 in the environment. With the so-called Paris Agreement, world leaders officially recognized the strong impact of anthropological activities on climate change and since then a great effort has been demanded to all fields of human sciences in order to guarantee a sustainable future for our society. In this framework, the concept of "artificial photosynthesis"[1] has gained momentum in view of a smart use of the atmospheric CO_2.

Inspired by the natural photosynthesis, carbon dioxide is converted back to chemicals and fuels by exploiting an electrochemical process[2]. This contribution describes the preparation of an easily synthesized catalyst made of metallic copper for the heterogeneous CO_2 reduction reaction (CO_2RR) in liquid phase in order to produce formic and acetic acid. The metallic copper-based catalyst was electrochemically synthesised on a gas diffusion layer (GDL) support made of carbon fibers as shown in Figure 1. Electrosynthesis allows the one step formation and deposition of the Cu film directly on the carbon paper substrate. Adapting an already reported procedure[3], the carbon paper electrode was pre-treated in 1M H_2SO_4 followed by soaking in pure EtOH. The role of the pre-treatment time on the surface properties of the support was thoroughly evaluated. In particular, the ratio between crystalline and amorphous carbon phases was optimised after investigation by Raman analysis on the single carbon fibers. Afterwards, electrodeposition of the Cu film on the carbon fibers support was achieved starting from an aqueous solution containing $Cu(NO_3)_2$ at room temperature and atmospheric pressure. The optimized catalyst was employed to carry out the CO_2RR in a typical H-Cell, in which a Nafion membrane divided the cathode side, containing the working electrode, from the anode side where a platinum gauze and Ag/AgCl electrode were used as counter and reference electrodes, respectively. The reaction was performed for one hour in $NaHCO_3$ aqueous solution. All the liquid products were collected in the catholyte and analysed by quantitative H^1-NMR, while the gas products were first collected in a gas sampling flask and analysed by Gas Chromatography. As first preliminary tests, several reactions were carried out both in continuous and discontinuous CO_2 flux at -1.1 V and -0.7 V vs RHE in which a CO faradaic efficiency (FE) up to 4,36% was obtained with a FE for H_2 evolution of 63,80% for the gaseous product. As for the liquid products, formic acid (up to FE = 4.46%) and acetic acid (up to FE = 6.69%) were obtained.

The increasing use of mobile devices and electric vehicles has brought as one of the greatest challenges of contemporary civilization the need for batteries that supplies this energy demand. Recently, spontaneous potential oscillations have been identified during the process of discharging lithium-oxygen batteries. Nonlinear dynamics in these systems are known to occur under conditions far from thermodynamic equilibrium as a result of the interaction between kinetic instabilities and mass transport properties. Understanding, therefore, the reaction mechanism can provide important clues to the birth and evolution of this temporal complexity, thereby enabling precise control and prevention of battery efficiency collapse. It was used lithium halides salts acting as redox mediator in the electrolyte composition, since during the oxidation of Li, the X^- of LiX is oxidized to X_3^- providing a decreasing in the charge overpotential. Besides that, the halides presence can act as a diffusional component that could help the emergence of electrochemical instabilities. Thus, it was assembled Li-O_2 batteries cells with and without LiBr which was submitted to different galvanostatic charge/discharge conditions in to comprise the effect of this species in the electrolyte. It was observed that the presence of bromide reduced the charge overpotential and improved the cyclability. Besides that, the role of applied current was evaluated and higher it was, less completed cycles were obtained. After determining an interval of current operation, galvanodynamic experiments will be conducted to obtain conditions under which spontaneous potential oscillations emerges. Thereby, it will be designed appropriated cells in which in operando experiments will be conducted to monitor spontaneous emergence of patterns with temporal resolution. Then, it is hoped to understand how experimental parameter can impact the nonlinear dynamics observed during the battery operation. Figure 1 presents the results obtained in cyclability Li-O_2 batteries tests with and without LiBr as redox mediator and using different galvanostatic conditions.

Conversions between O_2 and H_2O are an important part of many renewable energy production technologies. Alkaline water splitting electrolysis (Oxygen Evolution Reaction-OER) is considered as an effective and environmentaly acceptable route for the production of hydrogen and oxygen gas required as resources for energy production via fuel cells. Also, with the approaching commercialization of PEM fuel cell technology, search for active, inexpensive non-precious metal ORR catalyst materials to replace currently used Pt-based catalysts is necessary in order to reduce the system cost.

These renewable energy solutions require active, stable and low-cost electrocatalysts. In this work, we present our results on iron manganite synthesized by a relatively new synthesis method as a catalyst material for both OER and ORR reactions.

$FeMnO_3$ was synthesized via a sol-gel combustion synthesis process using glycine as fuel and nitrate ions as oxidizing agents and iron nitrate nonahydrate and manganese nitrate hydrate as precursors. After vivacious combustion a black ash-like powder was obtained. The amorphous powder was then sintered at 800 °C for 6 hours and structurally, morphologically and texturally characterized [1]. XRD showed phase content of a pure bixbyite cubic structure. The structure recorded with TEM and FESEM can be described as a plate-like, net-like formation, with particles ranging from 0.2 to 1 μm. About 10-20% of the particles' surface area was interconnected, as estimated from TEM images. With Kubelka-Munk function extracted from the light absorption spectrum the band gap of the synthesized powder was determined to be 1.69 eV, slightly lower than reported in literature.

$FeMnO_3$ was tested as a catalyst anode for both oxygen evolution reaction (OER) and oxygen reduction reaction (ORR) via linear voltammetry (LV) with Nafion as the carrier polymer agent, carbon black and graphene oxide. In OER $FeMnO_3$ with nafion as a carrier polymer agent exhibited 4.4 A g^{-1} mass activity and 3.3 A cm^{-2} surface activity, while in ORR activity was 2.4 A g^{-1} and 1.2 A cm^{-2}. Charge transfer resistance was measured by electric impedance spectroscopy (EIS) and mathematically fitted and was found to be relatively low (OER: $R_{CT}=27\ \Omega$ at E=1.15 V, ORR: $R_{CT}=230\ \Omega$ at E=-0.5 V). Electrode stability was tested with chronoamperometry (CA) measurements during 1 hour and the material maintained 57% of the initial current jump at the end of the trial period at the potential of E=1.15 V.

ABSTRACT: Noble metal catalysts have extraordinary catalytic activity but suffer from high cost; therefore single atom catalysis attracts tremendous attention. Here, we propose atom-scale dispersed palladium (Pd) in a layered TaS_2 lattice to form new compounds of Pd_xTaS_2, whose crystal structure was resolved by powder X-ray diffraction. The electrical conductivity of metallic $Pd_{0.1}TaS_2$ (1.36×10^4 S m^{-1}) is twice as large as that of TaS_2 (6.18×10^3 S m^{-1}). This compound applied as a new electrocatalyst for the hydrogen evolution reaction (HER) exhibits excellent catalytic performance with an onset overpotential of 77 mV, superior to those of other catalysts such as TaS_2 (295 mV) and Pd-loaded TaS_2 (114 mV). Density functional theory calculations reveal that the interaction of Pd-4*d* and Ta-5*d* orbitals results in the upshift of the Fermi level (TaS_2 *versus* $Pd_{0.1}TaS_2$) to decrease the barrier height for the HER. Furthermore, the hybridization of Pd-4*d* and S-3*p* orbitals builds up pathways along the c axis to improve the conductivity and promote HER performance. It is noted that the amount of Pd used in $Pd_{0.1}TaS_2$ is only 4 *wt.*%, compared with 20 *wt.*% in commercial Pd/C catalysts, which is beneficial for its practical application.

Carbon Nanomaterial-modified Inkjet Printed Silver Nanoparticle Paper Electrodes for Adsorptive Stripping Voltammetry of Ni(II)-chelate complexes

The development of low-cost, disposable electrode materials has been at the forefront of sensor technology in recent decades. Paper, offers possibilities for multi-functional, disposable and economically friendly sensing capabilities and has proved to be a suitable reagent storage and substrate material in paper-based analytical devices (PADs). In this work, we report a simple inkjet printing procedure on photographic paper for the fabrication of single analyte electrochemical sensors. A three-electrode systems, consisting of a 3 mm diameter working electrode (WE), a counter electrode (CE) and a reference electrode (RE) were prepared by inkjet printing of silver conductive inks. In a second step, modification of the working electrode surface with (a) an electrochemically reduced graphene oxide, gold nanoparticle (ERGO-AuNP) film, to improve electrode sensitivity and (b) a nafion dimethylglyoxime carbon black (N-DMG-CB) ink, as an environmentally friendly, metal-free approach was employed. Electrical and topographical characterization of the printed layers was performed in the fabrication process. Printing of Ag-NP ink showed good resistivity (1.8 – 6.3 Ω) on photographic paper. The prepared printed paper-based electrodes (PPE) offer a quantitative analysis of Ni(II), based on the accumulation of $Ni(dmgH)_2$ complexes at the modified electrode surfaces by square-wave adsorptive cathodic stripping voltammetry (SW-AdCSV). Instrumental parameters including deposition potential and deposition time were optimized for both electrochemical sensors. Improved sensitivities were achieved at the modified integrated electrodes with limits of detection (LOD) of 32.19 and 48.01 $\mu g\ L^{-1}$ for the ERGO-AuNP-CC-Ag-PPE and N-CB-DMG-Ag-PPE respectively. This is well below the EPA and WHO standards of 0.1 $mg\ L^{-1}$ or 0.1 ppm for Ni^{2+} in drinking water.

Exploring the Interfacial Behavior of Aluminum Electrodes in Ionic Liquids: an Impedance Study

Jinfeng Zhao, Ove Oll, Georg Gorbatovski and Enn Lust
Institute of Chemistry, University of Tartu
Ravila 14a, 50411 Tartu, Estonia
jinfeng,zhao@ut.ee

The expansion of renewable energy production and the growing number of energy storage devices demand improved and low-cost electrochemical energy storage technologies. To meet the future needs of energy storage, novel materials with high energy densities, readily available raw materials and safety are required [1]. Aluminum as the most abundant metal in the earth's crust attracts the electrochemists' attention, especially as the established recycling technology and price make aluminum very cost efficient. However, for aluminum as an anode in secondary battery some challenges remain. Pristine aluminum is intrinsically protected by a passive Al_2O_3 layer. This layer has two effects: making redox potential more positive and limiting the exposure of the active surface [2]. Furthermore, when aluminum has been used as the current collector in supercapacitor, the contact resistance increases over time.

Room temperature ionic liquid (IL) electrolytes present new possibilities for nonaqueous aluminum ion battery owing to their tunable physicochemical properties. One of main advantages is the high electrochemical stability [3]. However, several disadvantages of using ILs as electrolytes for aluminum batteries remain. One is the decomposition and dissolution of the cathode materials in chloroaluminate-based ILs. Another is the possibility of side reactions in chloroaluminate-based ILs. Worse, the chloroaluminate-based ILs are highly corrosive, hygroscopic and viscous, all of which aggravate their limitation as an efficient battery electrolyte [2]. Therefore, it is of importance to explore suitable non chloroaluminate-based ILs toward to aluminum battery electrodes.

Considered the above statements, it is of importance to address the covering layer when establishing an electrochemically active interface between the Al anode and the IL electrolytes. After all, electrochemical reactions at the interface reflect the fundamental understanding of the interfacial processes governed by double layer formation at electrode|IL interfaces. To overcome those obstacles, the interfacial behavior of Al and Al(111) electrodes in ILs is studied by cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) methods. Three different IL anions have been chosen for this study with the same cation 1-ethyl-3-methylimidazolium (EMIm), namely, bis(trifluoromethylsulfonyl)imide (TFSI), tetrafluoroborate (BF_4) and perchlorate (ClO_4). From the EIS results, relatively low capacitance values for capacitance vs. potential curves in the three studied ILs have been observed. The average capacitance value in this study are much lower than what have been shown in literature [4]. This implies that the fully metallic Al surface cannot be obtained from the ILs under this study. Interestingly, within the negative polarization range, the average capacitance values in three ILs can be clearly distinguished from the different anions. That is, it shows the lowest average capacitance values for the large TFSI anions. It suggests that, with regard to the ILs themselves, the interaction of IL and aluminum surface can form an anomalous layer structure which limits the exposure of the single crystal Al electrode. The stability of this surface layer has been explored.

gabriellaguaita@hotmail.com

The growing demand for lithium-ion batteries may, in the future, limit the available lithium resources, significantly influencing the cost and the own survival of technology. Therefore, new materials are investigated to replace the non-abundant and expensive raw materials that constitute the available cathode active material on lithium-ion batteries.[1] Among the emerging technologies, the one that uses sodium ion and iron stands out. Sodium orthoferrite, $NaFeO_2$, shows polymorphism with the α-phase stable up to 770 ºC and the β-phase stable at higher temperatures. The phase α-$NaFeO_2$ presents a lamellar structure that allows the diffusion of sodium ions in two dimensions, enabling its use as a cathode of Na^+ based batteries.[2] The investigation of this material is essential for the commercial application of these batteries. Thus, the aimed of this study was to synthesize α-$NaFeO_2$ via sol-gel route, not yet described in the literature, and to verify its crystallographic, morphological and electrochemical properties. The effect of the concentration of chelating agent (citric acid), of the calcination temperature and time, on the synthesis, were studied. X-ray diffraction shows the tendency to the formation of the α-phase in the ratio of 1:2 of citric acid and metals. By Rietveld's refinement of the calcined sample at 600 ºC for 4 days it was verified that the only phase containing the iron was α-$NaFeO_2$ with contamination with Na_2CO_3 of less than 5%. Spherical grains of the order of 200 nm were observed by scanning electron microscopy. Using the BET method, it was observed that the α-NaFeO2 phase synthesized by the sol-gel route had a surface area 4 times greater than that described in the literature for solid state synthesis. Electrochemical performance measurements revealed a charge capacity for the first cycle of about 113 $mA\ h\ g^{-1}$ in the potential range of 1.00 to 4.00 V *vs.* Na^+/Na. Even higher discharge capacity values, as well as superior electrochemical performance can be achieved by improving the synthetic parameters of the new route are in progress.

Lithium metal is considered the ultimate anode for energy-storage systems for its extremely high theoretical specific capacity (3860 mAh g−1), the lowest redox potential (−3.040 V vs the standard hydrogen electrode) and a low gravimetric density (0.534 g cm−3) [1]. However, the main issue associated with this electrode is the growth of metal dendrites, also known as high surface area lithium (HSAL), during charge/discharge cycles. Therefore, there is a great interest in the study of the mechanism of HSAL formation and the effect of the different variables involved. The final goal is the possibility to tune these variables to control the formation of HSAL. Such control remains elusive probably because it requires an important feedback between theory and experiments. Molecular simulations could help to improve this feedback, although the construction of an *ad hoc* model that connects the simulations parameters with the experimental measures is required. We have developed a computer model based on that of Mayers et. al. [2] to simulate the HSAL growth. One side of the simulation box, say the bottom, is considered an ideal electrode where lithium ions can be reduced and deposited. On the opposite side, the simulation box is connected to a constant density reservoir of lithium ions that maintain the system at a constant chemical potential. The motion of lithium ions is integrated using the Langevin equation that, together with the reservoir, set the system in the μVT thermodynamic ensemble. The deposition is a random event with probability P that may occur when a lithium ion approaches the implicit electrode or a previously deposited metal atom. This probability P can be connected to the experimental cell current. In this work we present the effects that different P values have in the resulting HSAL morphologies. The study of other processes like dissolution or surface diffusion within this model, and further extensions, are discussed.

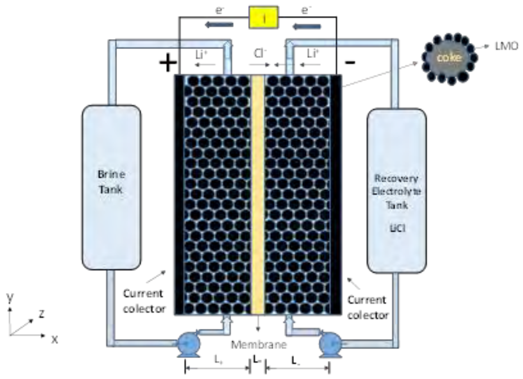
calvo@qi.fcen.uba.ar

We consider an electrochemical flow reactor with two compartments separated by an anion (chloride) selective membrane. The electrochemical reactor is comprised of two 3D compact porous bed electrodes with conducting petroleoum coke particles covered by the spinel oxide $LiMn_2O_4$. The cathode is a lithium deficient $Li_{1-x}Mn_2O_4$, and the anode is $LiMn_2O_4$, which exchange lithium ions. The architecture of this flow electrochemical reactor is similar to a vanadium flow battery and operates by a rocking chair lithium intercalation mechanism of lithium ion batteries



The reactions in each electrode are the following:

In the negative electrode,

$$LiMn^{III}Mn^{IV}O_4 \rightarrow Li_{1-x}Mn^{III}_{1-x}Mn^{IV}_{1+x}O_4 + xLi^+ + xe$$

in the positive electrode:

$$LiMn^{III}_{1-x}Mn^{IV}_{1+x}O_4 + yLi^+ + ye \rightarrow Li_{1-x+y}Mn^{III}_{1-x+y}Mn^{IV}_{1+x-y}O_4 \; (0 \leq x \leq 1, \text{ and } y \leq x)$$

We will present digital simulation (COMSOL® 5.2a) results of the interfacial intercalation, ion diffusion in the $LiMn_2O_4$ particles, ion transport by diffusion and migration under tertiary current distribution and liquid electrolyte circulation under constant current applied to the reactor. We analyze the experimental and digital simulation results with plots of cell voltage vs. time (or charge) under constant current and lithium concentration with a potentiometric ion selective electrode.

From the simulation results we obtain plots of concentration distribution in the electrolyte and electric potential in the electrodes. We have also studied the effect of Li^+ concentration, flow velocity, current density, etc.

We will present results of LiCl extraction in two steps, from natural brines of Olaroz and Hombre Muerto (Argentina), Uyuni (Bolivia) and Atacama (Chile) which demonstrate the method works with different natural brine compositions.

Method for the Accurate Prediction of pK_a and Electron Transfer Potentials from ab-initio Calculations

Michael Busch[1*], Elisabet Ahlberg[2], Kari Laasonen[1]
[1] Department of Chemistry and Materials Science, Aalto University, Espoo, Finland
[2] Department of Chemistry and Molecular Biology, University of Gothenburg, Gothenburg, Sweden
Michael.Busch@aalto.fi

The ability to efficiently and accurately predict acid dissociation constants (pK_a) and electron transfer (ET) potentials is critical for the success of computational methods in electrochemistry. Proton coupled electron transfer reactions are typically modeled using the computational hydrogen electrode A comparable simple and efficient procedure is, however, still missing for pure electron transfer reactions. Here, typically the absolute potential is used to compute the redox potential. While this method is computationally efficient it interferes with the inherent cancellation of errors from density functional theory (DFT) and implicit solvation models. The alternative use of a well studied and computationally undemanding electrochemical reference reaction such as the oxidation of a simple organic molecule, which would allow for this cancellation of errors, is limited by the almost complete absence of reliable electrochemical measurements for suitable compounds. This is opposed to the dissociation constants of acids which can be obtained experimentally with high accuracy for almost any material.

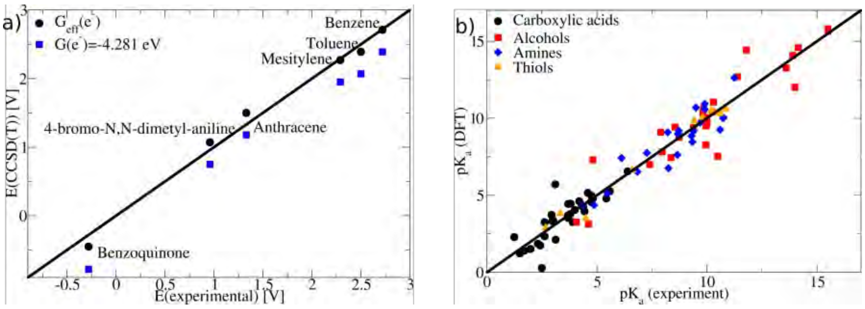


*Figure 1: : a) Comparison of ET potentials computed using coupled cluster CCSD(T)/Def2-TZVPP with experiment. b) Comparison between computed acid dissociation constants (PBE0/6-311++G**/SMD) using the effective proton solvation energy $G_{eff}(H^+)$ after correction for chemical similarity and experiment.*

In this contribution we will show a thermochemical cycle which connects the pK_a with electron transfer and proton coupled electron transfer reactions. This allows us to determine an effective absolute potential $G_{eff}(e^-)$ and an effective proton solvation energy $G_{eff}(H^+)$ for any ab-initio or DFT method using the experimentally well defined pK_a of an arbitrary acid as reference reaction. $G_{eff}(e^-)$ can be used to predict the ET potential. A comparison of high level coupled cluster CCSD(T) calculations with experimentally well characterized ET reactions on small organic molecules shows that our method is, due to the superior cancellation of errors, able to predict energetics of ET reactions with high accuracy (Figure 1a). In a subsequent benchmark with respect to CCSD(T) results the best performing DFT functionals were extracted.

In addition to computing ET potentials our method also allows for the prediction of pK_a values using the effective proton solvation energy $G_{eff}(H^+)$. The accuracy of the method can be increased further by including corrections for the differences in chemical similarity between the functional group considered in the reference reaction and those of the molecule of interest. The accuracy of the effective proton solvation method was tested for a set of 73 organic molecules with varying complexity. Our computations indicate that pK_a values can be predicted with chemical accuracy (Figure 1b).

Synthesis of activated carbon using sugarcane bagasse

Thaynara M. Costa, Daniel C. Sperandio, Nicolas P. Moraes, Leandro C. Trevelin, Ricardo B. Valim,
Liana A. Rodrigues, Robson S. Rocha*
Escola de Engenharia de Lorena – Universidade de São Paulo
Estrada do Campinho, sn, CEP 12602-810, Lorena, SP, Brasil
**robson.rocha@usp.br*

In the process of electrochemical synthesis of hydrogen peroxide, the main area is the development of the electrodic material modifier for oxygen reaction reduction (ORR) with the formation of H_2O_2. The present study evaluates the viability of using activated carbon from sugarcane bagasse (SCB) as organic carbon source, for the H_2O_2 electrochemical generation.
The sugarcane bagasse was crushed, washed and impregnated with H_3PO_4 solution (0%, 5%, 10%, 20%, 30%, 40% and 50%) for 3 days. Then, these materials were dried in an oven (3 hours at 150 °C) and calcined at 700 °C for 1 hour (heating rate 5 ºC min^{-1}). At the end of the process, the calcined material was ground to obtain a fine powder. For electrochemical tests, porous microlayers were prepared with each material following the literature[1]. Electrochemical experiments were performed with linear sweep voltammetry on microlayers of different materials deposited on an electrode rotating ring (Pt)-disk(GC). The electrochemical measurements were obtained with electrolyte K_2SO_4 0.05 mol L^{-1} (pH 2) using a potentiostat PGSTAT-bi-204N (Autolab/Metrohm) and RRDE (Pine Research).

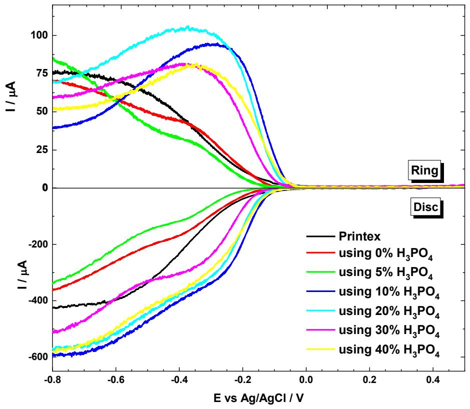

Figure 1: LSV catalyst (ORR) of SCB impregnated with H_3PO_4 and calcined at 700 °C for 1 h under uncontrolled atmosphere

The initiation reaction occurs from the potential of -0.15 V and the current diffusion limit starts from -0.3 V and -0.4 V for material with 10% and 20% of H_3PO_4, respectively. The analysis of the graph was based on the values above -0.2V, because it is possible to notice that with smaller values, the potential tends to zero volts, forming less hydrogen peroxide. By comparing the carbon values of SCB with acid to that without acid and Printex, it is already possible to see from the current values the effectiveness of the application of the acid. Note two important information in Figure 1, first is the maximum current reached in the ring, which the material with 20% acid reached approximately 110 μA compared to the Printex with 75 μA. Another important point is the potential at which these currents were observed, the SCB with 20% H_3PO_4 reached the maximum current at -0.4 V while the Printex reached the maximum current at -1.0 V.

ncholu.manyala@up.ac.za

Porous carbons are key electrode components of many electrochemical energy storage/conversion systems. With the aim of exploiting wasted derived by biomass plants, here, lignin was valorized as raw material for the production of carbons with tailored porous texture for a use in electrical double layer capacitors (EDLCs) and microbial fuel cells (MFCs). The lignin-derived activated carbon (LAC) was generated by a one-step carbonization route using $KHCO_3$ as mild activating agent. Different lignin-to-$KHCO_3$ ratios were explored. The performance of the LAC carbon electrode was investigated in supercapacitors and for oxygen reduction reaction (ORR) at neutral pH. LACs obtained at biomass/$KHCO_3$ mass ratios of 1:0.5 and 1:2 (LAC-0.5 and LAC-2) comprised of mesopores and micropores and displayed BETs of 1558 m^2g^{-1} and 1879 m^2g^{-1}, respectively. LAC-2 exhibited a superior specific capacitance and ORR electrocatalytic activity. A symmetric supercapacitor with LAC-2 electrodes and 2.5 M KNO_3 electrolyte displayed a specific capacitance of 28.5 F g^{-1}, corresponding to an electrode specific capacitance of 114 F g^{-1}, a specific energy of 10 Wh kg^{-1} and a specific power of 397 W kg^{-1}. A capacitance retention of 84.5% after 15,000 charge-discharge cycles was demonstrated. The ORR kinetics at LAC samples were studied using a rotating disk electrode (RDE) in a neutral medium. LAC-2 showed the highest electrocatalytic activity. The better performance of LAC-2 vs LAC-1 can be explained with a better interconnected porous network and higher surface area that make that the former lignin-derived porous carbons suitable electrode materials for dual applications, EDLCs and MFCs..

Nickel is widely used in energy storage and conversion, e.g. nickel-iron, nickel-cadmium, and nickel-metal hydride batteries. The behavior of nickel electrodes has been investigated extensively. However, a detailed understanding of surface processes on the atomic level is still missing.[1,2] In particular, there have been only a few fundamental studies of nickel single crystal electrodes related to their electrochemical oxidation.[3] The initial stages of the electrochemical deposition of nickel have been studied on Au(111).[4] The electrochemical fabrication of thin nickel overlayers on Au(111) and their electrochemical characterization have been investigated in detail.

The nickel overlayers have been electrochemically deposited onto Au(111) from a 0.01 M $NiSO_4$ solution and subsequently characterized by cyclic voltammetry in a 0.1 M KOH solution. Metallic nickel is highly sensitive to oxidation by ambient air, which requires very careful handling of the electrodes.[2,3] The transfer of the electrode from one electrochemical cell to the other has been done under inert gas atmosphere to guarantee stability and electrochemical performance of the nickel electrode surfaces. Figure 1 shows the current density-potential curve of a nickel overlayer on an Au(111) single crystal in comparison with the behavior of Au(111) and Ni(111) in 0.1 M KOH. The study of nickel monolayers on Au(111) helps to identify surface and bulk contributions of Ni electrooxidation. In addition, relations between structure of the Ni electrodeposit and its electrochemical behavior are addressed.

Monitoring temperature and humidity/moisture is widely present in many domestic, industrial and medical applications. Nickel manganite, a transition metal oxide cubic spinel oxide, has been previously applied as a Negative Temperature Coefficient (NTC) ceramic material for temperature sensing due to its stable characteristics, low room temperature resistivity and moderate temperature sensitivity. Electrospinning is a method used to obtain nanofibers from a solution using electric force generated by high voltage. Nickel manganite ($NiMn_2O_4$) nanofibers were obtained by electrospinning and subsequent calcination at 400 °C. TG/DTA of the as-spun fibers was performed. X-ray diffraction analysis confirmed the formation of a cubic spinel structure. The fiber surface area and pore size distribution was estimated using nitrogen porosimetry. The morphology of as-spun and calcined nanocrystalline nickel manganite nanofibers was analyzed by Scanning Electron Microscopy (SEM). Initial investigation of the material constant (B) of the nickel manganite nanofibers applied as paste on test interdigitated electrodes on alumina substrate, dried at 100 °C was determined as 4379 K in the temperature range 20-50 °C and temperature sensitivity of -4.95%/K at room temperature (25 °C) and is comparable with commercial devices using spinel based NTC ceramics, confirming the potential for application in flexible temperature sensors. Complex impedance monitored at room temperature (25 °C) in a climatic chamber in the relative humidity range 40-90% decreased noticeably with increase in humidity showing that this material can also be applied as a humidity sensor.

Electrochemistry and thermoelectrochemistry of ‘super-concentrated’ ferricyanide/ferrocyanide systems

Kristine Laws, M. A. Buckingham, L. Aldous
King’s College London
Britannia House, 7 Trinity Street, London SE1 1DB
kristine.laws@kcl.ac.uk

Internationally, most energy is produced from heat sources, such as fossil fuels or nuclear, where the vast majority of this is lost as low-grade waste heat. [1] However, waste thermal energy can be converted directly into electricity using electrochemistry. This can be achieved by an entropically driven thermoelectrochemical process, which uses a dissolved redox couple sandwiched between two electrodes held at different temperatures, as part of a thermoelectrochemical cell (or thermocell). [2] The $[Fe(CN)_6]^{3-/4-}$ redox couple is arguably the most investigated redox couple in thermocells; this is due to the high Seebeck coefficient, and fast-reversible electrode kinetics, resulting in high power outputs. [3] The power density of $[Fe(CN)_6]^{3-/4-}$ thermocells is known to scale proportionally with concentration [3], where the saturation limit at ambient temperature in aqueous solvent of the typically employed $K_{3/4}[Fe(CN)_6]$ redox couple is *ca.* 0.2 M of both $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$. A combination of alkali metal cations in the $[Fe(CN)_6]^{3-/4-}$ thermocell is known to have a synergistic effect on both the thermodynamics (Se coefficient) and kinetics (electrocatalysis) of the system.

Therefore, we investigate ‘super concentrated’ $[Fe(CN)_6]^{3-/4-}$ thermocells using a combination of the $K_3[Fe(CN)_6]$ and $Na_4[Fe(CN)_6]$.[4] Whereas K_3/K_4 have a combined solubility of 0.4 m (molal) when K_3/Na_4 are combined they have a combined solubility of 1.6 m, effectively 4-fold higher. Ultimately, the higher concentration increased the current and the power produced by the thermocell significantly, however, at very high concentrations, a plateau was also observed meaning that a 4-fold increase in concentration only resulted in an *ca.* 1.5x increase in the power produced. In order to investigate this phenomena, conductivity, viscosity, cyclic voltammetry simulation and rotating disk electrode (RDE) voltammetry were conducted and the results will be discussed in this poster.

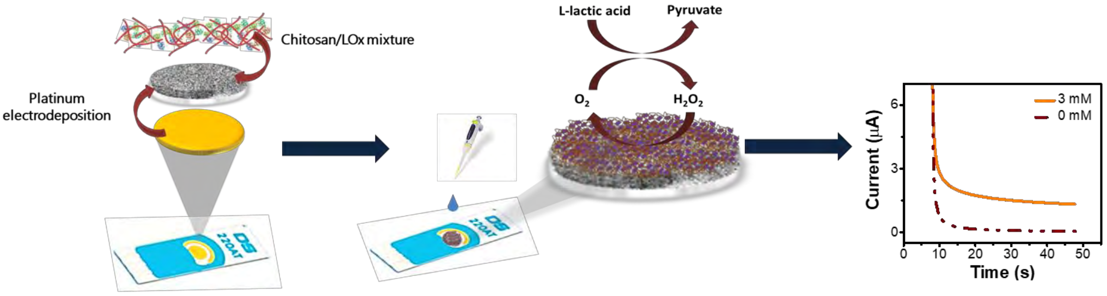
Julia.madden@tyndall.ie



Graphical Abstract

Abstract:

Blood lactate levels are used as an indicator of physical fitness as well as being of interest in the clinical diagnosis of a number of conditions. An increase in lactate levels has been linked with hypoxia [1], endotoxic shock [2], sepsis [3], diabetes [4] in addition to cancer diagnosis [5]. Blood lactate levels of a healthy human at rest have been reported at 0.5 mM - 2 mM [4]. Here we report a two-step modification with Platinum and a Chitosan/Lactate oxidase mixture to the gold planar screen printed disc electrode (Au/Pt/CHT-LOx) for electrochemical enzymatic lactate detection. This Au/Pt/CHT-LOx electrode was examined using chronoamperometry at 0.3 V vs. Ag SPE. The modified electrode responds linearly from 0 to 3 mM of lactate. The relative standard deviation (RSD) towards detection of a 1mM lactate concentration was determined to be 6.52% (n=4) demonstrating a good level of reproducibility. The sensor was challenged against the following interfering species: 5 mM glucose, 0.05mM L-ascorbic acid, 0.2 mM Uric acid and 10 μM acetaminophen. A 2.5 mM lactate response increased by 2 % in the presence of interfering species (n=4). The operational stability was assessed by carrying out 10 successive measurements in 1 mM lactate on three electrode surfaces. The RSD of each respective electrode was calculated to be 8 %, 4.7 % and 5 % indicating excellent re-usability.

Gold nanoparticles (AuNPs) are the most ancient metal nanophase ever used and they are among the most common metal nanomaterials employed even today [1]. Among the methods for metal nanoparticles preparation, the chemical reduction of metal ion species is widely applied, based on the use of precursor and reducing/stabilizing agents. Recently, few research groups have proposed steel corrosion to assist the synthesis of metal nanoparticles starting from a precursor salt, typically $HAuCl_4$ [2,3]. In this approach, stainless steel can be used as removable solid reductant in the aqueous preparation of gold nanocolloids. This innovative method is very easy, quick, cost-effective and scalable allowing the synthesis of highly stable nanoparticles without additional capping agents. However, the mechanisms behind this reaction are not yet fully understood. To date, two distinct reaction pathways have been proposed. According to the first hypothesis, Cl^- penetration through the passivating oxide layer on steel is invoked, thus assisting steel surface corrosion [2]. The second one considers that hydrogen, which is formed as a consequence of the reduction of protons mediated by the steel substrate, reduces $AuCl_4^-$ ions yielding AuNPs [3]. In order to support the system investigation, we carried out the syntheses recording the open circuit potential (OCP) to potentiometrically explore the electrochemical behavior of steel and track the solution potential [4]. The *operando* OCP monitoring has never been examined and it is useful to assess the role of steel corrosion in the synthesis mechanism. In particular, the experimental setup for AuNPs syntheses and simultaneous recording of OCP values consisted of a two-electrode cell, including the stainless steel working electrode mounted on a rotating bar and an Ag/AgCl (KCl sat.) reference electrode. The recorded potentials during OCP measurements are a combination of reduction potential of $AuCl_4^-$ ions in solution and corrosion potential of stainless steel. In addition, different experimental settings that may influence the synthesis process and final nanoparticle properties were evaluated. Particularly, the role of Cl^- concentration, pH of the precursor solution, as well as steel composition are described. In general, different initial potential values and OCP trends were found, depending on experimental settings. The OCP decrement towards more negative values reported in some cases suggested a higher trend to oxidation and a progressive dissolution process of steel metals such as iron, chromium and nickel. This phenomenon promotes the reduction of Au^{3+} to Au^0, thus leading to AuNPs synthesis. Hence, the different corrosion behaviors were examined and the best conditions for the AuNP synthesis were established. These findings were supported by a deep spectroscopic and morphological characterization carried out to correlate the synthesis parameters with the AuNPs characteristics. will be discussed. In this communication, results of OCP experiments together with the complete analytical characterization will be presented demonstrating the validity of this approach.

Abstract

In this work we synthesized carbon supported Ag 20% (w/w) nanoparticles (NPs), and then we successfully decorated them with ultra-small (0.8%) quantities of Pt. The resulting electrocatalyst was tested for the electrooxidation of glycerol. XRD, ICP, XPS, TEM and electrochemical characterization strongly support that the Pt atoms are located at the sub-surface of the Pt(0.8%)Ag/C and that the electrochemical excursion until the Ag_2O formation induces the Pt atoms segregation activating the material for the hydrogen evolution reaction, hydrogen Oxidation reaction and electrooxidation of glycerol (figure 1a). We showed that the Pt atoms of our catalyst are one order of magnitude more active (in terms of mass activity) than Pt/C commercial catalyst (Figure 1b).

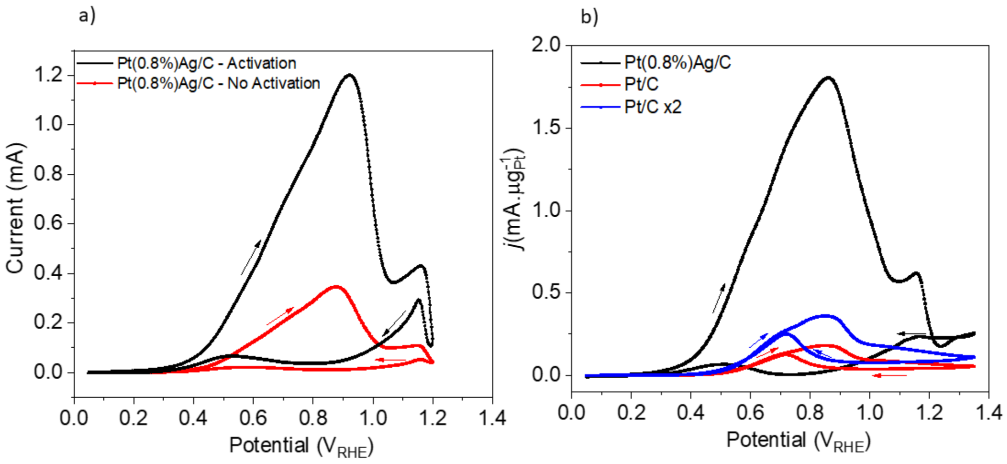

Figure 1. Cyclic voltammograms obtained in 0.5 mol.L^{-1} NaOH and 1.0 M GlOH solution at scan rate 10 mVs^{-1} for Pt(0.8%)Ag/C activation and no activation (**a**) and Pt(0.8%)Ag/C and Pt/C Normalizing the data by the Pt mass (**b**).

By performing *in situ* FTIR measurements, electrolysis experiments and HPLC analysis, we showed that both catalysts form mainly glycerate and lactate[1], but Pt/C is more prone to poisoning and to break the C-C bond of the molecule to form carbonate[2]. We suggest that this different behavior is attributed to the high dispersion of the Pt atoms on Ag NPs. The lower probability of finding neighboring Pt atoms (compared to Pt/C) diminishes the formation of multiple bonded intermediates, which are precursors for the formation of carbonate and some poisoning intermediates[2].

Enhanced oil recovery (EOR) technology is getting more attention, in which water flooding is one of the most common, economical, and efficient methods for secondary oil recovery. Generally, produced water or formation water from the oil well used for this purpose. This water consists of an aggressive ion such as chloride, sulfate, and bicarbonate ion that cause the failure of oil well pipelines. There are many techniques used to mitigate the corrosion inside the pipes. Meanwhile, cerium nitrate inhibitors are considered as an efficient inhibitor to use for different metals and alloy due to its low cost, abundance, and eco-friendly. Owing to this, cerium nitrate is investigated as an inhibitor for various solutions such as Sodium chloride, sodium sulfate, and sodium bicarbonate solution.

Further, immersion test, electrochemical polarization test, and electrochemical impedance spectroscopy are employed to study the corrosion inhibition. Consequently, the morphology and composition of inhibitor film formed on the metal surface are determined by SEM, XRD, and FTIR and discussed in detail. Based on all the results, cerium nitrate inhibitor found to be an efficient inhibitor in the case of bicarbonate and sulfate ion-containing solution with higher inhibition efficiency as compared to the chlorine ion-containing solution. The results proved that cerium nitrate inhibitor could be utilized as promising corrosion inhibitors for various industrial applications.

~~The Wet Etching Approach for Decreasing the Thickness of Mesoporous Silica Films Generated by Electrochemically Assisted Self-Assembly~~

~~Taisiia Sikolenko, Christelle Despas, Neus Vilà, Alain Walcarius~~
~~*Laboratory of Physical Chemistry and Microbiology for the Environment*~~
~~*UMR 7564, CNRS / Université de Lorraine*~~
~~*Taisiia.sikolenko@univ-lorraine.fr*~~

~~The design of new electrochemical sensors and their nanometrenanometre scale modification is always a challenge for scientific community. Electrode coatings based on organized mesoporous silica films (MSFs) is one of the branches which develops rapidly with respect to all demands[1]es[1,2]. Combining electrochemistry and sol-gel process (electrochemically assisted self-assembly, EASA[23]), the thin (thickness around 100 nm[34]) organized films with hexagonal mesostructure and pores, perpendicularly oriented to the electrode support cylindrical pores (2-3 nm in diameter), they can be obtained. The thickness of deposited film is important, since its decrease may help to facilitate mass transport through to non-inert silica poresTdecrease [56], to lower the unwanted accumulation of analysed probe and, hence, to gain in electrochemical response.~~

~~Under the operated conditions (100 mM TEOS, 32 mM of CTAB, 10 s of deposition at -1.3 V potential applied to ITO electrode), the generation of defectless and homogeneous MSFs gives a rise to a minimum thickness equal to 79±10 nm. With the aim of obtaining the thinner film, post-treatment by ammonium fluoride solution[7] (also known as wet etching procedure) was applied to deposits[4]. It was shown, that the evolution of the film thickness measured by profilometry ,with[8]time with etchant insideis the function of contact time between the etchant and silica sample. The presence of covalently bonded to MSF surface ferrocene species did not interfere the silica dissolution. Instead, the reduction of its electrochemical response while etching appeared to be another way to follow the film thickness decrease[5]. Transmittance electron microscopy characterization demonstrated that the vertically oriented hexagonal structure is still preserved after 1 hour reaction with 0.05M NH_4F while tAfter treatment, tt[9].he thickness becomes a third less relatively to the initial value.~~

~~The practical application of wet etching approach will be checked on sensor for glyphosate (GLYP) detection. The potential hazard of GLYP and the presence of the secondary amine in its structure makes it a perfect candidate to be analyzed by the electrochemiluminescence (ECL) reaction with tris(2,2'-bipyridine)ruthenium(II) ($Ru(bpy)_3$)[6], grafted on MSF surface. Typically, the best yields of the ECL reaction between GLYP and $Ru(bpy)_3$ are observed at pH 7-10[7], but deprotonation of pesticide in these conditions leads to negatively charged analyte, what complicates its mass transport through negatively charged silica film channels. Therefore, the effect of film thickness will be taken into the account and its decrease by wet etching is expected to improve the performance of ECL sensor.with~~

Formatted: Strikethrough

Commented [DC1]: Are you sure this is the labo?

Formatted: French (France), Strikethrough, Highlight

Formatted: Space After: 8 pt

Commented [DC2]: I don't understand what you want to say. At which properties do you think?

Commented [TC3R2]: I meant that with mesoporous silica coatings it is possible to change the pore size, thicknesses, grafted functional groups so that the material becomes suitable for use for different types of analytes. And with respect to all demands caused by various possible probes, it is easy to be modified, therefore the development is fast.

Commented [DC4]: NO It is not true : the silica wall presents at its surface silanolate groups. I think that these groups are not completely inert!!!

Commented [TC5R4]: Actually, it is written there. 'Non-' is added to show the opposite meaning, so non-inert = reactive

Commented [DC6]: NO you don't use unmodified silica but Ru modified film that lead to a global positive charge in the pore

Commented [DC7]: Reference : Highlighted text to be completed, corrected

Wet Etching Approach to Tune the Thickness of Electrochemically Assisted Self-Assembly Mesoporous Silica Films

The design of new electrochemical sensors and the continuous improvement at the nanometre scale stays a challenge for scientific community. Electrode coatings based on organized mesoporous silica films (MSFs) is one of the approaches[1,2]. By combining electrochemistry and sol-gel process (electrochemically assisted self-assembly, EASA[3]), the obtained thin (thickness 80-100 nm[4]) organized films with hexagonal mesostructure and pores, perpendicularly oriented to the electrode support (cylindrical shape with 2-3 nm diameter), they represent an interesting new class of nanomaterials. The thickness of deposited film is an important parameter influencing the mass transport ~~to~~through the electrode surface specifically because silica is a reactive material (silanol groups). The thickness decrease of silica film should reduce the diffusion constraint through the film while keeping the advantage of the coating (molecular sieve[5], preconcentration[6]) and, hence, gain in electrochemical response.

The electrogeneration of defectless and uniform MSFs onto ITO electrode (100 mM TEOS, 32 mM of CTAB) requests a minimum deposition time equal to 10 s at -1.3 V. The resultant thickness is 79±10 nm. Post-treatment of the silica film is needed to decrease its thickness. The selected approach is the drop wet etching with ammonium fluoride solution[7]. Profilometry measurements and electrochemistry monitoring (with neutral or ionic probes, or ~~with~~onto ferrocene grafted MSF[8]) report the decrease of the thickness in function of contact time with etchant and its concentration. The influence of the presence of CTA^+ kept inside the silica pores is demonstrated and discussed. Transmittance electron microscopy proved that the well oriented pores and regular mesostructure of the film is still preserved after 1 hour reaction with 0.05M NH_4F. After treatment, the coating is three times thinner than originally[9].

Field Code Changed

In view of possible application, the detection of glyphosate by electrochemiluminescence (ECL) with functionalized mesoporous silica films is also evaluated. Tris(2,2'-bipyridine)ruthenium(II) complex is grafted onto silica pores by click reaction to limit the mass transport to the pesticide diffusion through the film. The resulting ECL signal is discussed in function of the MSF thickness.

We have studied graphene oxide nanoribbons (GONRs) for a variety of applications since 2011. [1-14] In this study, Pt nanoparticles with the average diameter of around 4.3 nm were adsorbed on GONRs prepared with different microwave powers to form GONR/Pt nanocomposites. The GONR/Pt nanocomposites were then characterized by transmission electron microscopy, x-ray diffraction, Raman, x-ray photoelectron spectroscopy, and photoluminescence. For electrochemical measurements, the nanocomposites were drop casted on screen-printed carbon electrodes for methanol oxidation reaction (MOR) in an alkaline solution (1.0 M CH_3OH + 1.0 M KOH) with or without the illumination of a blue light. It was found that our Pt/GONR(200 W) exhibits the remarkable photo-enhanced MOR current density in cyclic voltammograms and the number is even higher than that of Pt/g-C_3N_4. [15] The photoeletrochemical activity of Pt/GONR nanocomposites could be due to the semiconducting nature of GONRs that may change along their processing parameters. More details of GONR/Pt electrocatalysts for photoeletrochemical MOR will be presented and discussed in this conference. These investigations on novel nanomaterials may benefit the further development of direct alkaline methanol fuel cells.

Sheet metal cutting is widely used in the tailoring of metal parts. The mechanical cutting, techniques, milling sawing, guillotine, punching, etc., are widely used but they often lead to localized material structure modifications (accumulation of unwanted residual stress) within the cutting area. Nor new techniques (Water Jet Machining, Abrasive Jet Machining, or Laser Beam Machining) cannot eliminate the disadvantages of the mechanical cutting [1]. Electrochemical Cutting (EC) can remove the disadvantages of the mechanical methods and ensure a high precision. EC is based on the controlled anodic dissolution of metals (Cu, Ni, Fe, Ti etc.) and their alloys [2]. In this research, the electrochemical corrosion and cutting of iron silicon alloys (ISA) were investigated.

The demand of soft materials like ISA in various applications like electrotechnical industry/electric power distribution systems, has greatly increased. Such materials have augmented magnetic properties due to grain size, crystallography of the material, the level of impurities (silicon concentration - up to 6.5% Si) but they lack in electrical conductivity [3, 4, 5].

The purpose of this research is to investigate the corrosion behavior during the EC of ISA in different types of electrolytes like sodium nitrate, sodium sulfate and sulfuric acid (in small concentration), in mono-component solutions and in mixtures, in order to setup an efficient (short time and small current demand) EC cutting process.

Optimal potential range, current densities, and electrolyte composition for the EC process of three types of ISA were established based on cyclic voltammetry and polarization curves.

Improvement of Analytical Characteristics of Lactate Biosensors Using Prussian Blue Nanoparticles and Siloxane-Perfluorosulfonated Ionomer Membranes

Darya V. Vokhmyanina, Elena E. Karyakina, Arkady A. Karyakin

vokhmyanina@gmail.com

Prussian Blue is recognized as the most advantageous low-potential transducer for hydrogen peroxide [1]. Due to high catalytic activity and selectivity which were comparative with enzyme biocatalysis, we even denoted Prussian Blue as ‘artificial peroxidase’. Recently we reported Prussian Blue based nanozymes [2] defeating natural peroxidase in term of their catalytic activity. Nanozymes were characterized by true enzymatic properties: (i) enzymatic specificity (an absence of oxidase-like activity) and (ii) an ability to operate in physiological solutions.

In contrast to bi-enzyme biosensors we propose the nanozyme-enzyme based ones substituting the enzyme peroxidase with the more active and stable Prussian Blue nanoparticles.

The procedure of sensor development involves the simple drop-casting of the nanozyme suspension onto the electrode surface with subsequent drying. The resulted modified electrodes characterized with even higher sensitivity to hydrogen peroxide as compared to conventional Prussian Blue sensors.

For immobilization of lactate oxidase the improved protocol with enzyme exposing to water-organic mixtures with the high content of organic solvent proposed earlier has been used [3]. Since lactate oxidase is among the less stable enzymes, further stabilization of the enzyme containing membranes is required for multiused commercial biosensors.

For this aim we've investigated the stabilization of the lactate oxidase containing siloxane membranes [4] with Nafion analogue – perfluorosulfonated ionomer (PFSI). The perfluorosulfonated ionomer induce the decrease of sensitivity of the resulting biosensors caused by negatively charged substituent able to shield the enzyme active site. However, it is possible to observe an absolute maximum of sensitivity. At the same point the apparent Michaelis constant of the corresponding biosensors displays the minimum for non-zero PFSI content in the membranes illustrating the highest affinity of the immobilized enzyme to lactate.

Operation stability of lactate biosensors has been evaluated as the number of lactate injections (0.2 mM) in flow-injection mode remaining the response at the level of 95% from its initial value. The highest operational stability has been registered for biosensors made from the mixture of 1.5 % γ-aminopropyltriethoxysilane and 0.2 % Nafion, which corresponds to the extremes in sensitivity and Michaelis constant. Operational stability of the corresponding biosensor in terms of the number of lactate injections remaining 95% activity (81 ± 4 injections) is almost 3 times higher as compared to the biosensor made without perfluorosulfonated ionomer (28 ± 3 injections). At the same time the decrease in sensitivity compared to the biosensors made without PFSI is only 35%.

Hence, an addition of 0.2% of PFSI to the membrane-forming mixture provides the significantly improved stability of the resulting siloxane based enzyme containing membranes. Thus improved protocol for lactate oxidase immobilization has been used for elaboration of the nanozyme-enzyme biosensor.

The resulting nanozyme-enzyme lactate biosensor displays twice higher sensitivity ($> 0.2\ A\cdot M^{-1}\cdot cm^{-2}$) compared to the Prussian Blue film based one [5]. Nanozymes “artificial peroxidase” are expected to find wide use in elaboration of oxidase based biosensors.

Bi-metallic IrSn catalysts supported on Montmorillonite - efficiency towards OER in PEMEC

Iveta Boshnakova, Elefteria Lefterova, Denis Paskalev, Evelina Slavcheva
Institute of Electrochemistry and Energy Systems-Bulgarian Academy of Sciences, Acad. Georgi Bonchev str., 10bl. Sofia, Bulgaria
boshnakova.iveta@iees.bas.bg

Global environmental concerns and increasing energy demands are the main drive to move from fossil fuels to renewable energy (such as wind or solar). The world has strong need for reliable, cost-effective, and renewable clean energy sources. Hydrogen shows a great potential as a fuel for a sustainable energy future. The electrolysis of water is the most attractive technology to produce carbon-free energy when coupled with electricity produced from renewable sources. However, a major challenge remains the high overpotential at the oxygen electrode and the use of expensive noble metals (e.g., Ir or Pt).

In this work bimetallic nanosized IrSn powders were synthesized and studied as anode electrocatalysts using non-carbon catalytic support (one cheap natural phyllosilicate mineral montmorillonite (MMT)) and reducing the expensive noble metal Ir by cheaper one (Sn). IrSn/MMT catalysts with different Ir:Sn ratio were obtained by sol-gel technique. Thus, prepared catalysts were characterized in terms of structural (XRD) and morphological (TEM) features. Their electrochemical behavior and catalytic activity towards the oxygen evolution reaction were investigated by cyclic voltammetry, steady state polarization curves and electrochemical impedance spectroscopy in a laboratory polymer electrolyte membrane electrolysis cell (PEMEC) at elevated temperatures 20oC – 80oC using. The efficiency of most active catalyst IrSn/MMT was compared with that of a previously investigated Ir/MMT catalyst [1]. It was found that Bi-metallic IrSn catalyst supported on Montmorillonite has a larger developed surface area (fig.1) and higher catalytic activity concerning OER. Due to synergetic effects between iridium and the used interactive oxide support, the loading of the noble metal can be reduced essentially without sacrifice of efficiency thus, decreasing the cost of catalysis.

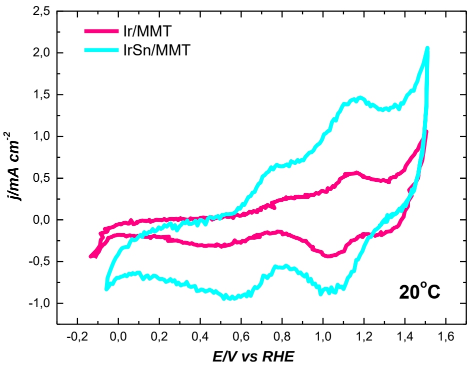

Figure 1: Cyclic voltammograms of the catalysts Ir/MMT and Ir18Sn12/MMT under study in PEMEC at 20^{o}C; potential scan rate 100 mV s^{-1}.

Recently, a lot of research has been done on the conversion of CH_4.[1] Compared to photo-catalysis and thermos-catalysis with precious metal catalysts and high reaction temperatures, the electro-catalysis path which are always performed at room temperature demonstrates more potential. In this regard, the electrochemical oxidation and conversion of CH_4 to commodity chemicals, such as wide-application liquid alcohols, shows obvious economic benefit and high energy/conversion-efficient. Zirconia (ZrO_2) has rich Lewis acid active sites and huge electron acceptability, showing a remarkable adsorption capacity of CO_3^{2-}.[2,3] Thereby, zirconia-based hybrids have attracted a lot of attention and have made some breakthroughs. Transition metal oxide doping ZrO_2 forming TMO/ZrO_2 compound demonstrates the potential of methane oxidation with CO_3^{2-} at room temperature. Compared to NiO and Co_3O_4, copper-based (Cu) catalysts have a high activity and a long-term durability on forming liquid and gas organics of C1 catalysis reaction system (CO_2 reduction reaction) at room temperature.[4] Hence, we present a facile strategy of using Cu ions doping ZrO_2 to activate the hybrid activity by manipulating its crystal and electronic structure. As except, the unique cylindrical ZrO_2:CuOx catalyst shows remarkable CH_4 oxidation performance with large current density differences (13.35 mA cm^{-2}) and long-term electrochemical stability (negligible attenuation (10 %) after 48 hours). According to theoretical and experimental observations of the CH_4 oxidation on ZrO_2: CuOx hybrid, the high activity and durability of the hybrid should be attributed to i) strong synergistic-coupling effect; 2) the unique doping structure forming favorable electronic and crystal structure; 3) fast oxidation reaction mechanism by shortening the reaction path. The mechanism could be described as that ZrO_2 facilitating CO_3^{2-} adsorption, then CO_3^{2-} as the oxidizing agent source rapidly oxidizes CH_4 adsorbed on the surface of Cu in zirconia.

Detection of complex biological events at the single cell level, such as release and reuptake cycles of a neurotransmitter at a synaptic contact, holds great potential for biomedical research. However, the combination of ultra-low analyte concentration and highly spatially confined and temporally resolved biochemical dynamics remains an unaddressed challenge for conventional analytical approaches. In this view, the development of miniaturized bioelectronic systems is of particular interest.

Here, we report the design of a novel electrochemical tool combining the unmatched temporal and spatial resolution of carbon nanoelectrodes (CNEs) with the amplified transducing capability of an organic electrochemical transistor (OECT) for biochemical detection at the single cell level.

The device was obtained from single and double barrel CNEs, whose fabrication was optimised to reach adequate control on the desired size and shape of the electrodes. Therefore, a thin film of organic semiconductor was electrochemically deposited on top of them, in order to create submicrometric, nanodisk-shaped gate and channel elements. The fully assembled device was characterized and showed the typical transistor behaviour upon gating. Overall, this is the first example of a needle-type OECT with cell-compatible dimensions, and we provide its proof-of-principle application for dopamine detection in biologically relevant concentration [1].

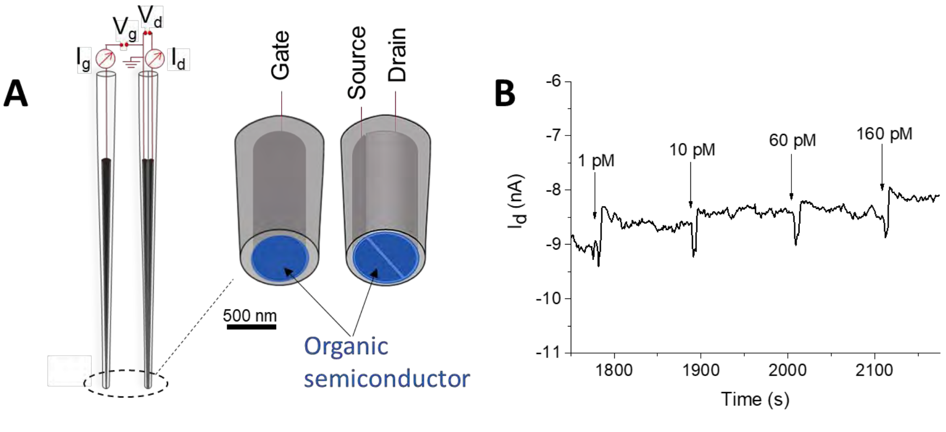

Figure 1. (**A**) Configuration of the needle-type OECT. (**B**) Current vs time curve recorded during increasing additions of Dopamine in the picomolar range ($V_g = -900$ mV; $V_d = -300$ mV).

The AEM water electrolysis based on alkali-doped polymer electrolyte membrane is an efficient method to produce hydrogen with higher purity which offers several advantages over the traditional technologies: higher current density, low ohmic resistance, possibility to operate at higher working pressure, as well as usage of platinum free electro catalysts. The technology still has some problems such as non-sufficient stability of the polymer electrolyte at elevated temperature, low conductivity of the commercially available membranes, and intensive corrosion on the bipolar plates of the cell. This work presents a research on development of highly efficient membrane electrode assembly (MEA) with carbon free electrodes containing non-noble metal catalysts (Co and Ni supported on Magnelli phase titania), and commercially available AB-PBI anion exchange membrane. It is found that the optimal amount of the catalysts for hydrogen and oxygen evolution reactions is 1.0 mg.cm-2 and 0.5 mg.cm-2, respectively. The electrochemical performance of the prepared MEA shows low over potentials concerning both partial reactions and stable behavior at elevated temperature of 80 oC with current density of 0.6A.cm-2 at cell voltage of 2.0 V. The enhanced efficiency of the electrolysis is explained with the observed homogeneous distribution of the nano-sized catalyst crystallites on the non-carbon carrier, reduced ohmic resistance of the electrode, and high anion conductivity of the used polymer electrolyte membrane.

405 rue de Vandœuvre, 54602 Villers-lès-Nancy Cedex, France
michel.perdicakis@univ-lorraine.fr

The spent nuclear fuel consists essentially of UO_2 that is highly insoluble in reducing media, but its apparent solubility increases dramatically under oxidizing conditions (from 4 to 10 orders of magnitude) because U(IV) is transformed into soluble U(VI). Thorium phosphate-diphosphate $Th_4(PO_4)_4P_2O_7$ (TPD) was envisaged by the 'Institut de Physique Nucléaire' (IPN) of Paris-Sud University for the immobilization of actinides (Ac) [1.2]. The TPD structure allows the replacement of large amounts of Th_4^+ by U_4^+, Np_4^+ or Pu_4^+ with formation of solid solutions $Th_{4-x}\ Ac_x(PO_4)_4P_2O_7$. Several successful leaching tests have been performed with $Th_{4-x}U_x(PO_4)_4P_2O_7$ (TUPD) in very corrosive media y [3].

In this work we examine the decrease of the electro-oxidizability two of TUPD samples, TUPD10 and TUPD50, where 10% and 50%, respectively, of the Th_4^+ ions in the TPD structure were replaced by U_4^+ ions.

The electrochemical experiments were performed using the Voltammetry of MicroParticles technique (VMP) [4] where TUPD microparticles were immobilized on the cross-section of graphite electrodes. The surfaces of these electrodes were characterized by XPS and µRaman spectroscopy before and after electrooxidation. The voltammograms of Fig. 1A show that TPD is not electroactive and TUPD compounds are more difficult to oxidize than UO_2.

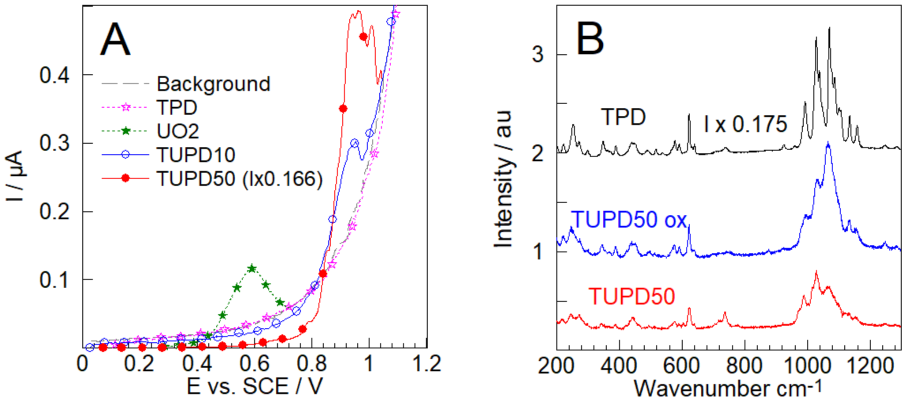

Fig. 1. (A) Voltammetric characterization of TPD, TUPD10, TUPD50 and UO_2 microparticles in 0.5 M $NaClO_4$ using VMP (scan rate 2 mV/s). (B) Raman spectra of TPD, TUPD50 and TUPD50 ox (oxidized TUPD50).

The insertion of U_4^+ ions in the TPD structure results in a significant decrease of the Raman signal (the more the U_4^+ content the less intense the signal). The electrooxidation of TUPD compounds leads to the release of about 12% of the uranium content in the case of TUPD10 and 20% in the case of TUPD50. The electrooxidized TUPD compounds are no longer electroactive and their Raman spectra become closer to that of TPD as it is shown in Fig. 1B for TUPD50.

rasa.pauliukaite@ftmc.lt

Nowadays, natural compounds in sensors are desirable. They are preferable to contribute in diminishing of climate changes and in line with the European Green Deal announced by the European Commission. Natural polymers are already used in sensor development, while polymers from natural monomers, e.g. amino acids, some vitamins or dopamine is a rather recent topic in sensing and especially biosensing [1]. Pesticides are important for a successful plant growth but they are harmful to human and animal organisms, therefore, it is important to monitor their concentration in plant products. Atrazine is a triazine class herbicide, residues of which can stay in crops or other cultivated plants.

Polymerized folic acid (PFA) or riboflavin (PRf) were already employed for detection of some compounds like glutamate, glucose and ascorbic acid [2,3]. These vitamins can be polymerized electrochemically under certain conditions [4,5]. Electrochemistry is a green synthesis method and obtained polymers from natural monomers can be used in sensors for medicine or food quality control or other biological samples.

PFA and PRf copolymer was synthesized on glassy carbon electrode in order to detect atrazine. The optimization of the copolymer composition and its electrocatalytical activity towards atrazine will be presented and discussed.

The possibilities of modern electroanalytical methods in environmental analysis or organic compounds are well recognized (low investment and running costs, reasonable and in many cases "fit for the purpose" sensitivity and selectivity, easy automatization, easy miniaturization resulting in portability of corresponding instrumentation, user friendliness and environmental friendliness ("green electroanalytical chemistry"). Nevertheless, the big problem connected with the use of modern electrochemical techniques in environmental analysis is the passivation of working electrodes by products/intermediates of electrochemical reactions or by components of an environmental sample which can adsorb on the electrode surface thus fouling the electrode and complicating the determination or even making it impossible. It is obvious that surface chemistry plays a deceive role in this process.

The following new approaches eliminating problems with electrode passivation in environmental monitoring of organic pollutants will be discussed and demonstrated on practical examples :

i) preparation, surface characterization and testing of new electrode materials resistant towards passivation (e.g. boron doped diamond, nitrogen-incorporated tetrahedral amorphous carbon, hydrophilic carbon prepared by pyrolysis of acetylene and hydrogenation, carbon films, nanostructured metals deposited on various substrates, bismuth and antimony films,

ii) elimination of passivation by electrochemical polishing/cleaning/pre-treatment of electrode surface between successive measurements,

iii) elimination of electrode passivation by measurements in flowing systems (liquid chromatography, flow injection analysis and batch injection analysis with electrochemical detection)

iv) prevention of passivating molecules from matrix to access the electrode surface by their preliminary separation via membrane filtration,

v) application of electrodes with easily renewable surface (dropping mercury electrode, hanging mercury drop electrode, static mercury drop electrode) and/or disposable electrodes for a single use (screen printed electrodes),

These approaches will be demonstrated on selected examples of passivating pollutants (phenols, nitrophenols, aromatic amines and nitrocompounds, dyes, drugs, etc.).

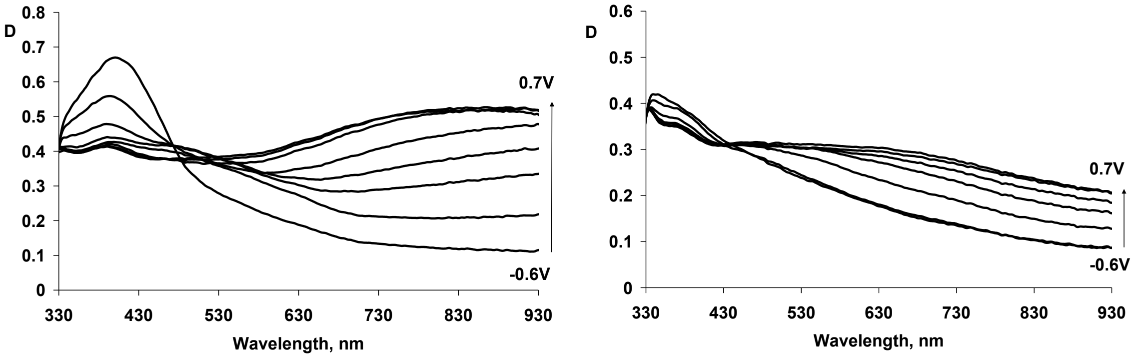
Polypyrrole (PPy) films were synthesized in galvanostatic mode in the presence of salt and acid forms of water-soluble sulfonated polyelectrolytes: flexible-chain poly(styrene-4-sulfonic acid) (PSSA) and poly-2-acrylamido-2-methyl-1-propanesulfonic acid (PAMPSA), semi-rigid-chain poly(4,4'-(2,2'-disulfonic acid)-diphenylene-iso-phthalamide) (i-PASA), rigid-chain poly(4,4'-(2,2'-disulfonic acid)-diphenylene-tere-phthalamide) (t-PASA).

The electronic and chemical structure of the PPy films obtained was studied by UV-Vis-NIR and Raman spectroelectrochemistry. UV-Vis-NIR spectroelectrochemical and cyclic voltammetric comparative studies were performed in water and organic (propylene carbonate) medium. It was shown that the structure of PPy depends strictly on the structure of polyelectrolyte and the nature of its cation.

In the presence of acid forms of flexible-chain polyelectrolytes PPy films are formed in protonated, more oxidized form with higher concentration of free charge carriers. PPy films electrodeposited in the presence of salt forms of all polyelectrolytes are less protonated, however they characterized by high absorption in the NIR spectral region. Their spectroelectrochemical properties are similar to those of PPy films obtained in inorganic electrolytes (Fig.1a). Contrarily, PPy complexes with rigid-chain polyacids exhibit lower doping degree, lower absorption in NIR region, which is indicative of lower concentration of free charge carriers (Fig.1b). At the same time, numerous cycling in propylene carbonate with 0.5M NaClO4 showed that films of PPy complexes with rigid-chain polyacids are more electrochemically stable.



a) b)

Fig.1 UV-Vis-NIR absorption spectra of the PPy-PSSA (a) and PPy-i-PASA (b) films at different fixed potentials in 0.1 M NaClO4 aqueous solution.

The differences are discussed considering peculiarities of pyrrole distribution in the synthesis solution depending on the hydrophobicity, conformational state and spatial distribution of sulfonic groups in polyelectrolyte coils.

Self-organization is a powerful tool that may be explored as a methodology for the synthesis of new materials with intricate structures. Oscillatory electrodeposition and electrodissolution reactions can enable the formation of nanostructured materials under micro and nanoscale through *bottom-up* processes.[1] The electrodeposition in an alkaline media containing copper sulfate and lactate yield periodic oscillations by only applying a constant current. The oscillations under galvanostatic regime occur in a broad range of different pH and current densities values, that directly affect the period and amplitude of the oscillations (Figure 1a).[2] Although direct relationships between experimental parameters, such as pH, current density and temperature can be obtained, multivariate statistical analysis revealed a more complex dependence on the frequency including quadratic terms (Figure 1b). The periodic oscillations related to alternate deposition of Cu and Cu/Cu_2O are recorded in the form of an ordered architecture in the electrodeposited film, the so-called multilayers. The period and amplitude of the oscillations is directly related to the thickness and composition of the layers of the electrodeposited film. Under high frequencies the thin thickness and the inhomogeneous deposition encumber the well-defined layer formation (Figure 1c), despite this, the formation of two distinct phases are clearly observed, consisting of copper oxide grains (in white) identified in Transmission Kikuchi Diffraction phase maps surrounded by a metallic copper matrix, in gray.[3] $Cu|Cu_2O$ interfaces are employed in many fields, including electrocatalysis, in the CO_2 electroreduction, in sensors, as glucose detectors, as nanowires in lithium-ion batteries, all of them who can benefit greatly from the use of new materials built through self-organized systems.

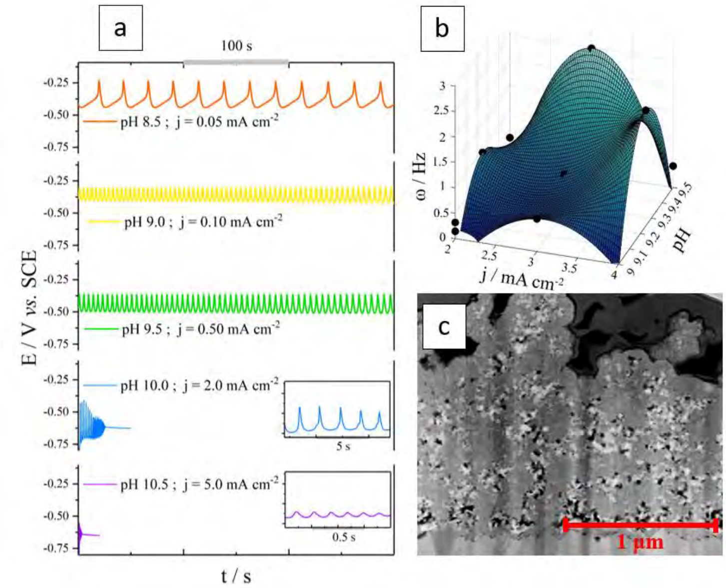

Figure 1: (a) Oscillations samples extracted from galvanostatic electrodeposition time-series with different pH values and current densities. (b) Response surface plot of the model for the Cu/Cu_2O oscillatory deposition at T = 35.0 ºC, in the pH range of 9.0 to 9.5 and current densities of 2.0 to 4.0 mA cm^{-2}. Ion-ion selectivity, the preferential removal of particular charged species in a competitive ionic environment, is an active and growing research topic in capacitive deionization (CDI) with potential water treatment applications such as heavy metal removal and agricultural water remediation[1]. We here study monovalent selectivity, the preferential removal of a monovalent ion in the presence of a divalent ion, with the aim of reducing the sodium adsorption ratio (SAR) of a test feed stream. SAR is an important agricultural water parameter, and excessive values can adversely affect plant health and reduce crop yields[2].

Using a flow-through electrodes (FTE) CDI device, we evaluate the performance of a cell with a cathode functionalized with sulfonic groups (S-P cell) for a feed water containing Na$^+$ and Ca^{2+} ions with initial SAR = 19.8 and conductivity κ = 1.75 mS/cm for a range of cycle times (6 – 30 min, equally divided into charge and discharge steps) and applied constant voltages. At cycle times of 15 and 30 min, SAR is increased above the feed value due to preferential Ca^{2+} removal. However, at a cycle time of 6 min, the S-P cell reduces SAR at voltages above 0.8 V, improving the water quality relative to the feed value (see **Figure *1***a), an effect due to greater relative removal of Na$^+$. Furthermore, we show that SAR reduction and high coulombic efficiency (>96%) are retained over a 1000-cycle experiment at 1.2 V and 6 min cycle time (**Figure *1***b), indicating the promise of functionalized electrode materials for applications involving monovalent selectivity. We discuss tradeoffs for conditions that achieve net reductions of SAR and conductivity, such as acidification of the desalinated water to pH < 6 and energy consumption of ~1 kWh/m^3 product water, the latter vs. ~0.01 kWh/m^3 for conditions that result in high Ca^{2+} selectivity.

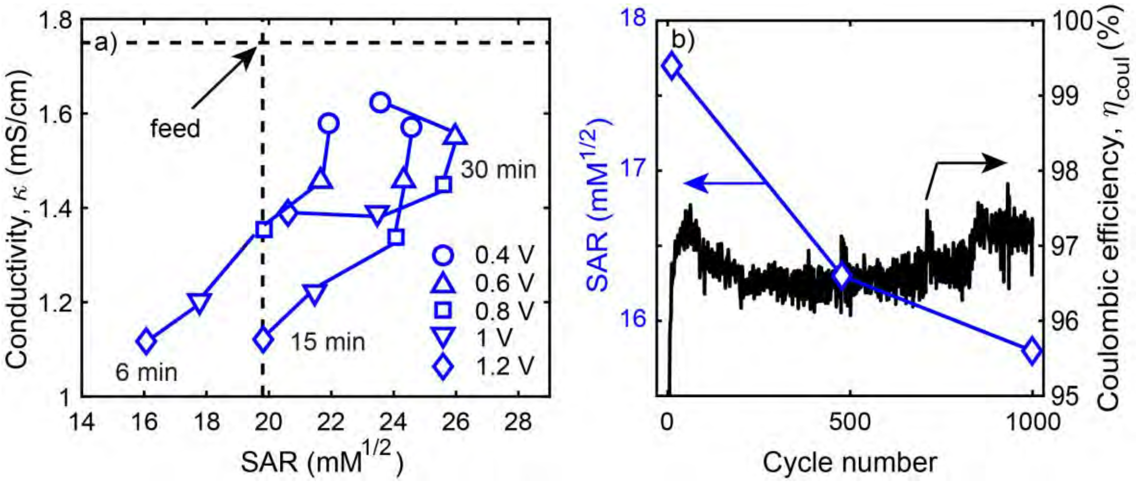

Figure 1: CDI performance in the S-P cell. a) The effect of charging voltage and cycle time on output water SAR and conductivity. Feedwater conditions are shown at the intersection of the dashed lines. b) Output water SAR and coulombic efficiency over a 1000-cycle experiment at 1.2 V and 6 min cycle time.

Electrochemical reduction of CO_2/CO to C2+ products assisted by Cu-Ag bimetallic catalysts

Floriane A. Rollier, Marta C. Costa Figueiredo, Emiel J.M. Hensen
Inorganic Materials and Catalysis, Chemical Engineering and Chemistry faculty, Eindhoven University of Technology
Building Helix, P.O. Box 513, 5600 MB Eindhoven
f.a.rollier@tue.nl

Witnessing both fossil resources scarcity and global warming consequences, it is crucial to develop sustainable answers to the rising demand in energy and chemicals. An innovative way of producing added value products for industry is to electrochemically convert carbon dioxide using electricity originating from sustainable energy sources (solar, wind, …). [1] More than mitigating greenhouse gas emission in the atmosphere, the process would allow the storage of surplus electrons produced during sunny or windy days into chemical bonds, making energy available for later use. The focus on producing long-chain compounds (C2+), having a higher energy density than one-carbon products, is a key point for further progress in CO_2/CO electroreduction (CO_2RR and CORR).

After decades of investigations, copper based electrocatalysts have proven to be active in CO_2RR towards C2+ products. [2] However, the selectivity and further improvement of the activity constitute the main challenges to overcome before any industrial applications. Despite a not fully understood reaction mechanism, carbon monoxide was shown to be the main reaction intermediate leading to C2+ products. [3] CORR focused studies have indeed been published this past decade in order to increase the selectivity towards high energy density products. [4] Knowing that CO like intermediates induce C-C coupling, some research groups [5][6] have recently investigated bimetallic system alloying copper with a CO-producing metal (e.g. Ag or Au) in order to provide localized CO production and spill over on copper domains where CO would react further. This approach enhances the CO coverage on copper and leads to increase in C-C coupling, further pulling up selectivity for C2+ compounds. Gewirth et al. [6] synthesized CuAg nanowires demonstrating a noteworthy near 100% faradaic efficiency (FE) for CO_2RR, with a 60% FE to Ethylene as well as a 25% FE for Ethanol at relatively low overpotential (-0.7V vs RHE). They also determined that half of the current density devoted to CO_2RR is directed towards Ethylene production, and one third towards Ethanol and CO formation.

These promising results constitute key knowledge for further optimization. In this work we present the study of CuAg based bimetallic systems for CO_2RR and CORR. Different electrodeposited CuAg catalysts will be presented (pure Cu, CuAg (1%at), CuAg (6%at) and CuAg (9%at)) as well as their performance in CO_2RR and CORR. Moreover, in this study we optimized the synthesis of the bimetallic catalysts by using different ligands (imidazole and triazole based) influencing the shape of the catalysts. The shape will impact the product distribution during reaction and ligands are investigated for this purpose.

Electrocoagulation using aluminum electrodes for boron removal

Douglas M. L. da Silva, Maria Tereza W. D. Carneiro, Josimar Ribeiro

Laboratório de Pesquisa e Desenvolvimento em Eletroquímica, Departamento de Química do Centro de Ciências Exatas da Universidade Federal do Espírito Santo, Av.: Fernando Ferrari, 514, Goiabeiras, Vitória, Espírito Santo, CEP.: 29075-910, Brazil
josimar.ribeiro@ufes.br

The efficiency of the electrocoagulation method in the removal of boron from synthetic effluent and mining effluent was investigated in this study. Different parameters such as pH, current density, electrocoagulation time and supporting electrolyte concentration were tested for both types of effluents [1]. The synthetic effluent was prepared from boric acid solution and the mining effluent was collected from an important brazilian mining company located in Vitória city. The results showed a percentage of boron removal higher than 60% for the synthetic effluent and close to 70% for the mining effluent, using aluminum electrodes, pH 7.5, a current density of 14.82 mA cm^{-2} and electrolyte support 0.200 mol L^{-1}. The methods of electrocoagulation and chemical coagulation were also compared in this study, where a percentage of 56.30% higher was obtained by electrocoagulation for the mining effluent. Thus, electrocoagulation was more efficient at removing boron, especially when appropriate parameters were applied. Thus, electrocoagulation proved to be an important technique for the removal of residues in industrial effluents and, consequently, a reduction of the environmental impacts caused by them [1].

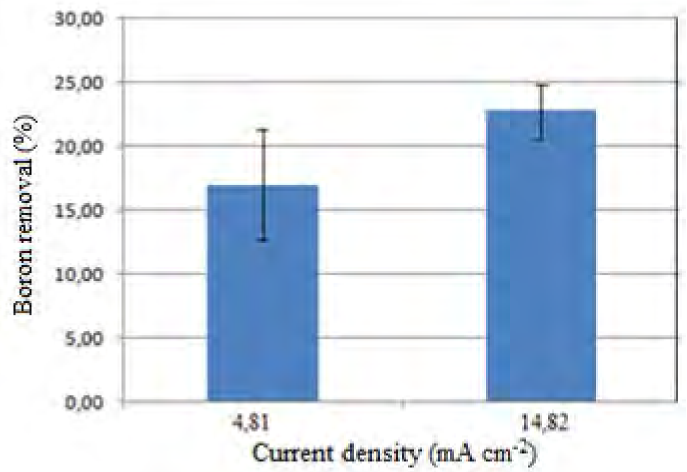

Figure 1. Percentage of boron removal at the current densities of 4.81 and 14.42 mA cm^{-2}, with a time of EC of 30 minutes and supporting electrolyte of 0.200 mol L^{-1}.

ruggero.poiana@uniroma1.it

The introduction of a polymeric electrolyte component in lithium batteries has dramatically increased safety of these energy storage devices, thus enhancing their employment in many commercial applications. In this context the electrical conduction is one of the most important features for the choice of a suitable polymer, together with good mechanical strength and chemical stability. Hence, polymeric electrolytes can be divided in two major classes depending on their features: dry solid polymer electrolytes (SPE), where the polymeric matrix acts as solid solvent, and gel polymer electrolytes (GPE), composed of organic solvents mixed together with an appropriate polymer [1]. In both cases polymer chains take part to lithium cation diffusion through the electrolyte, improving safety but slightly reducing its ion conduction respect to liquid systems.

This work is focused on the development of a versatile GPE for high voltage lithium batteries [2], enhancing safety of the device without undermining its electrochemical performances. Poly(vinylidene fluoride-co-hexafluoropropylene) (PVdF-HFP) copolymer is used as polymeric component, dissolved in a mixture of alkyl carbonate solvents with an easy room atmosphere procedure for the accomplishment of a dried separator with controlled thickness. Thermal characterization of the polymeric separator is carried out with thermogravimetric analysis (TGA), differential scanning calorimetry (DSC). The membrane is then stored under inert atmosphere, ready to be swollen in liquid electrolyte solutions to form a suitable GPE. The adaptability of the separator to electrolyte solutions of different nature is demonstrated with a liquid commercial electrolyte and innovative solutions obtained with the addition of the ionic liquid N-n-butyl-N-methylpyrrolidinium hexafluorophosphate ($Py_{14}PF_6$) [3]. Pulsed field gradient NMR measurements are performed to investigate GPEs lithium diffusion coefficients and relaxation phenomena, useful for the comprehension of the ion-conduction mechanisms [4]. GPEs are also characterized by rheological and electrochemical measurements, adopting a nickel-substituted manganese spinel $LiNi_{0.5}Mn_{1.5}O_4$ as high voltage cathode in lithium metal batteries. Enhanced safety of the polymeric matrix is demonstrated with flame tests on both GPEs and their liquid counterparts.

E-mail: heigoers@ut.ee

Ionic liquids (IL) are organic salts with remarkable stability and high charge density. These properties make them promising electrolytes for electrochemical applications such as supercapacitors. As the microscopic processes taking place at the interface affect the macroscopic characteristics of supercapacitors, molecular dynamics (MD) simulations are essential to study the electrode–IL interface structure and dynamics.

In this work, we have used density functional theory-based molecular dynamics (DFT-MD) simulations to explore the interface between graphene electrode and 1-ethyl-3-methylimidazolium tetrafluoroborate ionic liquid at different graphene surface charges. DFT-MD level of theory allowed us to examine the charge distribution and polarization on the graphene. The results indicate that overscreening is preserved upon the inclusion of quantum effects. Furthermore, we have divided the electrical double layer potential drop into two components to narrow the gap between classical and DFT-based MD simulations. The first involves atomic charges and arises due to the reorganization of the ionic liquid. The second quantifies the redistribution of the graphene electron density using atomic dipoles that correlate with the atomic charges. The latter term we have related to the concepts of Thomas–Fermi screening length, effective surface charge plane and quantum capacitance.

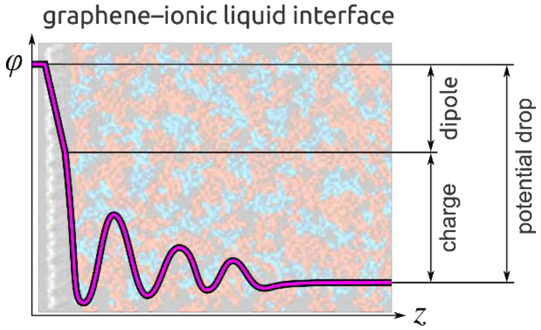

Figure 1. Interfacial potential drop disassembled into two main components arising from atomic charges and dipoles.

lhuidobro@leitat.org

Bioelectrochemical power-to-gas represents a novel solution for electrical energy storage. It allows converting electrical energy to methane (CH_4), therefore connecting the electricity and natural gas grids for a high-capacity and flexible energy storage. The technology can be coupled with membrane contactors for CO_2 capture, dissolving the CO_2 in wastewater before its feeding to the bioelectrochemical system. This way, the integrated system can achieve also carbon capture, in the scenario of a wastewater treatment plant application. In this study, such technology was developed in a medium-scale prototype of 32 L (Figure 1), operated for 400 days in different conditions of temperature, voltage and CO_2 capture [1]

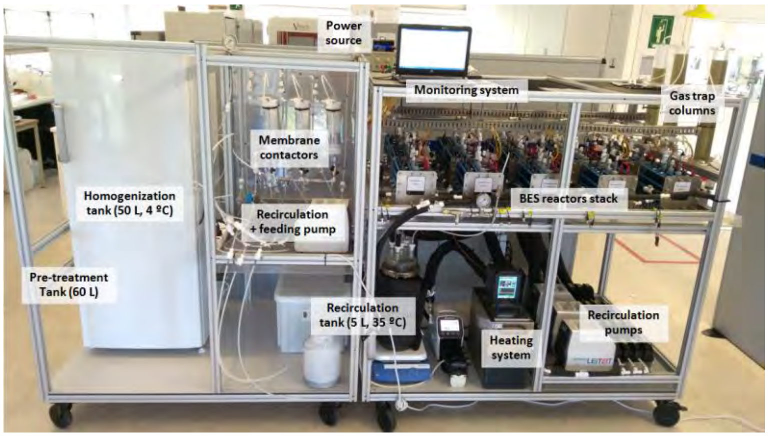

Figure 1 – Photo of developed prototype. Left side: CO_2 capture system. Right side: EMG-BES stack.

The prototype achieved the highest CH4 production rate (147±33 L m-3 d-1) at the lowest specific energy consumption (1,0±0,3 kWh m-3 CH_4) when operated at 25 ºC and applying a voltage of 0,7 V, while capturing and converting 22 L m-3 d-1 of CO_2 (Figure 2).

Traces of H_2 in the biogas, detectable during the periods of closed electrical circuit operation, indicated that hydrogenotrophic electromethanogenesis was taking place at the cathode. On the other hand, a relevant CH_4 production during periods of open electrical circuit operation confirmed the presence of acetoclastic methanogenic microorganisms in the microbial community, which was dominated by the archaeal genus Methanothrix (Euryarcheota). Different OTUs (operational taxonomic units) belonging to the bacterial Synergistes phylum were found at the anode and the cathode, having a potential role in organic matter degradation and H2 production, respectively.

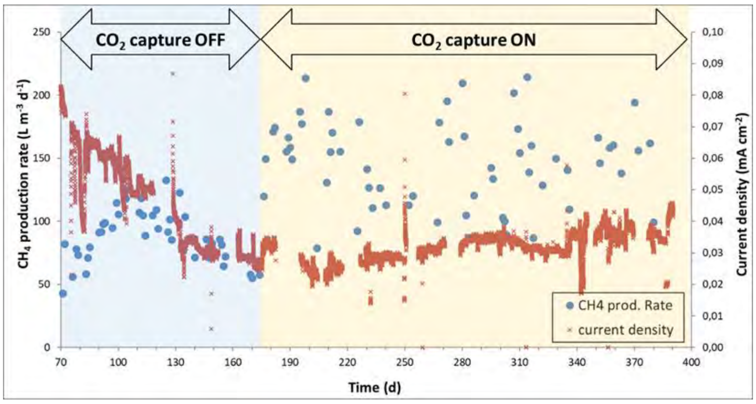

Figure 2 – Trend in time of CH_4 production rate, with and without CO_2 capture.

In the panorama of methanation technologies currently available for power-to-gas, performance of this EMG-BES prototype is not yet competitive, especially in terms of volumetric CH_4 production rate and power density demand. However, the possibility to obtain a high-quality biogas (almost respecting the quality standards of biomethane) at a minimal energy consumption represents a potentially favorable business scenario for this technology. This work has been financially supported by the Spanish Ministry of Economy and Competitiveness under the project Power2Biomethane (RTC-2016-5024-3, 2016).

ABSTRACT

Hydrogen is a renewable secondary energy source. Due to its high energy density and zero emissions, it has been accepted as a suitable alternative for conventional fossil fuels [1]. Environmentally friendly energy sources for sustainable renewable resources are of interest due to the rise in global pollution. Hydrogen, seen as the energy source of the future, can be obtained in different ways. However, the most suitable method is to obtain hydrogen by electrolysis. The electrical energy used in this method increases the unit price of H_2. In addition, it increases the unit price even more because it requires additional energy in over-potential consisting of electrodes and electrolytes. In order to overcome these problems, suitable electrode, working environment and catalyst are investigated [2, 3].

In this study, the hydrogen evolution reaction (HER) effect of CoW nanoparticles deposited on the Ni plated graphite eletrodes (CoWNi@C) were studied. The HER activity of the prepared electrodes were investigated by electrochemical techniques. Electrochemical analyses were carried out by the potentiodynamic polarization techniques and electrochemical impedance spectroscopy (EIS). Surface morphology and chemical composition of synthesized nanoparticles were investigated by scanning electron microscopy (SEM), and energy dispersive X-ray spectroscopy (EDX) techniques. The cathodic polarization curves of Ni @C and CoWNi@C in 1 M KOH solutions are given in Fig. 1. The addition of a small amount of CoW to the coatings in order to increase the catalytic activity led to significant differences in current densities. When current density values are compared as an expression of catalytic activity, it is seen that the CoWNi@C catalyst has higher activity than the Ni@C catalyst. It showed that HER efficacy of CoWNi@C catalyst in 1.0 M KOH solution was higher than Ni@C catalyst and showed lower potential.

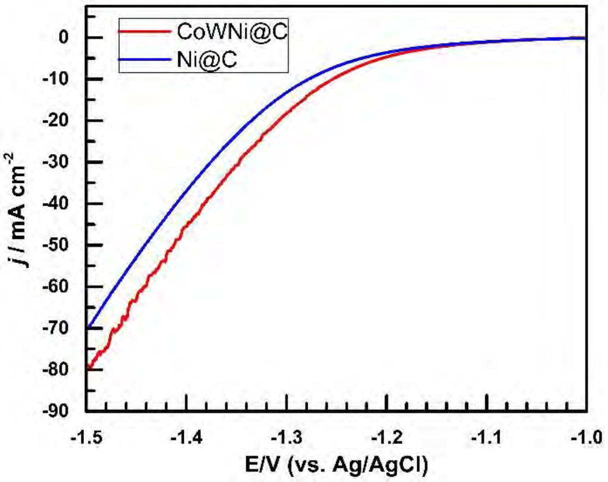

Fig. 1 The cathodic polarization curves for C, Ni@C and CoWNi@C catalysts in 1 M KOH.

Electrochemical Surface-Enhanced Raman Spectroscopic Study of *p*-Bromide Nitrobenzene on AgNPs@Ag Electrode

Jia-Liu, Zhuan-Yun Cai, Wei-Xin Sun, Jia-Zheng Wang, De-Yin Wu
State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Collabora-tive Innovation Center of Chemistry for Energy Materials (iChEM), Xiamen University,

dywu@xmu.edu.cn

Identification of the intermediates on the electrode-molecule surface is significant for understanding electrochemical reaction mechanisms. Surface-enhanced Raman spectroscopy (SERS) is a powerful *in situ* technique to get the molecular fingerprint information of interface reactions.[1] During the electroreduction of *p*-bromonitrobenzene (pBNB) under $NaClO_4$ aqueous electrolyte, structural transformations of surface molecules have been investigated by *in-situ* electrochemical SERS in this work.

Figure 1a shows the cyclic voltammetry of pBNB from 0.1 to -1.22 V vs. Ag|AgCl. Two cathodic waves for the nitro group reduction are observed both on the first and second cycles (red and blue curves, respectively). A pair small redox waves can be observed at -0.21 V and -0.23 V in the second CV cycle. This is similar to nitrobenzene reduction, which is identified as the redox of hydroxylamine and nitroso intermediates.[2] However, there is lack of evidence of the molecular transformation. Figure 1b presents the potenital-dependent SERS spectra in the 600-1800 cm^{-1} region. The initial spectrum of pBNB observed at 0.1 V has the typical band at 1350 cm^{-1}, which is from the nitro group. When sweeping the potential to negative potential, this results significant change in SERS. New peaks at 1168, 1339, 1386 cm^{-1} appeared in -0.4 V correspond to the reduction intermediate nitroso derivative. These bands disappear at -1 V and the SERS bands at 819 and 993 appear to prove the reduction to amino derivatives. Finally, the SERS bands at 987, 1061, 1134, and 1224 cm^{-1} can be identified as the intermediate product hydroxylamine derivative when the potenital was applied in the reversed sweep to -0.2 V.

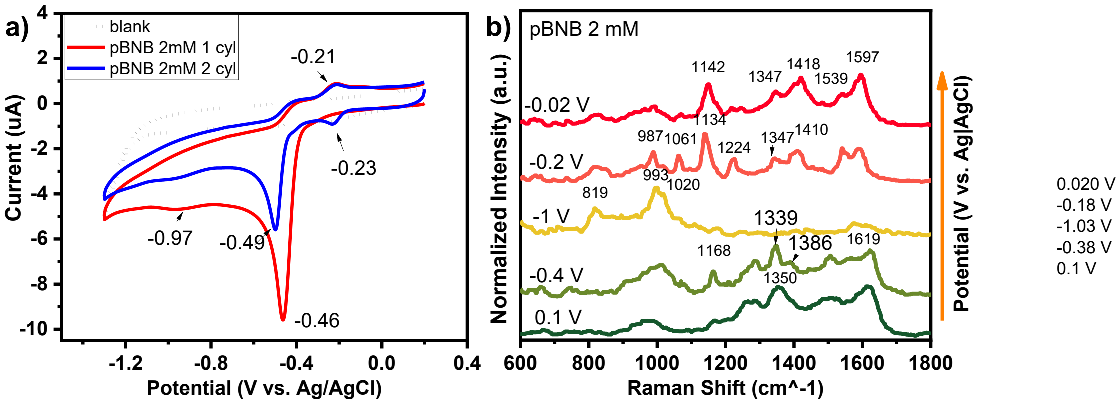

Figure 1 (a) Cyclic Voltammetry (CV) of 2 mM pBNB recorded at a scan rate of 0.1 V/s on Ag electrode. Dashed line is the first scan circle, and solid line(red) is the second circle, blank is shown in black dash line. (b) Sequence of EC-SERS at representative potentials for the reduction of pBNB obtained during CV at scan rate of 0.05 mV/s, at Ag NPs@Ag electrode. SERS spectra conditions: The integration time is 1 s. the laser wavelength 532 nm, and laser power is 150 µW, the 10×, N_A=0.3. All experiments were recorded in 2 mM pBNB under 0.1 M $NaClO_4$ solution. The reference electrode is Ag|AgCl, the counter electrode is Pt.

Determination of Aluminum stripping & plating kinetics parameters in EMimCl/AlCl$_3$ by pulsed voltammetry for Al-ion battery

M. Eckert, B. Rana, S. Suthar, J.-F. Drillet,
DECHEMA Forschungsinstitut
60486 Frankfurt am Main, Germany
drillet@dechema.de

The development of alternative battery systems that rely on cheap, non toxic, easy to recycle and worldwide available materials is of great importance for supplying huge energy storage market. One very promising candidate is the Aluminum-ion battery (AIB) that uses Graphite as intercalation material for positive electrode and an Aluminum foil or foam as negative electrode[1]. To overcome aluminium passivation and H_2 evolution, most common AIB chemistry relies of water-free ionic liquid electrolyte such as EMimCl/AlCl$_3$ mixture. During charging, large AlCl$_4^-$ anions intercalate in graphene sheets and Al is plated on the anode according to following reactions:

$$C_n + AlCl_4^- \rightarrow [C_nAlCl_4] + e^-$$

$$4\,Al_2Cl_7^- + 3^- \rightarrow Al^0 + 7\,AlCl_4^-$$

During discharging step, Al stripping occurs while AlCl$_4^-$ ions de-intercalate from graphite matrix. One crucial issue is related to graphite volume change during cycling. While a few articles report on kinetics of Al dissolution step [2,3], not information about Al deposition kinetics in ionic liquid was published yet. Herein kinetics parameter of both Al stripping & plating from/on an Aluminum foil in different EMimCl/AlCl$_3$ concentrations were evaluated by using cyclic voltammetry and high-resolution pulsed chronopotentiometry. The Tafel slopes of Al-stripping & plating were found to be in the range of 120 – 150 mV dec^{-1} while corresponding exchange current densities accounted for about 3 – 5 mA cm^{-2}. Experiments on determination of activation energy will be presented as well.

Mesoscopic Effects in Electrocatalysis: from Concept to Catalyst Synthesis and Performance Evaluation

Matthias Arenz
Department of Chemistry and Biochemistry, University of Bern
Freiestrasse 3, 3012 Bern, Switzerland
matthias.arenz@dcb.unibe.ch

In the last decade the interest in electrocatalyst design has been boosted by the increasing availability of regenerative energy in the form of electricity. The intermittent nature of energy sources such as photovoltaic power and wind energy requires suitable energy storage technology to be able to align the *"production"* with the *"demand"* of energy. While battery technology for mobile applications shows continuous progress, the storage and re-conversion of electricity in the form of energy carriers such as hydrogen gas still faces significant challenges. Complementing strategies to utilize renewable energy for the production of gases, liquids or chemicals of interest, summarized under the *"Power to value"* or *"Power2X"* label, are even more in their technological infancy. However, for an efficient regenerative energy management on a global scale such technologies are indispensable.

For all these technologies a fundamental understanding and rational design of (electro-)catalysts, on which many surface reactions of interest take place, play an essential role. In state-of-the-art academic electrocatalyst design, the focus is on optimizing the surface structure of the catalyst on a nanometer scale. This design principle, however, only takes kinetic factors into account – which are important, but not sufficient for catalytic applications. Furthermore, the electrocatalyst performance is determined at significant lower reaction rates than required for applications.

I will present our research concept that focuses on a different, complementary design approach for supported electrocatalysts in order to optimize their properties. In supported electrocatalysts, the active phase consists of metal or alloy nanoparticles distributed over a conducting support, mostly carbon based. Our aim is to elucidate *the role of mesoscopic properties* – such as the interparticle distance on the support – for their performance in a comprehensive and systematic manner by combining electrochemical measurements with (ex-situ and in operando) spectroscopy and microscopy. Mesoscopic properties have so far received only little attention in academic electrocatalyst design, yet some few studies demonstrate that they bear significant potential for improving the electrocatalyst performance. A proof of concept has been our pioneering work on the particle proximity effect on size-selected Pt clusters[1]. Different colloidal catalyst synthesis strategies[2, 3] developed allow the investigation of mesoscopic effects with a significantly broader perspective.

Experimental results are presented related to the electrochromic behavior of vanadium pentoxide (V_2O_5) thin films deposited with a custom-made spray pyrolysis system using ammonium metavanadate as precursor. The effect of precursor concentration, deposition time and annealing on the basic characteristics of the films and their functionality was investigated in details. The films were found to exhibit quite good electrochromic behavior with four main color changes (light brown, light blue, light green and yellow). Annealed films were more stable exhibiting faster response time and larger change in the transmission between the colored and the bleached phase. These results concern a preliminary study, aiming in the development of efficient electrochromic layers using low cost and simple materials, low cost and easily adapted to a production line deposition technique, offering the possibility of developing large scale windows.

ABSTRACT

Pt-based nanocrystals have been largely studied due to their high activity and stability as electrocatalysts in fuel cell and water electrolyzer. For optimal electrocatalytic performance, adsorption properties of the Pt surface should be tailored toward the sweet spot where the turn over frequency is maximized while surface coverage of spectator ions is minimized. Traditionally, various approaches have been suggested with nano-architecture of Pt-based nanocrystals, including control over size, alloy composition, morphology, and surface dopants. However, there have been limited studies on the impact of carbon support surface on the adsorption properties of Pt nanocrystals. In this study, we report an unexpected change in adsorption behaviors of Pt surface when supported on the N-functionalized carbon surface. Affinity toward both protons and oxygen species are highly modulated, resulting in tailored electrocatalytic properties in acidic and alkaline electrolytes. This study will suggest the importance of carbon surface as another factor toward tailoring the performance of nano-particulate electrocatalysts.

Carbon nanofibers doped with metals for air-cathodes. Oxygen reduction reaction characterization and application in microbial desalination cells

P. Bosch-Jimenez,[1] Laura Huidobro,[1] S. Matencio,[2] M. Canal Rodriguez,[2] M. Aliaguilla,[1] D. Morillo,[2] S. Martinez,[2] E. Borràs[1]
[1] *LEITAT Technological Center, C/ de la Innovació, 2, 08225 Terrassa, Spain*

Bioelectrochemical Systems (BES) are novel technologies using microorganisms to catalyse different electrochemical processes. Among BES applications, Microbial Desalination Cell (MDC) (Figure 1) constitutes an emerging energy efficient desalination technology. The main advantage of MDC is lower energy required to drive desalination process (potentially 0.5 $kWhm^{-3}$) compared to reverse osmosis (3 $kWhm^{-3}$). MDC performance depends on the performance of key components (anode, cathode and membranes). In the present study, air-cathodes, based on carbon nanofibers (CNFs) doped with metal nanoparticles (Fe and Co), were developed using electrospinning. Oxygen reduction reaction (ORR) kinetics were assessed by chronopotentiometry, cyclic voltammetry and OCV.[1] CNFs demonstrate suitable ORR performance which is essential for use as air-cathode-MDC electrodes. CNFs incorporating Fe nanoparticles further enhanced ORR. Finally, an air-cathode-MDC reactor was constructed with optimized electrodes, observing high relationship between material ORR performance and desalination rate. Developed cathodes are an alternative to Pt-based cathodes and are suitable to be used in others BES and electrochemical technologies. Research leading to these results has received funding from EU-Horizon 2020 programme. GA Nº685793 (MIDES project).

Molybdenum selenide/sulfide with carbon nanotubes as attractive electrode materials for electrochemical capacitors

Maciej Tobis, Elżbieta Frąckowiak
Poznan University of Technology
60 – 965, Poznań, Berdychowo 4, Poland
maciej.p.tobis@doctorate.put.poznan.pl

Electrochemical capacitors (ECs) are considered to be the most promising high-power energy storage devices for various application including portable electronics, hybrid vehicles or communications due to their stable long-life cycle and high specific capacitance. Carbon materials such as activated carbons, carbon nanotubes or carbon fibres are the most common electrode components used in ECs. Although, while constructed in ECs cells in comparison to other materials, they offer relatively small specific capacitance due to limited specific surface area or non-uniform distribution of pores.

Among various electrode materials, 2D transition metal dichalcogenides (2D-TMDs) are interesting choice due to their two dimensionality, large specific surface area and large diversity of compounds. TMDs are layered material with a formula of MX_2, where M is the metal atom, e.g., Mo, V, Re etc. and X is the chalcogen atom, e.g., S, Se or Te. Atoms are bonded with each other by strong covalent bond and layers are stacked together with weak van der Waals forces. While assembled in ECs, 2D-TMDs can store charge through adsorption of ions at the electrolyte/electrode interface and also through faradaic reactions occurring on the surface of the electrode. Their structure can be tailored to obtain high specific surface area which will ensure the space for adsorption of ions and active sites for faradaic reactions [1].

$MoSe_2$ as a representative of 2D-TMDs is a semiconductor which gained significant attention due to a high theoretical capacity and a low cost. It possesses slightly higher intrinsic electrical conductivity than MoS_2 mainly due to the metallic nature of the Se. Additionally, unsaturated Se edges possess stable structure and can occur in multiple electrochemically active sites which is a beneficial for the faradaic capacity and decrease the internal resistance. $MoSe_2$ as a mainly pseudocapacitive material suffers from poor electrical conductivity which in total decreases the overall electrochemical performance [2].

It was already proven that multiwalled carbon nanotubes (MWCNTs) show superior electrical conductivity and could serve as a good percolator of various electrode materials in ECs. Combination of highly conductive MWCNTs with faradaic $MoSe_2$ resulted in obtaining stable, highly capacitive composite with improved conductivity. Moreover, the addition of MWNCTs increased the overall lifespan as they prevent the $MoSe_2$ from volume expansion during charge/discharge which has its origin in more metallic nature of Se. Several $MoSe_2$/MWCNTs composites with various composition were prepared by simple hydrothermal method. For comparison MoS_2/MWNTs composites have also been prepared. The obtained composites were characterized with various textural/structural methods, e.g., scanning electron microscopy, X-ray diffraction and Raman spectroscopy. The electrochemical performance of the prepared ECs cells were studied by cyclic voltammetry, galvanostatic charge/discharge and electrochemical impedance spectroscopy. Two- and three-electrode cells were tested. Neutral aqueous solutions (sulfates) have been selected as electrolytes to extend operational voltage of EC.

An important and novel group of fluorophores that are tetra-coordinated six-membered boron compounds with O- B- N moiety, are called Oxazaborines (Figure 1b). These molecules have ignited great interest to be investigated due to their aggregation-included emission and for obtaining the forming donor-acceptor (D-A) chromophores.[1] The investigation of Oxazaborines' properties yield a high photoluminescence (PL) of 70-75% which is relative to their first redox behavior. The use of the electrochemiluminescence (ECL) method demonstrates the high ECL intensity which has a value four times higher than the standard dyes, therefore opening novel applications within the ECL luminophores field (Figure 1a).[2][3] Finally, all of these novel compounds were analyzed under the same conditions, in order to make it possible to create a comparison between them. Thus, the ECL analysis of the above compounds was carried out in an aprotic solvent.[4]

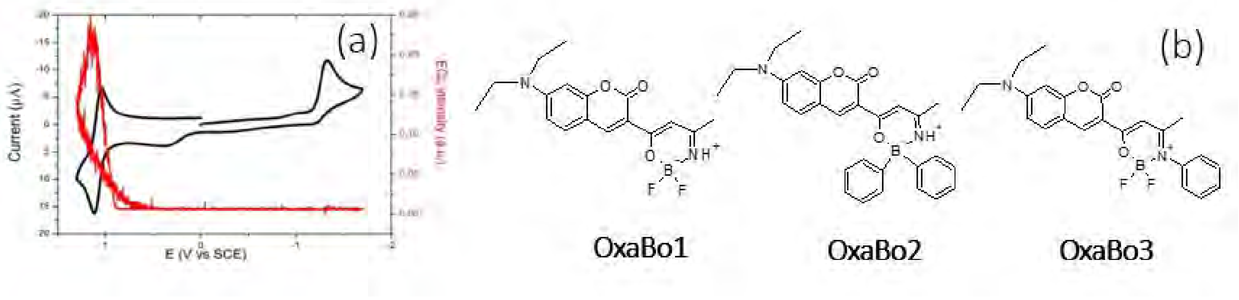

Figure 1: (a) ECL intensity vs potential for 5.10^{-4} M OxaBo3 (current in black and ECL in red) in CH_3CN/Bu_4NPF_6 (0.1 M). Cysteine detection at mesoporous Silica Films functionalized with Ferrocene

Himanshu Maheshwari*, Grégoire Herzog, Neus Vilà, Alain Walcarius
Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l'Environnement
UMR 7564 405, rue de Vandoeuvre 54600 Villers-lès-Nancy, France
* *himanshu.maheshwari@univ-lorraine.fr*

Cysteine is a thiol containing semi-essential amino acid which plays an important role in cellular functionality to counter oxidative stress in living cells [1]. It also has a role in certain cell signaling pathways [2] and regulatory functions [3]. Since, the cysteine amino acid is a part of glutathione tripeptide, selective detection of cysteine over glutathione always remains a challenge.

Herein, we report a novel strategy for the selective detection of micromolar concentrations of cysteine over glutathione, taking advantage of the electrocatalytic properties of ferrocene in the electrochemical oxidation of cysteine [4]. Ferrocene functionalized mesoporous silica films have been used for this purpose (Figure 1).

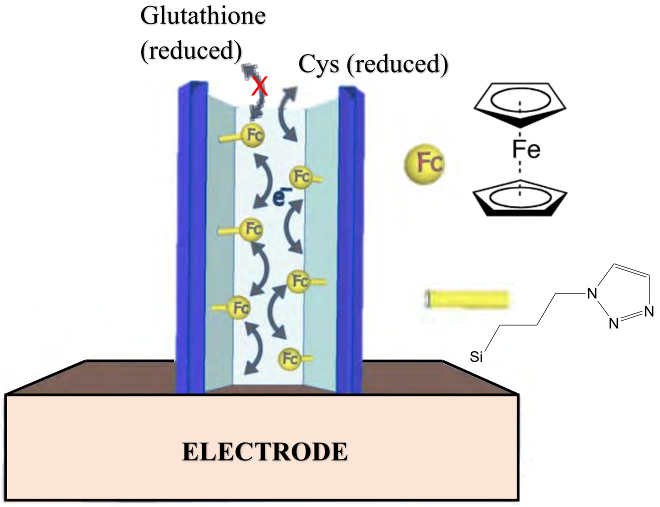

Figure 1: Selective oxidation of cysteine over glutathione and electron hopping effect in the ferrocene functionalized silica film

The films were prepared by electrochemically assisted self-assembly (EASA) method followed by copper-catalysed azide-alkyne Huisgen cycloaddition reaction [5]. Vertically aligned mesoporous silica films display good selectivity [6] and sensitivity [7]. The pores of the films are ~2 nm in diameter and offer a highly selective surface for small molecules. These ferrocene functionalized films were characterized by cyclic voltammetry and show good electrocatalytic activity for the oxidation of cysteine [8]. Further, we also discuss the electron transfer kinetics for such an electrocatalytic reaction and the effect of diffusion of molecules in the 1D mesochannels of mesoporous films. In order to improve the detection sensitivity, flow injection amperometry has been performed and is used for selective detection of cysteine in the concentration range from 3 to 100 µM in buffer solution.

Friction at electrode surface: Effect of adsorbates and potential

Inhee Park and Helmut Baltruschat*
Institute of Physical and Theoretical Chemistry University of Bonn
Roemerstr. 164, D-53117 Germany
Baltruschat@uni-bonn.de

Friction between sliding AFM tip and the surface of electrode in contact help us to understand interfacial and tribological behavior on nanoscale. The measurement of friction in an electrochemical cell allows controlling the interfacial interactions in situ easily. Our interest has been focused on the adsorption of foreign metals, ranging from (sub)monolayer (underpotential deposition(UPD)) to multilayer (bulk deposition) and the adsorption of organic adsorbate depending on a potential on single crystal electrodes in aqueous electrolyte[1-3]. In addition to studies made in aqueous electrolyte, ionic liquids have been introduced for friction study to investigate their structures depending on a potential.[4, 5].

In this study, we investigate the interfacial properties on Au(111) in aqueous electrolyte. The structure of Ag UPD layers is extremely sensitive to co-adsorbed anions such as ClO_4^-, I^- and SO_4^{2-}. In perchlorate electrolyte, Ag UPD layers show different structure depending on the existence or nonexistence of the iodine adlyer on Au(111)[6,7]. We found that the iodine adlayer on Au(111) forms a $(\surd 3\times\surd 3)R30°$ structure using the results of atomic stick-slip. It changes to a $p(3\times3)$ and $(\surd 3\times\surd 3)R30°$ structure after 1st Ag UPD and 3rd Ag UPD, respectively. The results of the friction on potential shows that the incomplete Ag UPD layer on Au(111) leads to relatively high friction. It is in good agreement that for low and moderate coverages, the tip drags the adsorbates along the surface resulting in high friction, whereas for higher coverages the tip slides above the adsorbates resulting in low friction[6]. The results of the friction on load on I-modified Au(111) shows three apparent regimes. Under the low normal load (F_N<30nN), the friction force is independent on Ag UPD, meaning that the tip is interacting with iodine layer. Under critical normal load, the friction shows a rapid increase, which indicates that the tip penetrates into the iodine layer. Under the high normal load (F_N>100), the friction shows moderate increase, which represents that the tip is interacting with Ag UPD layer.

Revealing the mechanism of the performance discrepancy between Li and Na metal anodes

Shuai Tang
Center of Green Catalysis, and College of Chemistry, Zhengzhou University
College of Chemistry, Zhengzhou University, Zhengzhou 450001, P. R. China
stang@zzu.edu.cn

Lithium and sodium metal anodes are promising candidates for next-generation energy storage systems because of the high theoretical capacity and low working potentials. It is reported that the high affinity between Li/Na metals and the electrodes can help suppress the dendrite growth and thus improve the reversibility of Li/Na plating/stripping cycles.[1-3] However, we find that the average Coulombic efficiency and lifespan for Na is superior to that of Li in literatures (Figure 1a). Therefore, we systematically investigate the fundamental electrochemical behaviors and interphase chemistry of Li and Na metal anodes. We uncover that the reversibility difference is correlated with the plating geometry, which originates from the concentration polarization at the interphase between Li/Na metal and the electrolytes (Figure 1b, c).[4] More importantly, we propose ways to ameliorate the reversibility of Li metal anodes. We believe the work can shed light on the researchers for the understanding of Li and Na metal anodes and further designing high-performance Li and Na metal battery.

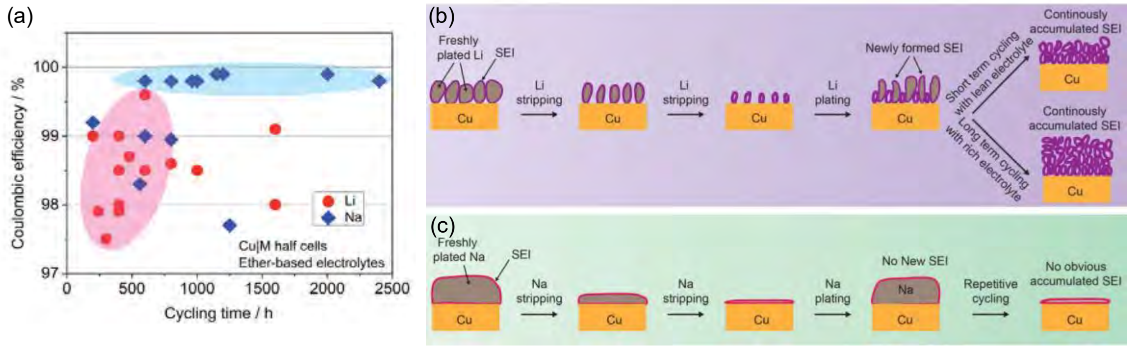

Figure 1. (a). Summary of coulombic efficiencies and cycling time of the Li and Na plating/stripping cycles reported in the literature. The scheme of the cycling process of (b) Li and (c) Na metal anode.

Nickel-based composite coatings have been used widely in various industries due to its good corrosion protection ability and graphene-oxide have attracted enormous interest due to its wide range of properties, such as excellent mechanical properties, impermeability, chemical stability and thermal stability. In the present work, we have fabricated nickel -graphene oxide (Ni-GO) composite coating on mild steel substrate by facile and cost-effective electrodeposition techniques, and characterized by XRD, FE-SEM, and EDX. XRD analysis shows that the growth of Ni-GO coating is along the 111 and 200 planes. FE-SEM image indicates the enhancement in the compactness of the coating and EDX confirmed the successful incorporation of the carbon content in the Ni-GO coating. Further, electrochemical polarization test and electrochemical impedance spectroscopy are carried out to study the corrosion resistance of the coating in 3.5% NaCl solution. The effect of various current densities (10, 20, 30, 40, 50 mA/cm^2) on the morphology and corrosion protection properties on the coating is also investigated and discussed in detail. The corrosion rate is found to be lowest at the current density of 40 mA/ cm^2 due to its better compactness of Ni-GO coating. Moreover, immersion test is also performed for three days where the corrosion rate of composite coating is reduced as compared to bare steel. This work finds a new way to fabricate GO-based composite coating on mild steel for effective corrosion protection.

Catalytically Active Re-Ni and Ni-Re-P Coatings as Electrocatalytic Materials for Hydrogen Evolution Reaction

Electroplating and electroless chemical deposition are used for formation of catalytically active Re–Ni coatings. Re–Ni deposits prepared by electrodeposition contain 55–88 at. % of rhenium. It is found that these coatings have an amorphous structure and contain metallic nickel and both metallic and oxides forms of rhenium. The oxidized forms of rhenium are obviously oxides containing rhenium in the intermediate oxidation states. Re–Ni cathodes demonstrate high catalytic activity in 1.0 M sodium hydroxide solution. The logarithm of exchange current density of the hydrogen evolution reaction (HER) for the most catalytically active Re–Ni alloys containing 80 at.% of rhenium is –3.4. The obtained materials are stable in alkali solutions under electrolysis conditions, but they are unstable in acidic media.

On the contrary, Ni–Re–P coatings obtained by electroless deposition using sodium hypophosphite as a reducing agent are promising candidates for HER electrocatalysis in acidic solutions. The deposits are also X-ray amorphous and contain metallic rhenium, metallic and oxidized forms of nickel, and some phosphorus.

Therefore, Re–Ni coatings prepared by electrodeposition are promising for electrocatalysis of HER in alkaline solutions, whereas Ni–Re–P deposits obtained by electroless deposition are attractive candidates for hydrogen evolution in acidic solutions.

Developing nonprecious metal, efficient and stable electrocatalysts is still a big challenge for industrial water electrolysis to produce hydrogen and oxygen gas. Elemental doping to modulate electronic structure, and morphology engineering have proven to be effective for enhancing materials' catalytic activity. In this work, we report a facile and practical method to fabricate self-supported NiFeP coated nickel phosphide rods on Ni foam (NiFeP@NiP@NF) by phosphorizing NiFe Prussian blue analogues (PBAs) coated on nickel phosphate hydrate rods grown on Ni foam. The NiFeP@NiP@NF electrocatalyst shows efficient oxygen evolution activity, exhibiting low overpotentials of 225 and 252 mV at current densities of 10 and 100 mA cm^{-2}, respectively, in 1.0 M KOH. NiFeP@NiP@NF can also work as an active electrocatalyst for hydrogen evolution reaction with a low overpotential of 99 mV at a current density of 10 mA cm^{-2} in the same solution. Thus, the catalyst can act as both anode and cathode in an electrolyzer, requiring a cell voltage of 1.56 V to afford a 10 mA cm^{-2} current density. Furthermore, the composite material exhibits outstanding stability for continuous water electrolysis over 120 h. The high catalytic activity and excellent durability of this material are attributed to the synergistic effect of nickel and iron phosphide, and the core-shell rods structure. This method could be applied to prepare other bimetallic phosphide electrocatalysts with similar structure in the future.

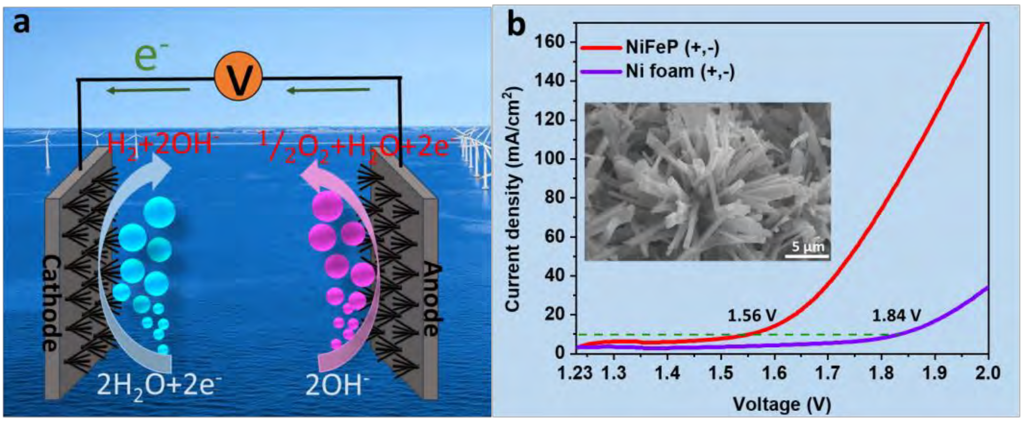

Figure 1. a. Scheme of water splitting (left). b. Polarization curves of NiFeP@NiP@Ni foam (+,-) and Ni foam (+,-) for overall water splitting in a two-electrode electrolyzer (right); Inset: SEM image of NiFeP@NiP@NF.

Thin films of molybdenum-based 2D or amorphous materials for the hydrogen evolution reaction

Ariane Schmidt and Aldo J. G. Zarbin

arianeschmidt@ufpr.br; aldozarbin@ufpr.br

Hydrogen has been considered a promise for clean and sustainable energy resource to replace the finite and traditionally fossil fuels. The water can be split into hydrogen and oxygen with the aid of electricity or solar radiation, which is a renewable and sustainable technology for hydrogen generation. A limiting factor for water splitting is the shortage of low-cost and high-efficiency catalysts. At the date, Pt provides the best hydrogen evolution reaction (HER) catalysis, but it is too expensive and scarce. Molybdenum-based materials, such as 2D-MoS_2 and amorphous MoX (X= S or O), is pointed out as favorable alternative to the Pt HER catalysts. In this work, we have investigated the performance of molybdenum-based two-dimensional (2D) and amorphous thin films as catalyst for HER. Samples have been prepared according a methodology developed by us[1] based on a reaction between ammonium molybdate and ammonium sulfide in acidic media, directly in one phase reaction or in a liquid/liquid (L/L) interfacial system. The samples were characterized by Raman spectroscopy, X ray diffraction, scanning electron microscopy (SEM) and linear sweep voltammetry. The synthesis carried out in one phase system leads to an amorphous powder composed by molybdenum sulfide and oxide that can be easily converted to a mixture of crystalline MoS_2/MoO_3 with a proper annealing at inert atmosphere. Otherwise, the synthesis at the L/L system gives rise to a thin film of amorphous MoX directly at the L/L interface. Also, with liquid phase exfoliation in acetonitrile of the mixture between MoS_2/MoO_3 these two materials were separated, yielding a homogeneous and stable dispersion of 2D-MoS_2, which is separated from the undispersed MoO_3 by centrifugation. The dispersion was used to prepare thin films of 2D-MoS_2 based on the L/L interfacial method.[2] The deposition of the MoX and 2D-MoS_2 can be made in any kind of substrate. In order to analyze the potential of the materials for HER, the films were deposited over ITO or glassy carbon. The linear sweep voltammetry was made in H_2SO_4 0.5 mol L^{-1} as electrolyte. It was observed that the electrode plays a crucial role in the performance of HER. Both materials showed currents below 2.5 mA cm^{-2} when deposited over ITO, however a totally differently behavior was observed when the materials were deposited in glassy carbon instead, in which MoX and 2D-MoS_2 showed an overpotential of 255 mV cm^{-2} and 344 mV cm^{-2} at 10 mA cm^{-2}, respectively. The difference in the overpotentials could be addressed to the wrinkly morphology and composition of the amorphous film, which provides vacancies along the sample, that improve the catalytic behavior for HER comparable to the 2D-MoS_2, which have the active sites only in the edges. An overview of the work is presented in Figure 1. Overall, this works presented a simple, original and versatile route to prepare different molybdenum-based materials thin films and showed the potential of the materials as catalyst for hydrogen generation by water splitting.

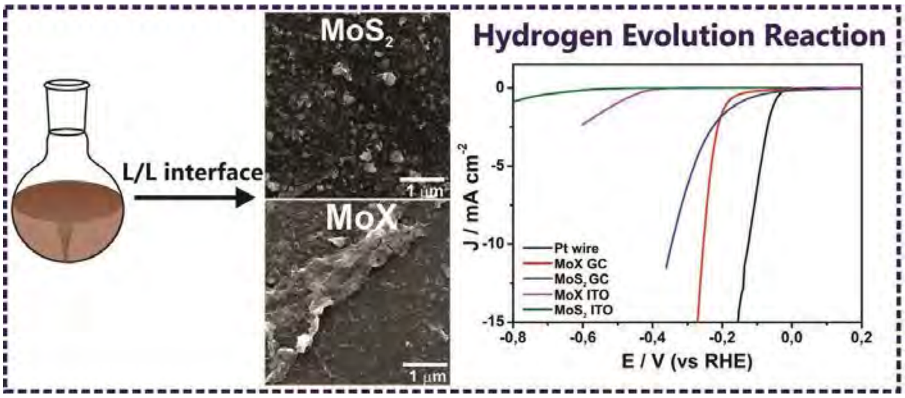

Figure 1. Summary of the materials obtained and the performance in HER.

Antibiotic resistance has a significant impact on health and therapeutic efficacy, the World Health Organization (WHO) recommending a careful monitoring of the use and disposal of this class of drugs. Therefore, there is a rising demand for highly sensitive sensors able to selectively detect low concentrations of antibiotics from different matrices in a fast and decentralized manner.

The purpose of this study was to develop an electrochemical sensor for the detection of azithromycin from various conventional (urine, plasma) and nonconventional (tears) biological fluids, by combining the convenient synthesis and analytical robustness with the tailored selectivity offered by molecular imprinting.

For molecular recognition and signal transduction a thin (~75 nm) imprinted polymeric film, using 3-thienyl boronic acid as functional monomer and 2,2´-bithiophene as crosslinker, was electropolymerized on the surface of a glassy carbon electrode. The resulting polymeric layer, both by covalent interactions (cyclic ester formation with the cis-diol moieties) and steric/functional complementarity of the imprinted cavities, is rendered highly selective towards the template molecule (azithromycin).

The surface morphology and the analytical performances of the developed sensor were assessed by scanning electron and atomic force microscopy, electrochemical impedance spectroscopy and cyclic voltammetry. By employing an indirect electrochemical detection using cyclic voltammetry in the presence of 10mM ferro/ferricyanide as redox probe, the sensor exhibited a very wide dynamic range (13.33 nM to 66.67 μM), with an estimated detection limit in the subnanomolar range (0.85 nM azithromycin). Under the optimized conditions the simple to construct sensor could be reused multiple times (>5) without significant loss in the signal intensity, has a good shelf-life (>1 month) and exhibits remarkable selectivity over a wide number of structurally related and non-related antibiotics, commonly associated drugs and endogenous compounds. The fabricated sensor was successfully applied for the quantitation of azithromycin from different biological samples (urine, plasma, tears).

A Desalination Fuel Cell

Shada Abu Khalla[1], Imri Atlas[2], Matthew E. Suss[3]

Shadak@campus.technion.ac.il

Desalination has evolved into a viable alternative to fresh water supply, increasing water availability and decreasing scarcity. Reverse osmosis (RO) is the most-widely used technology today for desalination, and requires significant electrical energy investment, about 4 kWh/m^3 of treated water, when desalinating sea water. In contrast to such conventional desalination systems which utilize energy, we here introduce the desalination fuel cell, which takes chemical energy as input, in the form of hydrogen and oxygen gas, and produces both desalted water and electricity simultaneously. Thus, water can be desalinated without any external electrical supply required. The desalination fuel cell is based on continuous energy conversion from chemical to electrical, and thus is not cyclic as with capacitive deionization.

As with an ED cell, our cell consists of one anion and one cation exchange membrane which sandwich a desalination channel fed with feedwater. Unlike an ED cell, on the opposite side of the anion exchange membrane is a hydrogen anode and anolyte, while an oxygen cathode and catholyte are placed opposite to the CEM. During operation, the reductant present in the anolyte (hydrogen) and oxidant present in the catholyte (oxygen) react spontaneously at the anode and cathode surfaces, respectively, providing an electric current between the anode and cathode which can be delivered to a load. The half-reactions also give rise to a spontaneous ionic current through the cell, which drives ion removal from the desalination channel[1].

The cell was characterized experimentally in single-pass mode for various catholytes and anolytes, including using feedwater as anolyte and catholyte (feedwater was 0.5 M NaCl). When using a slightly acidic catholyte (pH = 1) and basic anolyte (pH = 13), the cell demonstrated significantly higher voltages and electricity production during desalination. The results of the latter experiments are shown in Fig. 1 for varying feedwater flowrates. Fig. 1a shows polarization curve measurements that were performed. A high open circuit voltage (OCV) of ~1.6 V was reached, while the flowrate affected voltage at higher currents (~ 5 mA/cm^2). Fig. 1b shows the effluent concentration at the downstream end of the desalination compartment. We can see that at lower flowrate (0.1 ml/min), the cell performed near-complete desalination at a single pass. Furthermore, we calculated the desalination efficiency and recovery efficiency and compared it to a dedicated thermodynamic model that we developed for chemical energy driven desalination systems.

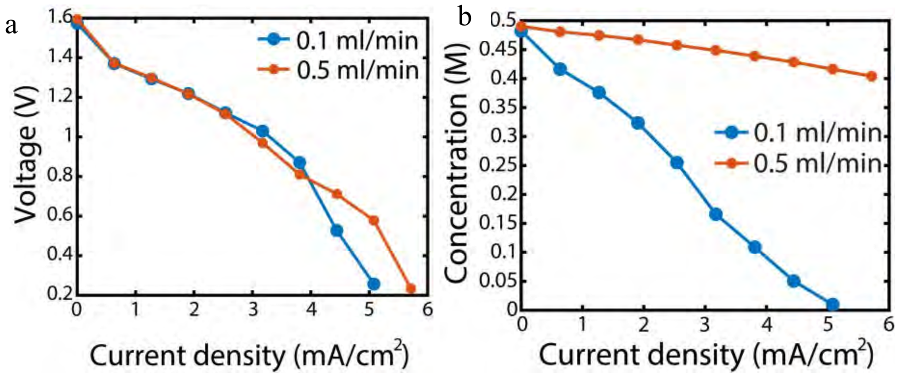

Fig. 1: Experimental results from our desalination fuel cell prototype device. a) Polarization curve measurements. b) concentration of the desalted effluent leaving the cell after a single pass.

The poor electronic/ionic conductivity and low cyclic performance of iron-based oxides hinder their practical application as electrode materials for high-performance pseudocapacitors. Owing to this, introduction of defects such as oxygen vacancies in iron-based oxides could alter their electronic/ ionic conductivity and thereby, improve the energy storage performance. Herein, we have fabricated nanoparticle and nanofibers of $CaFe_2O_4$ (CFO) by combustion and electrospinning technique, respectively, and characterized by XRD, FE-SEM, TGA, TEM, and BET. EPR and XPS reveal the presence of higher concentration of oxygen vacancies in nanofibers of CFO than their nanoparticles. The energy storage performance of CFO is further investigated by CV, GCD, and EIS. The specific capacitance of CFO nanofibers is found to be 380 (±10) F g^{-1} at 1 A g^{-1} in 3M KOH, which is higher than their nanoparticles (225 (±10) F g^{-1}). The improved performance of nanofibers of CFO is attributed to the alignment, high aspect ratio, and void/gaps present in the nanofibric architecture. These voids/ gaps are beneficial to facilitate smoother percolation of electrolyte to the interior of active electrode materials and enable high and stable capacitance. In addition to morphological features, the presence of higher concentration of oxygen vacancies in nanofibers leads to better electronic/ionic movement. This work opens a new strategy to develop Fe-based oxides as high-performance electrode materials for pseudocapacitive applications.

Comparison of In-situ ^{57}Fe Mössbauer Spectroscopic Data for Differently Prepared Fe-N-C Catalysts

L.Ni; C.Gallenkamp; M. Kübler, S. Paul; V. Krewald, U.I. Kramm
Department of Materials- and Earth Sciences & Chemistry
Otto Berndt-Str. 3, 64287 Darmstadt
Lingmei.ni@ese.tu-darmstadt.de

Electrochemical energy conversion in proton exchange fuel cells (PEFCs) is very promising for world-wide energy demand, especially in the transportation sector [1]. Currently, the application is hindered by the high costs of platinum-based catalysts. For the oxygen reduction reaction, Fe-N-Cs are promising to replace Pt based catalysts.

^{57}Fe Mössbauer Spectroscopy is powerful in obtaining detailed information of iron sites, with respect to structural composition, electronic states as well as magnetic environment [2-3]. The active site structures have been debates for a long time and different geometric structures have been proposed for differently prepared catalysts by multi-characterization methods, which indicate there might be indeed different active site structures from different preparation routes [4-5].

In this work, in-situ Mössbauer spectroscopy coupled with electrochemistry is used to get more insights on similarities and differences between differently prepared catalysts. The in-situ data are compared and similar trends on the active sites will be summarized for the three different catalysts. Based on this, further insights on the active site structure in Fe-N-C catalysts can be gained.

Ion-transfer Voltammetry as a Powerful Tool in Electrochemical Investigation of Biogenic Amines

Konrad Rudnicki, Łukasz Półtorak, Paulina Borgul, Sławomira Skrzypek
Department of Inorganic and Analytical Chemistry, University of Lodz, Tamka 12, 91-403 Lodz, Poland
konrad.rudnicki@chemia.uni.lodz.pl

Electrochemistry at the liquid – liquid interface, or the interface between two immiscible electrolyte solutions (ITIES) gains more and more interest among scientists due to its wide range of applications including electrochemical sensing. Detection at ITIES is not dependent on oxidation or reduction processes (common in electroanalysis) and can ensue from a simple interfacial ion transfer reaction – truly unique property [1]. Biogenic amines (BA) are biologically active compounds supplied to the human body together with food we consume. It was recognized that at elevated concentration (e.g. in some cases, 5-10 mg of histamine can lead to human poisoning) these compounds are directly related to the health risks, from light to heavy intoxication or disorder of many metabolic processes. Their increased content in food products results from microbial decarboxylation of amino acids during fermentation, processing and storage of raw materials or endogenous enzymes activity contained in raw materials. Furthermore, the presence of increased concentrations of BA can be directly related to the food spoiling. Consequently, simple and cheap methodologies have to be develop to monitor these species at different stages of food storage and processing.

Within this paper, the electrochemical behavior of selected BA at the ITIES has been studied using ion–transfer voltammetry (ITV). Voltammetric experiments were performed in the conventional four electrode macroscopic cell (macro-ITIES, see Fig. 1) using 10 mM HCl as an aqueous phase while the organic phase was the solution of hydrophobic salt dissolved in 1,2-dichloroethane. The effect of concentration of the investigated BA on the analytical signal was studied. Based on obtained results analytical parameters such as: linear dynamic ranges (LDRs), limit of detections (LODs) and sensitivities were established. Furthermore, the effect of pH on the analytical signal was tested and the results are plotted in a form of ion partition diagrams. The precision and repeatability of the method were also checked. The obtained results showed that the elaborated procedure can be successfully apply for screening purposes.

Fig. 1. Traditional macroscopic ITIES cell.

Development of a Sandwich Molecularly Imprinted Polymer Based Sensor for Adenosine Detection

Laura-Elena Gliga, Bogdan-Cezar Iacob, Ede Bodoki*, Radu Oprean

"Iuliu Hațieganu" University of Medicine and Pharmacy, Analytical Chemistry Department, Louis Pasteur 4 street, 400349, Cluj-Napoca, Romania

**e-mail: bodokie@umfcluj.ro*

Abnormal concentrations of adenosine, an endogenous purine with vital roles in all cells of the human system, represents a diagnostics marker of several metabolic disorders and diseases. The purpose of this study was to develop an innovative sandwich MIP-based electrochemical sensor for fast and reliable detection of adenosine in biological samples.

A novel electropolymerized sandwich molecularly imprinted polymer (MIP) was designed. The MIP film relies on the formation of covalent-imprinted biomimetic recognition sites generated by the overlapping of two polymeric layers. The first one is a boronate-affinity bithiophene layer (consisting of 2,2´-bithiophene and a boronic acid functional monomer) and an overlaying poly(3-indolacetic acid) intended to extend the selectivity towards adenosine. The selective binding of adenosine is occurring by a double recognition mechanism (IF ~ 4.5), both through functional (covalent and noncovalent) and spatial complementarity. Indirect electrochemical detection is performed in the presence of ferro/ferricyanide as redox probe. Electrochemical impedance spectroscopy and cyclic voltammetry was employed for sensor characterization, whereas differential pulse voltammetry served for the quantitative determination of adenosine. The MIP based sensor can be used multiple times without significant loss in the signal intensity, exhibiting a linear response in the range of 37.4 nM – 37.4 µM, with a LLOD of 21 nM in pH 7.4 phosphate buffer solution. The selectivity of the MIP sensor towards adenosine against other nucleosides and other relevant structurally-related interferents was also demonstrated. The developed sensor was applied for the fast and quantitative assessment of adenosine in spiked urine samples with good recoveries (102.98% - 106.34%).

Gold nanoparticles are important components for biomedical application, offering unique optoelectronic and catalytic properties. As such, they continue to attract considerable interest in electrocatalysis and in the design of chemo- and biosensors. Cysteine can be used to control the size and shape of chemically or electrochemically obtained gold nanoparticles. By adding L-cysteine to the $HAuCl_4$ solution used for gold electrodeposition, the number of nucleation sites and overall process kinetics are improves without major changes in the purity of deposits.

The present study aimed to investigate the enantioselective interaction of a model chiral drug molecule, propranolol at the surface of L-cysteine functionalized gold nanoparticles using electrochemical techniques (differential pulse voltammetry and electrochemical impedance spectroscopy) and computational modeling (molecular dynamics simulations).

L-cysteine modified gold nanoparticles were potentiostatically (-0.4V vs. Ag/AgCl, 3M KCl) electrodeposited on the surface of a glassy carbon electrode, followed by the spontaneous adsorption of propranolol's enantiomers on the gold surface. The differences in the differential pulse voltammetric behavior of the two physisorbed enantiomers was investigated in pH 7.0 phosphate buffer.

Computational modeling served for the identification of the main attractive forces responsible of the chiral molecular interactions between the covalently bound L-amino acid and the enantiomer adsorbates. It was shown that the R(+) antipode is involved in a significantly higher number of hydrogen bonding than the S(-) antipode, being responsible of the recorded enantiospecific electrochemical signal.

Correlating electrochemical data with computational modeling allows a deeper understanding of fundamental molecular interactions occurring at the electroactive surface and may enable a more rational design of future chiral electrochemical sensing platforms.

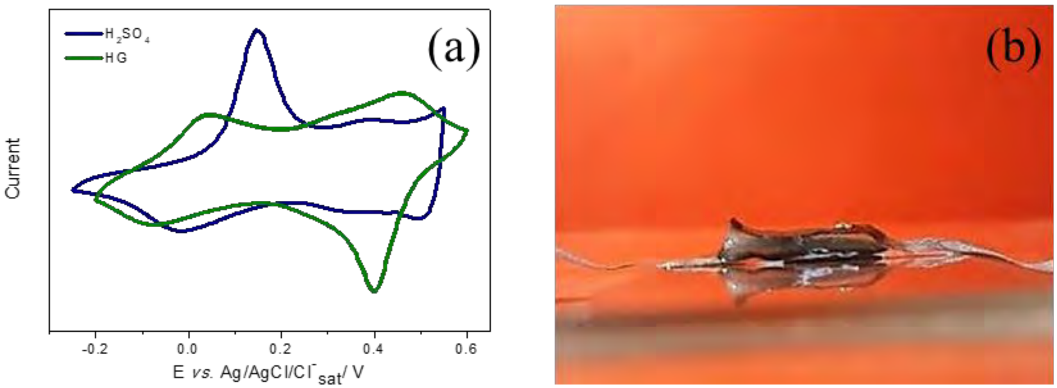
The electric power generation industry increasingly seeks to replace energy matrices based on fossil fuels with more sustainable sources. The need to develop high performance devices, capable of storing the electricity generated by these alternative sources, arises in this context. An example of devices that can perform this function are supercapacitors, which combine the high energy density of batteries with the high power density of conventional capacitors[1]. Supercapacitors have attracted the attention of researchers mainly for their versatility, once their architecture can be diversified in distinct ways, which allows their use in different applications. An application that is growing in the energy storage field is flexible and wearable electronic devices. For the development of a supercapacitor, it is necessary to have an electrode and an electrolyte. The literature is rich in studies on materials and morphologies for electrodes, however there are few studies on electrolytes, mostly on those capable of acting as electrolyte for solid devices[2]. Thus, it is interesting to develop a material that can act as an electrolyte and also present adequate viscosity, allowing its use in solid and flexible devices. In this work, a hydrogel-type electrolyte was developed from sodium alginate, a natural polysaccharide with low toxicity and low environmental impact[3]. The hydrogels were prepared from different proportions of sodium alginate, nitric acid and calcium chloride, and were characterized by cyclic voltammetry. Later, they were applied to the assembly of a supercapacitor device that combined the gel electrolyte with electrodes modified by polyaniline. The device was subjected to galvanostatic charge and discharge tests, for the evaluation of the device's specific capacitance. It was possible to establish proportions between the aforementioned reagents which allowed the charge to be transported, even with the expected diffusion limitations for an electrolyte of this type. In addition, it was possible to build a supercapacitor device in the sandwich architecture. Hereafter it is expected to test this supercapacitor device in other architectures and use this electrolyte with others conducting polymers electrodes.



The ciclic voltammetry (a) of polyaniline electrodes in H_2SO_4 1 mol L^{-1} electrolyte in blue and hydrogel electrolyte in green and a picture (b) of the supercapacitor device.

anabiancolli@hotmail.com

To overcome several limitations of Proton Exchange Membrane Fuel Cells (PEMFCs), anion-exchange membranes (AEM) have been developed for application in anion-exchange membrane fuel cells (AEMFC)[1]. This type of fuel cell can potentially reduce CO poisoning and allow for the possibility of using non-noble metal catalysts. Recent studies demonstrated very high performance for fuel cells containing AEMs based on the radiation-grafting of vinylbenzyl chloride onto ETFE (ethylene-tetrafluoroethylene) with a subsequent functionalization using either trimethylamine (TMA) or n-methylpiperidine (MPRD)[2]. In this work, anion exchange membranes (AEMs) based on ETFE films were synthetized under different conditions. The films were irradiated by using an electron beam source at room temperature (RT) under air or N_2 atmospheres, and also over dry ice (air atmosphere). This study evaluated the effect of dose rate and dose conditions on the grafting by vinylbenzyl chloride (VBC) and subsequently amination step. The anion exchange ionomers (AEI) responsible for conducting ions in the catalyst layer in the fuel cell are also a very important component in AEMFCs. These ETFE-AEIs, in powder form, as well as the membranes, were irradiated, grafted and functionalized by TMA. The literature presents two types of synthesis for ETFE-based AEIs: in isopropanol and in aqueous media. In the first[3], the IEC of the AEI is around 1.2 mmol g^{-1}, while in the second method[2] the IEC is around 2.0 mmol g^{-1}. However, despite this difference in IEC values, the fuel cell results are essentially the same. This is due probably to the fact that the synthesis in isopropanol provides smaller powder particles (and larger surface area in the triple phase boundary) than in the case of synthesis based on aqueous media. A major disadvantage of isopropanol synthesis is that four times more VBC is needed than in water synthesis, and this reactant is extremely toxic. Thus, besides analyzing the irradiation parameters effects on AEMs, this work also investigated the ETFE-AEIs synthesis, varying the medium, duration of the reaction and the irradiated dose. The aim was to combine smaller particle sizes with high IEC, low quantities of VBC and high final power density. AEMs synthesis results revealed that higher degree of grafting (DoG), as well as higher ion exchange capacities (IEC), are obtained at higher irradiation doses. It is important to mention that water absorption capacity follows exactly the same trend. Besides that, the switch from air to N_2 atmosphere during the irradiation process allowed higher DoGs for the same doses. For example, a membrane irradiated with 40 kGy under air normally reaches 60% of DoG after 16h of reaction, while the membrane irradiated at the same dose but under N_2 presented 82% of DoG after 16h and 63% after only 4h of reaction. The membranes irradiated on the dry ice have also shown an improvement on the DoG compared to the traditional ones irradiated at RT. At 100 kGy dose, membranes prepared over dry ice have presented 142% of DoG while membrane obtained under air results in approximately 90% of DoG. This unprecedented improvement in the way of irradiating ETFE films will allow the synthesis of membranes with the same ion exchange capacity and conductivities with lower dose rates, resulting in mechanically more stable membranes. H_2/O_2 single fuel cells tests with improved AEM and AEI showed a power density of the order of 1.13 W cm^{-2} (Fig. 1), which corresponds to a similar performance to the corresponding state-of-the-art PEMFCs obtained under similar conditions.

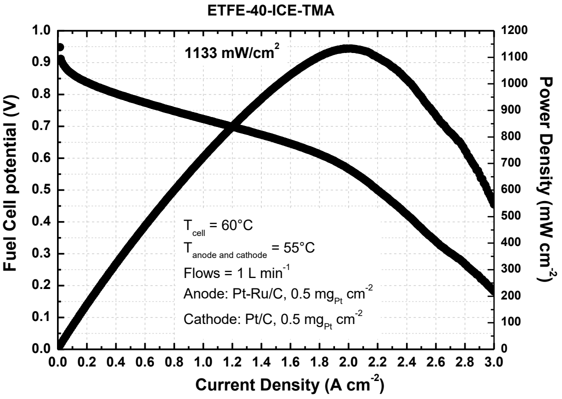

Figure 1. H_2/O_2 Fuel cells test with ETFE-AEM irradiated over dry ice.

High detection resolution of gas and liquid products using capillary inlet DEMS setup for the CO2 reduction reaction

J. Ferreira de Araújo, S. Renfrew, X. Wang, W. Ju, P. Strasser,
Technische Universität Berlin, Str. des 17. Juni 124,10623 Berlin, Germany
jorge.ferreira@tu-berlin.de

Rapid analytical assessment on the electrochemical CO_2 reduction reaction (CO2RR) is fundamental for the understanding of reaction mechanism and intermediates. A special attention is given to the complexity of multiple gas and liquid products evolving during CO2RR. The current analytical techniques are limited in terms of spatially resolved product sampling, which hinders the detection of product intermediates as well as the identification of reaction processes.

In the current work, we present the assessment of products using a liquid electrochemical cell coupled through a liquid loop interface with a high-resolution mass spectrometer (DEMS technique).

Up to now, DEMS measurement are done with the specific cell design that restricts the ideal reactions conditions. Moreover, there are only few reports on kinetics onset potentials during CO2RR for Cu metal with ethylene around $-0.74\ V_{RHE}$ and methane around $-0.9\ V_{RHE}$ and a lack of analytical identification of intermediate products.

The goals of this work are to discuss the merits of combining mass spectrometer analysis with optimized electrochemistry operating conditions, to describe the methodology for direct cell DEMS measurement and thus to stimulate further development on CO2RR. Also, we will present, for the first time with DEMS, C3 oxygenates (propionaldehyde and propanol) evolution accompanied with C3 hydrocarbons, such as propane (m/z = 39,41,42), which are essential for the synthesis of cyclic and economic fuel production. In this work, we examine the products of CO2RR on copper metal catalysts and compare them for different pre-treatment conditions. For further validation of the catalyst activity assessment, we present our methodology using isotope-labeling.

The capillary inlet DEMS setup is a patented technology that will soon be commercially available at LiquidLoop, a TU Berlin Spinoff.

A Statistical Design Approach for Impedance Spectroscopy of Li-ion Battery

Salim.Erol@aum.edu.kw

Energy storage systems face challenges regarding safety and performance since they can operate under different conditions. In this sense, multiple factors can affect the performance of Li-ion batteries. Cell potential and temperature are considered major factors among them. Robust development of energy storage devices requires a deep understanding of the relationship between the operation conditions and electrochemical features. The influences of cell potential and temperature on battery parameters of commercially available $LiNiMnCoO_2$/graphite coin cells were statistically investigated and discussed by using electrochemical impedance spectroscopy combined with the Taguchi method. The experimental design provides a combination of measurements that enables fast and reliable results and detailed analyses. The experiments based on the experimental design minimize the adverse and unavoidable effects that can be defined as noises in the design terminology and increases confidence level for the results.

The Taguchi design of experiment was applied to interpret the influence of factors on the regressed elements of the developed equivalent circuit model. The synergistic effects of the battery potential and temperature on the response variables were monitored based on the statistical analysis. The factor dependency of the fitting parameters obtained from impedance response of the battery is presented in detail by a variance analysis as well as the response table.

The results showed that the sustainable Li-ion battery can be optimized in terms of battery dynamics by selecting the optimum temperature and potential obtained in this study. Temperature was determined to more significant factor compared to cell potential, suggesting that this factor should be selected carefully when the battery dynamics is desired to be optimized. This approach is suggested to be applied for different types chemistry and geometry of batteries. The results of the Taguchi design method combined with the electrochemical impedance spectroscopy would pave an effective way for the researchers improving the battery management systems in real applications.

Lithium–matrix Composite Anode Protected by a Solid Electrolyte Layer for Stable Lithium Metal Batteries

Lithium (Li) metal with an ultrahigh specific theoretical capacity and the lowest reduction potential is strongly considered a promising anode for high-energy-density batteries. However, uncontrolled lithium dendrites and infinite volume change during repeated plating/striping cycles hinder its practical applications immensely. Herein, a house-like Li anode (housed Li) was designed to circumvent the above issues (Figure 1)[1]. The house matrix was composed of carbon fiber matrix and affords a stable structure to relieve the volume change. An artificial solid electrolyte layer was formed on composite Li metal, just like the roof of a house, which facilitates uniform Li ions diffusion and serves as a physical barrier against electrolyte corrosion. With the combination of solid electrolyte layer and matrix in the composite Li metal anode, both dendrite growth and volume expansion are remarkably inhibited. The housed Li | LiFePO4 batteries exhibited over 95% capacity retention after 500 cycles at 1.0 C in coin cell and 85% capacity retention after 80 cycles at 0.5 C in pouch cell. The rationally combination of solid electrolyte layer protection and housed framework in one Li metal anode sheds fresh insights on the design principle of a safe and long-lifespan Li metal anode for Li metal batteries.

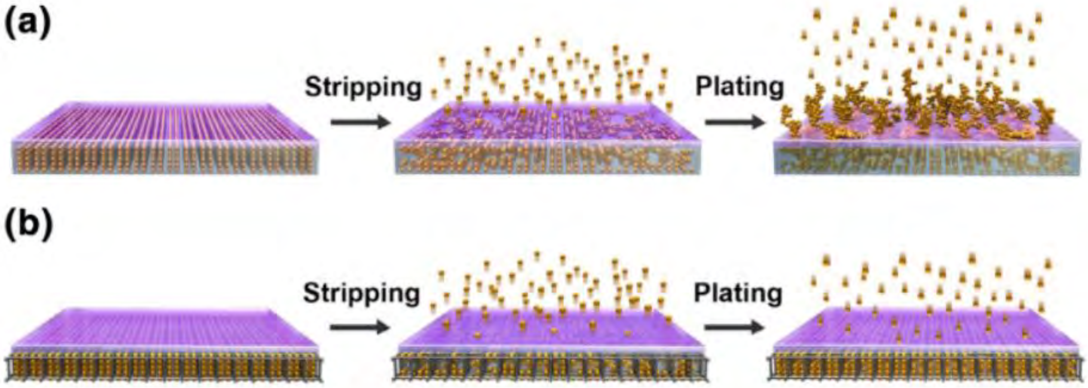

Figure 1. Schematics of morphology evolution on (a) bare Li and (b) housed Li during stripping/plating cycles.

The effect of process parameters was investigated on electrochemical treatment of textile dyeing wastewater containing Reactive Violet 5 (RV5) using Pt/Ir electrodes in the presence of 75%NaCl+25%Na_2CO_3 (w/w) supporting electrolyte mixture in a batch electrochemical reactor. Effect of process parameters were operated in the range of 300-1500 mg/L textile dye concentration, 4-20 g/L electrolyte concentration, 5-15 mA/cm^2 current density, and 20-60°C reaction temperature in 120 min electrolysis time. Decolorization yield was analyzed using UNICO 4802 model UV/Vis double beam spectrophotometer at 520 nm wavelength. Merck Spectroquant COD cell tests used for the COD analysis. Energy consumption for dye decolorization was obtained as much lower than COD removal due to the degradation of azo bond is the first step of the electrochemical degradation of the textile dyes. The energy consumption decreased with increasing textile dye concentration, electrolyte concentration and reaction temperature, while decreasing the current density. In the study, energy consumption values were evaluated for textile dye decolorization (t=15 min) and COD removal (t=120 min) as 3.8-23.5 kWh/kg dye decolorization and 64.7-321.1 kWh/kg COD removal, respectively.

Table 1. Effect of process parameters on energy consumption in electrochemical treatment of textile dyeing wastewater containing Reactive Violet 5 (RV5) using Pt/Ir electrodes

Parameter	**Process Conditions**	**E_D (kWh/kg dye decolorization) (t = 15 min)**	**E_{COD} (kWh/kg COD removal) (t = 120 min)**
Textile dye concentration	300-1500 mg/L (J=10 mA/cm^2, T=40°C, electrolyte=12 g/L)	7.4 - 22.2	100.6 - 314.7
Electrolyte concentration	4-20 g/L (J=10 mA/cm^2, T=40°C, RV5=900 mg/L)	6.4 - 20.4	111.4 - 321.1
Current density	5-15 mA/cm^2 (RV5=900 mg/L, T=40°C, electrolyte=12 g/L)	3.8 - 15.1	64.7 - 275.6
Reaction temperature	20-60°C (J=10 mA/cm^2, RV5=900 mg/L, electrolyte=12 g/L	6.8 - 10.1	134.1 - 139.6

e-mail:helzan@chem.uw.edu.pl

Anticancer drugs such as daunorubicin and doxorubicin, except for their interactions with DNA [1,2], are known to possess antibacterial properties. Moreover, some other antibacterial substances like levofloxacin [3], or nitrofurantoin [4], also interact with DNA. Question is therefore whether the electrochemical properties of new prospective antibacterial drugs might interact with DNA in a similar, or maybe in a different way than the anticancer drugs?

We have earlier studied the electrochemical properties of a new prospective anticancer drug 4-chloro-6-(1*H*-imidazo[4,5-b]phenasine-2-yl)benzene-1,3-diol (Cl-IPBD) in terms of its interactions with DNA [5, 6], using DP voltammetry to show the redox properties and ACV method to detect accumulation of the Cl-IPBD on the Glassy Carbon electrode (GCE) in terms of redox properties as well as capacitative/resistive properties. Similar strategy we are using now to study the properties of two, new prospective antibacterial drugs: 6-tert-butyl-2-(2,4-dihydroksyfenylo)-4H-tieno[3,2-d][1,3]tiazyn-4-on (TDTT), 5-(2,4-dihydroksyfenylo)-1-metylo-3-propylopirazolo[4,3-d][1,3]tiazyno-7(1H)-on (DMPT).

The difference in the conditions of the current experiments is however in the pH used. For the anticancer drugs, we have used pH 4.7, the pH often regarded as more suitable for the study of their cancer properties. This time, to obtain proper solubility of the prospective antibacterial substances, we used pH 7 to study the antibacterial drugs. For the sake of comparison, we have also tested the prospective anticancer drug Cl-IPBD at pH 7.

Comparison of Electrochemical Degradation Kinetics of Imidacloprid and Abamectin Pesticides in Aqueous Medium using Boron-Doped Diamond Electrodes

Bahadir K. Körbahti, M. Ceyhun Erdem
Mersin University
Faculty of Engineering, Chemical Engineering Dept., Çiftlikköy 33343 Mersin, Turkey
korbahti@mersin.edu.tr, korbahti@gmail.com

Electrochemical degradation of imidacloprid (IMD) and abamectin (ABA) pesticides were investigated using boron-doped diamond (BDD) electrodes in a batch electrochemical reactor. Reaction conditions were operated at 40-200 mg/L initial IMD concentration ($COD_{IMD,o}$=140-385 mg/L), 2-10 mg/L initial ABA concentration ($COD_{ABA,o}$=125-865 mg/L), 2-10 g/L supporting electrolyte (Na_2SO_4), 4-20 mA/cm^2 current density, and 20-60°C reaction temperature at 120 min reaction time. Merck Spectroquant COD cell tests used for the COD analysis. Process optimization was accomplished with response surface methodology in CCD designed experiments using Design-Expert 12 software in order to determine the effect of independent factors on COD reduction along with the experimental conditions. The optimum operating conditions under specified constraints were obtained for the highest desirability as outlined in Table 1.

Table 1. Optimum operating conditions for electrochemical degradation of imidacloprid and abamectin pesticides in aqueous medium using BDD anode

Parameter	**Imidacloprid**	**Abamectin**
Initial concentration	100 mg/L	5 mg/L
Na_2SO_4 concentration	4.4 g/L	6.4 g/L
Current density	8.6 mA/cm^2	11.8 mA/cm^2
Reaction temperature	60°C	60°C

In a batch electrochemical reactor, the overall electrochemical conversion rate of pollutants was expressed based on COD concentration. Reaction kinetics were determined by the method of initial rates, and specific reaction rate constants (k) were obtained using Arrhenius equation. The reaction kinetic parameters for electrochemical degradation of imidacloprid and abamectin pesticides in aqueous medium using boron-doped diamond anode were evaluated under response surface optimized conditions and given in Table 2. The reaction order of the electrochemical degradation of both pesticides were determined as 1. The activation energy (E_a) depends on the nature of the reaction, and fast reactions generally have small E_a values. It is known that the activation energy for a diffusion-controlled homogeneous reaction is <40 kJ/mol.

Table 2. Reaction kinetic parameters for electrochemical degradation of imidacloprid and abamectin pesticides in aqueous medium using BDD anode

Parameter	**Imidacloprid**	**Abamectin**
Reaction order (n)	1	1
Activation energy (E_a)	5.29 kJ/mol	9.28 kJ/mol
Reaction rate constant (k)	0.0105 min^{-1}	0.0100 min^{-1}
Frequency factor (k_o)	0.089 min^{-1}	0.624 min^{-1}

UV-photodegradation process can remove many organics that can not be removed from water by conventional treatments due to their chemical stability. Removal is based on oxidation via hydroxyl radical, •OH, strong oxidant produced by UV radiation. There are many attempts to catalyze the oxidation, commonly using certain oxides [1]. MoO_3 has many important applications, like in electrochromic devices and Li-ion batteries [4, 7], but it was also used as catalyst in some reactions [2, 3]; its crystal structure, activity and other properties depend on the synthesis conditions, thus several synthetic procedures are used, mostly hydrothermal [2, 3]. Electrochemical procedure was also applied due to its numerous advantages [4, 5]. In this work, MoO_3 is synthesized by galvanostatic electrodeposition, followed by thermal treatment, and used as a catalyst in UV-degradation of a dye Reactive Orange 16 (RO 16).

Electrodeposition was done in 0.05 M solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ at pH 6.0 in two-electrode cell on Ti substrate (cathode) at a current density of 10 mA cm^{-2} during 90 minutes. Deposited material was peeled off, dried, and thermally treated in air at 600°C for 90 minutes. Cyclic voltammogram of Ti substrate in deposition solution was recorded in three-electrode cell using SCE as a reference electrode. The same electrode setup was used for cyclic voltammetric determination of the material band gap. The obtained material was examined by SEM, EDX, XRD and FTIR. Dye degradation was performed using the obtained material (500 mg dm^{-3}) in UV chamber at 254 nm and 1950 μW cm^{-2}.

Cyclic voltammogram contains broad cathodic peak which originates from irreversible molybdate reduction. SEM revealed micro-crystalline, mostly rod-like morphology. EDX showed the Mo:O atomic ratio % of 19.9: 80.1, which is close to the elements ration in MoO_3 with little higher O-content. XRD revealed well crystalline α-MoO_3 (orthorhombic space group 62:Pnma, parameters a =13.84, b = 3.69 0 and c = 3.96; angles $\alpha = \beta = \gamma = 90.0°$ and V = 202.33 $Å^3$). FTIR spectra contain bands between 490 and 990 cm^{-1}, typical for α-MoO_3, but there is evidence of the traces of some other MoO_3 phase, most likely h-MoO_3 [6]. The calculated band gap is 3.23 eV.

RO 16 is stable to UV radiation under the applied conditions, and it is not adsorbed by synthesized MoO_3. When exposed to UV radiation in the presence of MoO_3 catalyst, a series of RO 16 solutions ranging from 10 to 50 mg dm^{-3} was completely decolorized. Reaction takes place via •OH radicals, generated at the catalyst surface excitated UV radiation. Decolorization time increased with the increase of initial dye concentration, being about 120 minutes for the highest one. Decolorization reactions follow the pseudo-first order kinetics. Catalyst activity was 95% of its initial after 5 consecutive uses.

Zinc molybdates have some important applications, like supercapacitor, electronic, optical devices technology and catalysis, so several synthesis procedures have been developed, including coprecipitation, various types of hydrothermal procedures or electrochemistry – assisted laser ablation, which affects their chemical composition, crystal structure and activity [1-5]. Advanced oxidation processes, including plasma, are developed in order to degrade organic compounds which are difficult to remove by conventional procedures. Organics are successfully degraded by plasma, however, there are recent attempts to enhance this process by application of catalysts [6]. In this paper, molybdenum zinc oxide was synthesized by electrochemical procedure, and applied as a catalyst in plasma degradation of a dye reactive Orange 4 for the first time, to the best of our knowledge.

Synthesis was done in two-compartment electrochemical cell by electrodeposition at Ti cathode in the solution containing 0.01 M $(NH_4)_6Mo_7O_{24}$ and 0.1M $ZnSO_4$ at constant current density of 10mA cm^{-1} during 120 minutes. Cyclic voltammetry was performed in the same solution in three compartment cell using SCE as reference electrode. Material was peeled off the cathode and characterized by SEM. EDX and XRD. Plasma dye degradation was performed by the self-made atmospheric pressure non-thermal plasma open reactor system, based on positive pulsating corona electrical discharge. The multipoint anode was placed above the liquid surface, which acted as a cathode. The corona discharge was created in the gas phase between them. All experiments were done at 40 kHz and current density of 9.15 $\mu A/cm^2$ [7]. Catalyst concentration was 50 mg dm^{-3}.Cyclic voltammogram showed broad cathodic peak which originates from co-deposition of Zn (II) and molybdate ions. SEM analysis showed flaky morphology, with particles of undefined shapes and size varying from 1 to more than 20 µm. EDX showed the presence of Zn, Mo and O with non- uniform distribution and average atomic ratio: 16.77: 8.91:74.32%, respectively, which close their ratio in $Zn_5Mo_2O_{11}\cdot5H_2O$. XRD revealed that the synthesized material is composed of mostly rhombohedral $Zn_5Mo_2O_{11}\cdot5H_2O$, which was obtained at the cathode by co-deposition of Zn (II) species and molybdate. Some minor presence of metallic Zn, as well as some amorphous phase, most likely amorphous $Zn_5Mo_2O_{11}\cdot5H_2O$ was also detected. Dye was completely degraded by plasma treatment. Total decolorization time was lower by about 50% in the presence of catalyst in the dye initial concentration range from 5 to 40 mg dm^{-3}. Decolorization proceeds via hydroxyl radical, •OH, which is generated by decomposition of plasma-generated H_2O_2 [7].The catalyst enhances generation of •OH from H_2O_2. Degradation reactions follow the pseudo-first order kinetics. After five consecutive uses, the catalyst kept about 94% of its initial activity.

Structural stability of K and Nb co-doping $Li_{1.167}Mn_{0.583}Ni_{0.25}O_2$ cathode material on enhanced rate and cycling performance

Gang Yang, Cong Liu, Yuhong Li, Hongmei Ji,
Jiangsu Lab of Advanced Functional Material, School of Materials Engineering, Changshu Institute of Technology, Changshu, 215500, P. R. China
gyang@cslg.edu.cn

The $Li_{1.167-x}K_xMn_{0.583-y}Ni_{0.25-y}Nb_{2y}O_2$ ($x = 0$, 0.05 and $2y = 0$, 0.01) samples are successfully prepared through ball mill and high-temperature treatment. The impact of K^+ and/or Nb^{5+} doping on the crystal structure, particle morphology and electrochemical properties of samples are investigated. The XRD patterns demonstrate that K^+ and/or Nb^{5+} doping does not significantly change the structure of $Li_{1.167}Mn_{0.583}Ni_{0.25}O_2$. Tiny changes in the lattice parameters of all samples indicate that K^+ and/or Nb^{5+} are successfully doped into the sample. The K^+ doping can expand the Li^+ diffusion channel and inhibit the transition of the layered structure to the spinel structure, and thus improve the cycleability and rate performance. The Nb^{5+} doping significantly improve the discharge specific capacity of the materials, but the single Nb^{5+} doping is not conducive to the cycling stability of the material. At 2C rate in a half cell, the bare LMN sample delivers capacity of 123.9 and 32.1 mAh g^{-1} at the 1st and 300th cycle, but the K^+ and/or Nb^{5+} doping significant the capacities, 141.9 and 110.2 mAh g^{-1} for LMN-K, 161.1 and 110.1 mAh g^{-1} for LMN-Nb, 162.5 and 140.6 mAh g^{-1} for LMN-K/Nb. In the full cell, the LMN-K/Nb sample also delivers the highest discharge capacities than the bare LMN and the single elemental doping samples. In addition, the XRD, SEM and XPS analysis of the positive and negative electrodes taken out from the full cell after cycling show that the crystal structure is effectively stabilized by the K^+ and Nb^{5+} co-doping, and the side reactions of the electrode and electrolyte are suppressed during the long cycle. These results demonstrated that the K^+ and Nb^{5+} co-doping are feasible strategies to enhance the performance of Li-rich layered cathode materials.

1-Hydroxyethylidene-1,1-diphosphonic acid as a corrosion inhibitor of AISI 304 stainless steel

Juliana Panceri Franco, Josimar Ribeiro

Laboratório de Pesquisa e Desenvolvimento em Eletroquímica, Departamento de Química do Centro de Ciências Exatas da Universidade Federal do Espírito Santo, Av.: Fernando Ferrari, 514, Goiabeiras, Vitória, Espírito Santo, CEP.: 29075-910, Brazil
josimar.ribeiro@ufes.br

The novelty of this work is the analysis in a medium containing sulfide ion due to the generation of this ion in petroleum industries, in the refining stage (the sulfide ion is also present on the produced water)[1]. The performance of 1-hydroxyethylidene-1,1-diphosphonic acid inhibitor (HEDP) was investigated by potentiodynamic polarization, electrochemical impedance spectroscopy, and weight loss measurements in a dissolution of AISI 304 stainless steel immersed in a solution containing chloride and sulfide ions. The protection of the stainless was increased with the addition of divalent cations (Ca^{2+}, Zn^{2+}, and Mg^{2+}). Potentiodynamic polarization studies have shown that the inhibitor alone has anodic protection, but the addition of Ca^{2+} (10 mg L^{-1}) favors the cathodic protection, and the addition of Zn^{2+} (20 mg L^{-1}) and Mg^{2+} (10 mg L-1) mixed-type is observed. Electrochemical impedance spectroscopy was performed at three distinct potentials: -0.3 [V vs. SCE], Ecorr [V vs. SCE], and 0.1 [V vs. SCE] (see **Fig. 1**). This revealed that calcium is responsible for favoring the formation of the film and the other elements (zinc and magnesium) favor the stabilization of the protective film. Scanning electron microscopy analysis revealed that the addition of cations provided the adsorption of HEDP on the metal surface. Weight loss results showed that the presence of zinc in a solution containing HEDP favored greater inhibitor efficiency (Zn^{2+} $\eta m = 85.2\%$ and for Mg^{2+} $\eta m = 70.4\%$) [2].

The rapid development of technology and the short life of electrical and electronic equipment has resulted in the production of a large amount of waste electrical and electronic equipment (WEEE), with a production rate of two to three times higher than other urban waste [1]. The recycling process of WEEE also plays a vital role in the management of the cumulative waste from the electronics industry [2]. For all the electronic devices, the printed circuit boards are the most valuable items [3]. Their recycling can be fulfilled by using electrochemical processes which have high environmental compatibility, high energy efficiency and can be performed with minimal involvement of auxiliary materials. As a result, the recovery of metals from waste printed circuit boards (WPCB) by using electrochemical methods can reduce the reagent consumption and allows to recuperate the valuable metals without or with less loss [4].

For the selective electroextraction of copper from the leaching solutions obtained during the recycling of WPCB, in this work, cyclic voltammetry (**CV**) and selective electrodeposition of Cu in galvanostatic mode were performed. The cathodic support material was stainless steel 316.

For the beginning, measurements were performed on synthetic electrolyte solutions (**SES**) similar to the real samples (**RS**). **SES** contain KBr + HBr as supporting electrolyte background and different concentrations of $CuBr_2$ and / or $SnBr_2$ and $PbBr_2$, respectively. **CV** tests demonstrated the possibility of selective electroextraction of Cu if the electrode polarisation is more positive than the electrodeposition potential of Sn and Pb.

Selective electroextraction of copper from **RS** occurs if the Cu concentration in solution at least as 12 g/L is maintained. Selective electrodeposition of Cu is possible in a wide range of current densities, between 200 and 600 A/m^2. Under these conditions, the purity of Cu obtained deposits can exceed 99.6%.

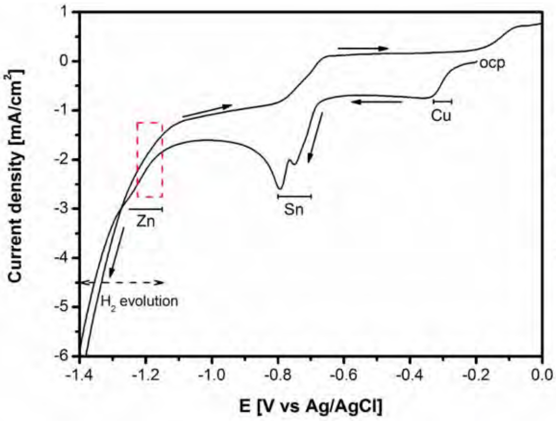
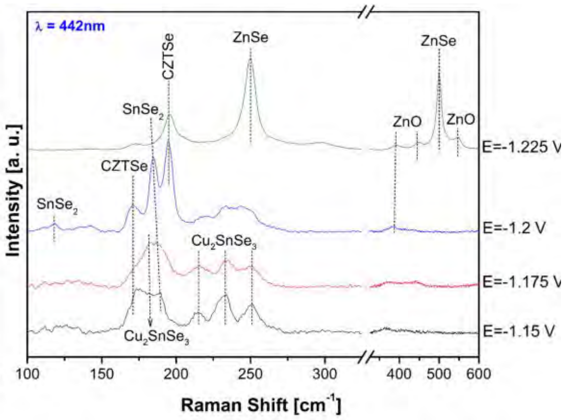
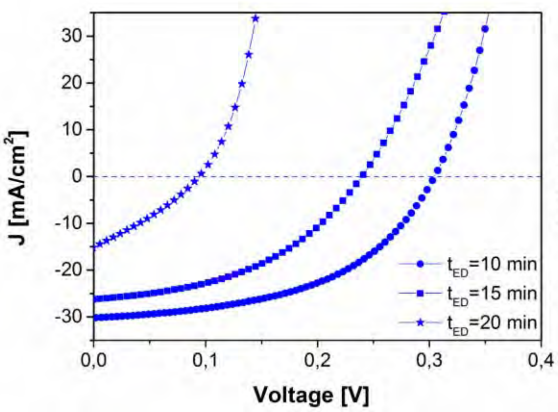
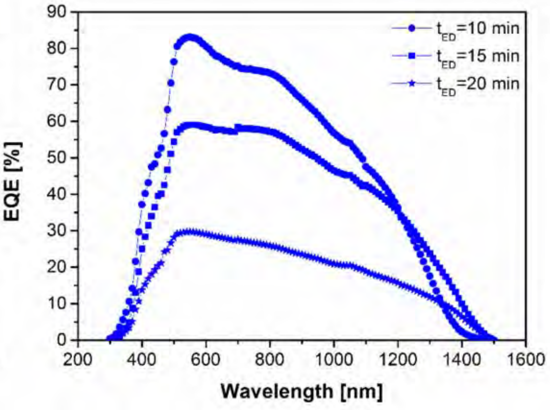
Electrodeposition is one of the most attractive techniques for the synthesis of thin films chalcogenides for photovoltaic applications, in particular for earth abundant kesterite. In this work, the influence of core parameters of this technique, such as the applied potential and deposition time, on the chemical composition of co-deposited Cu-Zn-Sn precursors is studied. Indeed, how the precursor composition affects the final composition of $Cu_2ZnSnSe_4$ after reactive annealing in Se atmosphere is also investigated, not only at the film level but also in solar cell devices. X-ray based techniques (XRF and XRD) reveal that the chemical and phase composition of electrodeposited precursors is highly sensitive to small modifications (25 mV) of the applied potential during electrodeposition. Only when the applied potential is -1.2 V (vs. Ag /AgCl) the precursor composition matches to what is required for operating devices. Multi-wavelength Raman spectroscopy of selenized precursors confirms that lower potential than -1.2 V favor the formation of Sn-rich secondary and ternary compounds after selenization, while a higher overpotential led to the formation of ZnSe in the film. On the other hand, the use of longer deposition times enhance the incorporation of zinc in the film, modifies the morphology of the precursor and promotes the formation ZnSe after selenization. Photovoltaic devices were only obtained at an electrodeposition potential of -1.2 V, and reaching a maximum efficiency close to 5% for a 10 minute electrodeposited CZT precursor.









Ternary PtCuSn Catalyst for Oxygen Reduction Reaction in Proton Exchange Membrane Fuel Cells

Dae Jong You*, Yun Sik kang, Eunyoung You
Fuel cell engineering Team, Hyundai Mobis co. LTD.
Yongin 16891, Republic of Korea
*daejong73@mobis.co.kr **

In fuel cells, Platinum (Pt) and its alloys have been widely used as the best electro-catalysts for the oxygen reduction reaction (ORR) owing to its intrinsic catalytic activity and stability, but its high price and scarcity limit among many major technical barriers of proton exchange membrane fuel cells (PEMFCs) still needs to be overcome in the development of electrochemical catalysts for widespread commercialization of PEMFCs [1]. In response to these issues, many researchers have been exploring novel catalyst with superior ORR activity that can effectively lessen the dependence on noble metal Pt in order to reduce the cost of fuel cells [2].

In this study, Platinum–Copper-Tin (PtCuSn) catalysts supported on carbon (XC-72R, cabot) were investigated as a cathode catalyst for oxygen reduction reaction (ORR) in proton exchange membrane fuel cells (PEMFCs). The PtCuSn catalyst was synthesized via a modified polyol process in teflon-sealed reactor by microwave-heating. From X-ray diffraction and transmission electron microscopic analysis, the PtCuSn catalyst exhibits a face-centered cubic structure, similar to platinum (Pt), which is attributed to form a good solid solution of Cu atoms and Sn atoms in the Pt lattice. The PtCuSn nanoparticles with average diameter of 3.5 nm were uniformly distributed on the carbon support. The electrochemical surface area (ECSA) and ORR activity of PtCu, PtSn and PtCuSn catalysts were measured using a rotating disk electrode technique with cyclic voltammetry and the linear sweep method. The PtCuSn catalysts showed the highest performances for ECSA and ORR, which might be attributed both to formation of small nanoparticle by tin atom and to change in lattice constant of Pt by copper atom. Furthermore, The PEMFCs single cell performance employing PtCuSn catalyst exhibited an enhanced cell performance compared to a single cell using the PtCu and PtSn catalysts. This result indicates the importance of electric and geometric control of Pt alloy nanoparticles that can improve the catalytic activity. This synergistic combination of copper and Tin with Pt could provide the direction of development of Pt catalyst for fuel cell system.

Discharge Morphology and Mechanism of Magnesium-air batteries

Fanglei Tong, Xize Chen, Shanghai Wei, Wei Gao
Department of Chemical & Materials Engineering, Faculty of Engineering, the University of Auckland
5-7 Grafton Road, Auckland 1142, New Zealand
s.wei@auckland.ac.nz

Abstract:

Metal-air batteries have attracted much attentions due to their high capacity and low cost. Magnesium-air battery is one type of them with high theoretical voltage (3.1 V) and theoretical energy density (6.8 $kW\cdot h\cdot kg^{-1}$). However, magnesium (Mg) metal anode shows low anodic efficiency due to its high self-corrosion rate and discharge product accumulation on the surface. Much effort has been attempted to enhance Mg-air battery performance, but rare research has focused on the discharge mechanism of pure Mg anode in Mg-air battery. In this work, morphology of Mg anode before and after remove discharge product have been studied. Pure Mg was discharged at different current densities range from 50 $\mu A\cdot cm^{-2}$ to 5 $mA\cdot cm^{-2}$. A large amount of lamellar structure formed on Mg anode surface at low current densities, while anode surface is more uniform with pitting morphology at high current densities. Furthermore, discharge morphology of Mg metal anode shows schistose with preferred orientation. Grain boundary plays a critical role in preventing Mg self-corrosion diffusion.

fran.garcia@unc.edu.ar

High power high-density lithium rechargeable batteries are necessary to meet the energy demand of electric vehicles and high-power stationary grids. Li-S batteries represent a potential solution to obtain high-performance electrochemical energy storage devices. This is so because of their high theoretical specific capacity 1672 mAh g^{-1} and high energy density 2600 Wh kg^{-1}.[1] However, there are many difficulties to be solved before a practical application. Sulfur has high electronic resistivity (10^{24} Ωcm)[2], and the reactions with lithium lead to an increase in volume (80%) that may result in the rupture of contact with the current collector[3]. Another important issue is the formation of long-chain polysulfides (Li_2S_n, $n \geq 4$) during sulfur lithiation. Polysulfides are soluble in the commonly used ether-based electrolytes and therefore can migrate to the anode where they undergo further reduction, which ultimately leads to the passivation of the lithium anode.[4] This process is known as the shuttle effect, which also causes the loss of active material by conversion to non-reversible structures during cycling.

In this work we use a combination of carbon structures on the cathodic side of the cell to achieve electronic and ionic conductivity, and, at the same time, the mitigation of the shuttle effect. Thus, a conductive matrix of activated carbon was just mixed with sulfur to contain the volume-change during the charge and discharge processes and to increase the conductivity of the electrode. Also, to retain the polysulfides in the cathode and prevent their migration to the anodic part of the cell a nanostructured carbon (NC), obtained from natural raw clay, was used to directly coat the sulfur cathode. XPS measurements were made on both NC-coated and uncoated cathodes, the S2*p* spectrum showed that the sulfur in the cathode interacts with the NC promoting the formation of $COSO^{2-}/SO_3^{2-}$ species before cycling. These species can help to immobilize sulfur atoms and therefore serve as mediators to retain and confine polysulfides in the cathode. Electrochemical studies of cyclability, rate capability, cyclic voltammetry, and electrochemical impedance studies (EIS) were carried out for both the pristine and NC coated cathodes. The cyclability study showed that the NC-coated cathode had excellent stability with more than 200 cycles, capacities of 75% relative to the theoretical capacity of sulfur, and coulombic efficiencies of 99.7%. The C-rate proved that this system could reach reversible capacities up to 950 mAh g^{-1} at rates as high as 1C. EIS and cyclic voltammetry showed that there is a significant increase in the electrical and ionic conductivity of the NC-coated cathode. In this manner, through a simple modification, the electrochemical performance of the system was substantially improved using simple and economic methodology.

Increasing POM Loadings into POM@ZIF-67 Nanocomposites to Drastically Boost their Oxygen Evolution Reaction (OER) Activity

Víctor K. Abdelkader-Fernández, Diana M. Fernandes, Salete. S. Balula, Luís Cunha-Silva and Cristina Freire
REQUIMTE/LAQV, Departamento de Química e Bioquímica, Faculdade de Ciências da Universidade de Porto, Rua do Campo Alegre, 4169-007 Porto, Portugal
victor.fernandez@fc.up.pt

The efficient electrocatalysis of the Oxygen Evolution Reaction (OER) is a key factor regarding the real implementation of fuel cell/electrolyzer systems in industry and transport. For this reason, the development of low-cost and robust catalysts with better performances than those of the benchmark materials (RuO_2 and IrO_2) is mandatory. In this context, polyoxometalates (POMs) and metal-organic frameworks (MOFs) as well as their smart integration into electrocatalytically active nanocomposites play a protagonist role.**[1]** In our previous work,**[2]** we took advantage of the complete size complementarity between zeolitic imidazole frameworks (ZIFs) cavities and Keggin-type POM units and prepared two POM(guest)@ZIF(host) materials involving individually encapsulated SiW_9Co_3 POM units inside the ZIF cages. By using two isostructural ZIF frameworks —ZIF-8 and ZIF-67, including Zn and Co nodes, respectively— we demonstrated the necessity of the existence of Co nodes in the ZIF frameworks to generate a POM ↔ ZIF-67 bidirectional synergy leading to a significant OER activity. Now, we have extended this phenomenon to another more easily synthetized cobalt-containing POM, $SiW_{11}Co$, and successfully increased the POM loadings.**[3]** Interestingly, the resulting high POM loading nanocomposites (labelled as $SiW_{11}Co$[h]@ZIF-67 and SiW_9Co_3[h]@ZIF-67) present extremely modified frameworks far away from the canonical ZIF structures, being these drastic structural changes —along with the POM loading increments themselves— the origin of their boosted OER activities. A thorough compositional/structural characterization (via ICP-OES, XPS, ATR-IR, PXRD, N_2-adsorption, SEM, TEM and EDS analysis) revealed the coexistence of two structurally/morphologically differentiated phases in these complex electrocatalysts, both of them including homogeneously dispersed POM clusters. In addition, CV, LSV and chronoamperometric tests allowed the estimation of the ECSAs and OER activities developed by these samples in alkaline electrolyte and their long-term stability as well. These tests have shown up a remarkable OER performance of the POM@ZIF-67 nanocomposites, much higher than that exhibited by the pristine ZIF-67 (**Table 1**), and an intrinsic activity comparable —and, in some cases, even higher— to the expensive commercial RuO_2 and IrO_2 powders (**Figure 1**).

Table 1. OER activity parameters of pristine ZIF-67 and POM@ZIF-67 nanocomposites.

	OER parameter			
(ref) sample	E_{10} (V *vs. RHE*)	η_{10} (V)	$j_{1.75}$ (mA cm^{-2})	*Tafel Slope* (mV dec^{-1})
(1) ZIF-67	1.81	0.58	7.2	144.3
(2) $SiW_{11}Co$@ZIF-67	1.69	0.46	15.0	141.6
(3) $SiW_{11}Co$[h]@ZIF-67	1.66	0.43	23.0	95.3
(4) SiW_9Co_3@ZIF-67	1.70	0.47	14.2	113.6
(5) SiW_9Co_3[h]@ZIF-67	1.65	0.42	28.9	93.9

Using Ionic Liquids to Increase Selectivity and Sensitivity in Heavy Metal Ion Detection

Fabian Schmitt, Tizian Venter, Markus Biesalski, Gui-Rong Zhang, Bastian J.M. Etzold

Technische Universität Darmstadt, Ernst-Berl-Institut für Technische und Makromolekulare Chemie,
Alarich-Weiss-Strasse 8, Darmstadt, Germany.
f.schmitt@tu-darmstadt.de

Electrochemical sensing of heavy metal traces, such as Pb, Cd and Hg is known to be a user-friendly, mobile point-of-care solution. High sensitivity can be obtained by electrochemical methods, such as square wave anodic stripping voltammetry (SWASV) in presence of surface modifiers (e.g. Hg or Bi), as reflected by impressive limits of detection far below WHO suggestions. Nevertheless, unsatisfying selectivity as also low stability hinders vast commercialization of electrochemical detection in this field. Liu-Liu et al. demonstrated that modifier free sensors using technical grade graphite foil can exhibit high stability and also satisfying sensitivity [1]. The current work aims to use ionic liquids (ILs) to further improve the selectivity and sensitivity based on the modifier free concept. ILs are capable of selectively extracting and preconcentrating heavy metals from aqueous solutions due to their high solubilities in ILs, which provides the basis for this study. As a suitable IL protonated betaine bis(trifluoromethane)sulfonimide [HBet][NTf_2] was chosen as it combines two crucial properties: 1) It extracts metal ions from aqueous phase with different distribution coefficients, enabling discriminating preconcentration [2] and 2) it is reported for the direct electrochemical detection of metal oxides in the sub-ppb range [3]. Furthermore, for the first step of extraction this IL allows for facile and intensive mixing as also phase separation, as above the upper critical solution temperature of 55 °C a homogeneous mixture occurs and below phase separation is induced. As a conceptual study the extraction of Pb-ions from aqueous phase, temperature induced phase separation and subsequent ion detection via SWASV was investigated using only technical grade graphite foil as working and counter electrodes (Fig. 1 A). A reproducible extraction and detection of Pb^{2+} for concentrations of 2 ppm in the aqueous phase can be realized and SWASV-peaks of several 100 µA resulted (Fig. 1 B). Future work can build on this concept, which is especially promising for improving selectivity.

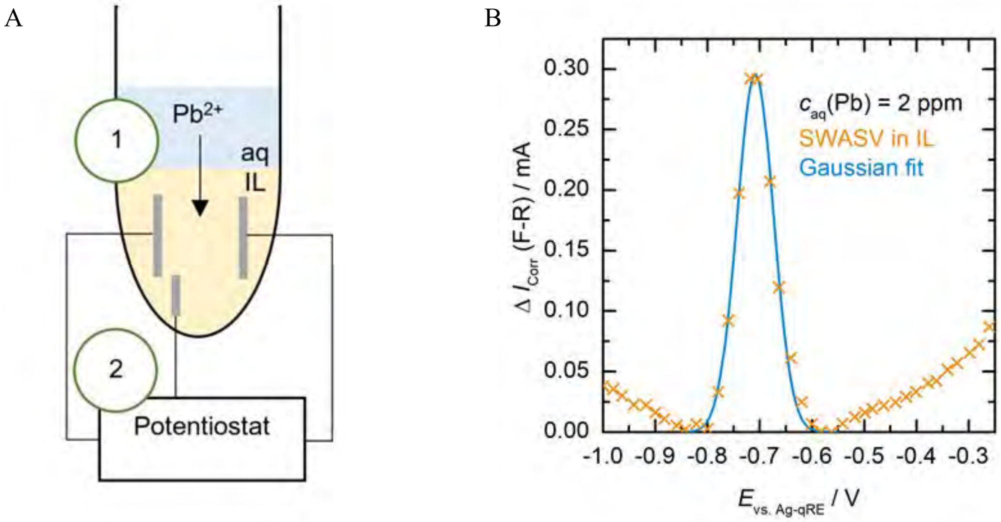

Fig. 1 A: schematic procedure of the Pb^{2+} extraction (step 1) from the aqueous to the IL phase ($V_{IL}/V_{aq}=1$) via single-phase-generation and the electrochemical detection (step 2) by SWASV. B: SWASV response signal for a starting concentration of 2 ppm Pb in the aqueous phase (parameter: deposition: 10 min @ -1 V *vs.* Ag-qRE, stripping: f=100 Hz, E_P=100 mV, E_S=20 mV).

Protein Film Electrochemistry is a technique consisting in immobilizing enzymes on a rotating disc electrode in a configuration where the electron transfer is direct, and the enzymatic activity is monitored as an electrical current [Figure 1]. This technique has proved extremely useful to study various aspects of the activity of metalloenzymes [1]. Generally, the consumption of the substrate at the surface of the electrode is compensated by a flow of a fresh buffer imposed by the rotation of the electrode. However, this was not the case for CO dehydrogenase (CODH), which is an enzyme that catalyzes the reversible reduction of CO_2 into CO following this equation: $CO_2 + 2e^- + 2H^+ \leftrightarrows CO + H_2O$

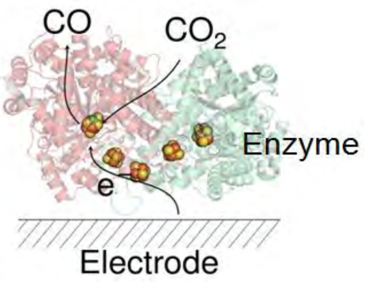

Figure 1. schematic representation of protein film electrochemistry

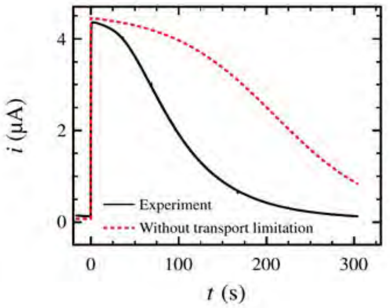

Figure 2. experiment in which the CODH is exposed to a transient injection of CO

This enzyme is so fast that the catalysis is mostly limited by the transport of the substrate (CO) towards the electrode, and not by the catalyzed chemical reaction, even at a high rotation rate. This limitation hides information about the catalysis in the electrochemical response [2] [Figure 2]. As this problem couldn't be overcame by the rotating disc electrode, we chose to design a completely different type of electrochemical cells (based on jet flow cell) in which the buffer is pumped towards a static electrode [3].

We screened different jet flow cell geometries by means of numerical simulation. Then, we selected and built one with promising transport properties (a high and homogenous mass transport coefficient, and a low shear stress at the surface of the electrode) [4]. In this work, we optimize the current design by simulation, and we further test the performance of the new setup experimentally by using simple redox couples such as Fe $(CN_6)^3$/ Fe $(CN_6)^{3-}$ or by detecting the catalytic current given by an adsorbed enzyme, the nitrite reductase which catalyzes the reduction of nitrite to ammonium. This new cell should provide enhanced transport but also a much greater flexibility for changing the concentration of the species that the enzyme is exposed to. Therefore, it will be useful for studying other metalloenzymes that do not even require high mass transport.

Redox-Driven Deformation and Electrode Reaction of Viologen-Incorporated Polymer Hydrogel

Bo Wang, Hironobu Tahara, and Takamasa Sagara
Graduate School of Engineering, Nagasaki University
Bunkyo 1-14, Nagasaki 852-8521, Japan
bb52316205@ms.nagasaki-u.ac.jp

Stimuli-sensitive hydrogels have a wide variety of flexibility and mobility. They can be used as a material of an actuator in an assembled molecular robot. We focused on a redox driven hydrogel, because redox reaction in the gel can quickly and drastically change the properties of the gel, resulting in fast and large-scale motion of the gel. With an aim at developing redox driven hydrogel, we use redox reaction of viologen (**Figure 1a**) as the engine of fast and large amplitude deformation. We designed a hydrogel shown in **Figure 1b**. Viologens were covalently attached via amide linkage to poly-peptide, α-poly-*L*-lysine (PLL). Then, glutaraldehyde was used for cross-linking of free ε-amine groups to give a hydrogel, PLLV gel. The hydrogel with a 25% viologen pendant rate contracted 93%-volume within 100 s upon reduction of viologens by dithionite, whereas it exhibited slow re-expansion upon reoxidation by dissolved O_2 [1]. One-electron reduction of a viologen (V^{2+}) to radical cation $V^{\bullet+}$ induces the stacking of $V^{\bullet+}$ units and desolvation of the viologen sites. The former process draws the polymer chains to be entangled and to accelerate inter-site electron transfer, while the latter process drains water from the gel (**Figure 1c**). A decrease of positive charges on viologens results in the change of osmotic pressure to egress of water from the gel. All these changes upon reduction contributed to the contradiction of the hydrogel.

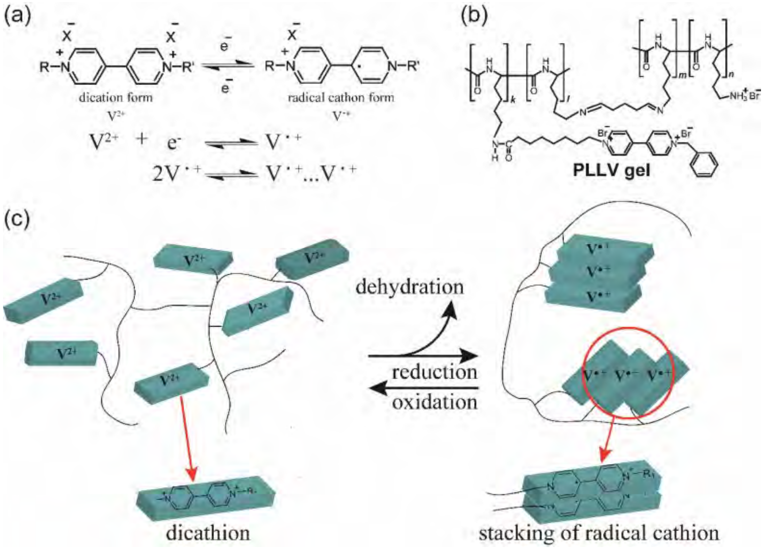

Figure 1. Chemical structure and redox process of viologen (a), chemical structure of PLLV gel (b), and mechanism of target hydrogel deformation (c).

Electrochemical and spectroelectrochemical characterization of the PLLV gel was made by sandwiching a piece of gel between a Au disk electrode and the inner wall of an optical window of the cell. We observed cyclic voltammetric response of apparent diffusion in the range of sweep rate between 2 and 200 mV s^{-1}. The feature of obtained electroreflectance spectra was of the enriched $V^{\bullet+}$ dimers.

We examined the effect of the viologen pendant rate as well as the introduction of a conductive filler and polymer electrolyte counter anion. The 25% pendant rate gel showed contraction faster and larger amplitude than the others. We added conductive fillers in the gel for accelerating electron transportation and re-expansion. The fillers included Au nanoparticle, graphene nano-platelet, and carbon nanotube. The initial contraction of the gel with fillers was faster than the gel without fillers. However, re-oxidative swelling was still slow. The contraction and re-swelling largely rely on egress and ingress of water. To boost the penetration of water and accelerate re-oxidative swelling, the anionic polymer, polystyrene sulfonate (PSS), was incorporated into the gel. The incorporation made the re-oxidative swelling faster and the swelling amount greater. PSS accelerated water ingress into the gel and made the re-oxidation swelling faster and the extent larger, while it diminished the contraction amplitude.

These results pave a new way to a hydrogel crawling on an electrode by redox control.

TiO2/SnO2 nanocomposites for lithium-ion batteries

Xize Chen, Yuguang Pu, Shanghai Wei, Peng Cao,
Department of Chemical & Material Engineering, University of Auckland, Auckland, New Zealand.

Lithium-ion batteries(LIBs) have been widely used as electrical energy storage (EES) devices for portable electronic devices, such as laptops and smart phones. LIBs are also being considering as EES system for electric vehicles and grid scale energy storage. These applications require batteries have higher energy density and lower cost. [1]. In present study, TiO2/SnO2 nanocomposites have been synthesized as anode materials for lithium ion batteries. Firstly, Tin(II) oxide hydroxide was synthesized with sol-gel method, and then coated with TiO2 by using wet chemistry method. The tin(II) oxide hydroxides are pyramid-shape nanoparticles. TiO2 coated pyramid-shape nanoparticles were heated at 600°C to form TiO2/SnO2 hollow nanocomposites(TSHNP). These nanocomposites show a unique hollow structure with particle size about 200 nm, and original pyramid structure was destroyed during the oxidation process in the heat treatment. The TiO2/SnO2 nanocomposites have been tested as an anode for lithium ion batteries in half-cell. Compared to SnO2, TSHNP shows longer cycle life with maintaining 200 mhA/g in 50 cycles, which is due to the special hollow structure[2]. In addition, TiO2 and Li2O matrix act as a mechanical support system for SnO2 volume expansion during the de/lithiation process. However, C-rate performance are not ideal because of the polarization and relatively low electron conductivity, which are the challenges of transition metal-oxides.

Coupling Micro-Hydropower with electrolyzing, case study

Maël Le Marre[1,2] Philippe Mandin[1,2] Praveen Thappily[1,2]
Jean-Louis Lanoisellé[1] Thierry Sauvage[2]
[1] Université de Bretagne Sud, IRDL, UMR CNRS 6027, Lorient (France)

mael.le-marre@univ-ubs.fr philippe.mandin@univ-ubs.fr

The energy used to pump and treat water for residents and industry represents between 2 and 3% of the world's energy consumption {1}. The consumption can be reduced by 25% through solutions like micro-hydropower (MHP). Pressure reducing valves (PRV) are installed in the water distribution network (WDN) to reduce the leakage losses, which is directly related to the pressure in pipe {2}. The reducing of pressure in PRVs lead to hydraulic losses into thermal losses, replace PRV with MHP system is a good solution to recover a part of those losses. On the other hand, the transport area, with a thermal motor, is one of the main issues for slowing global warming. Replace thermal motor with electrical motor supplied by fuel cells is a good solution. One of the biggest water tanks in Rennes (France) called "Les Gallets" is an interesting site to implement MHP installation, the huge site area allows to implement a electrolyze installation to supply hydrogen cars. Coupling the production of hydrogen with MHP system is a solution to get a green energy production. The scheme of the installation is presented in figure 1.

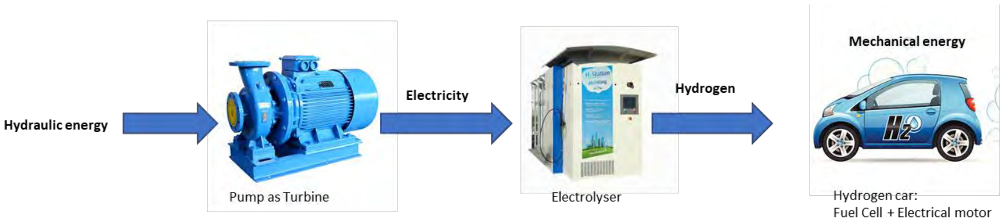

Figure 1: Installation's scheme

The site "Les Gallets" is composed of two water tanks, one is called "Les Gallets Haut", the other one is called "Les Gallets Bas". Two MHP systems can be installed, one upstream the first water tank, and one between both water tanks. Conventional turbines are not massively available on the market, hence they are expensive and lead to strong payback periods for MHP, to face this problem, the use of pumps in reverse mode (pumps as turbines) is a solution {3}. Indeed, those pumps have good efficiencies (between 50 to 85%) and can be divided by 10 times the payback period of an installation compared to conventional turbines installations. For this study, an average efficiency of 65% for Pumps as turbines installations is considered.

Flow conditions of both installations are detailed in table 1.

Site	Flow rate (l/s)	Head (m)	Load factor (h/year)	E_{lost} (MWh/year)	Producible (MWh/year)	H_2 Producible (kg H_2/year)
Gallets Haut	208	11	7366	165,7	107,705	1795
Gallets Bas	100	19	6647	137,6	89,44	1490

Table 1: Flow conditions of Gallets sites

The total electricity production in "Les Gallets" will reach about 197MWh per year. Considering that the electrolyzer absorb 60 kWh of electricity to create 1kg of Hydrogen. The electrolyzer will be able to produce about 3285kg of H_2 per year. Considering a conventional Hydrogen car, with an autonomy of 500km, and a Hydrogen's consumption of 1kg of H_2/100km, it will be possible to load the car's fuel cell 625 times per year.

Nitrogen-rich covalent organic frameworks for high-performance sodium batteries

Yixin Li, Ruijuan Shi, Jun Chen*
Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University, Tianjin 300071, China
** Corresponding author: chenabc@nankai.edu.cn*

Covalent organic frameworks (COFs) have attracted increasing attention as idea cathode materials duo to the designable periodic skeletons and ordered nanopores. However, the reported COFs based cathode materials are plagued by limited capacity and unsatisfying rate performance. Herein, we designed a honeycomb-like nitrogen-rich COF (TQBQ-COF) with good intrinsic electronic conductivity and studied the electrochemical performance in sodium battery. The sodium storage ability of pyrazines and carbonyls and the up-to twelve sodium-ion redox chemistry mechanism for each repetitive unit have been demonstrated by in/ex-situ Fourier transform infrared spectra and density functional theory calculations. The TQBQ-COF cathode exhibits high capacity of 452 mAh/g (0.02A/g), excellent cycling stability (96% capacity retention after 1000 cycles), and high rate performance (134.3 mAh/g at 10 A/g). A pouch-type battery (energy density of 101.1 Wh/kg) is assembled to prove practical applications of conjugated polymers in rechargeable sodium batteries. This work will promote the function-oriented design and application of COFs-based materials for high-performance sodium storage devices.

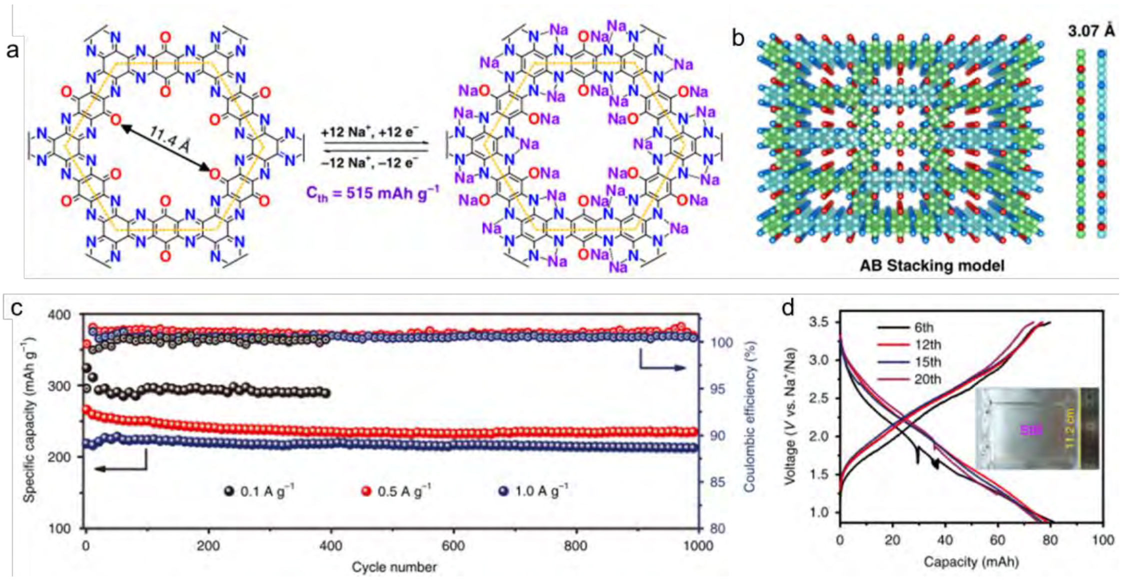

Figure 1. (a)The chemical structure and possible electrochemical redox mechanism of TQBQ-COF with a theoretical capacity of 515 mAh/g. (b) Top and side views of the schematic AB stacking model of TQBQ-COF layers with a packing distance of 3.07 Å. (c) Long cycling stability of TQBQ-COF electrodes at different current densities (0.1, 0.5, and 1.0 A g^{-1}). The capacities are all calculated based on the mass of TQBQ-COF. (d) The selected charge/discharge curves of pouch-type Na//TQBQ-COF batteries at a current of 50 mA. The capacity is calculated based on the mass of the full cell.

Photovoltaic activity of simple photosystem I/conducting glass electrode

Krzysztof Gibasiewicz,* Sebastian Szewczyk, Rafał Białek, Gotard Burdziński
Faculty of Physics, Adam Mickiewicz University, ul. Uniwersytetu Poznańskiego 2, 61-614 Poznań, Poland
**e-mail: krzyszgi@amu.edu.pl*

We demonstrate photovoltaic activity of electrodes composed of fluorine-doped tin oxide (FTO) conducting glass and a multilayer of trimeric photosystem I (PSI) from cyanobacterium *Synechocystis sp.* PCC 6803 yielding, at open circuit potential (OCP) of + 100 mV (vs. SHE), internal quantum efficiency of (0.37 ± 0.11)% and photocurrent density of up to (0.5 ± 0.1) $\mu A/cm^2$.[1] The photocurrent measured for OCP is of cathodic nature meaning that preferentially the electrons are injected from the conducting layer of the FTO glass to the photooxidized PSI primary electron donor, $P700^+$, and further transferred from the photoreduced final electron acceptor of PSI, F_b^-, via ascorbate electrolyte to the counter electrode. This observation is consistent with preferential donor-side orientation of PSI on FTO imposed by applied electrodeposition. However, by applying high-positive bias (+ 620 mV) to the PSI-FTO electrode, exceeding redox midpoint potential of P700 (+ 450 mV), the photocurrent reverses its orientation and becomes anodic. This is explained by "switching off" the natural photoactivity of PSI particles (by the electrochemical oxidation of P700 to $P700^+$) and "switching on" the anodic photocurrent from PSI antenna Chls prone to photooxidation at high potentials. The efficient control of the P700 redox state (P700 or $P700^+$) by external bias applied to the PSI-FTO electrodes was evidenced by ultrafast transient absorption spectroscopy. The advantage of the presented system is its structural simplicity together with in situ-proven high intactness of the PSI particles.

Magnesium and Calcium Insertion/De-insertion into the Sb Modified Au Electrode and determination of the diffusions coefficients

D. Xing, and H. Baltruschat*

Institute of Physical and Theoretical Chemistry, University of Bonn
Roemerstr.164, D-53117, Germany
baltruschat@uni-bonn.de

Antimony has been suggested as an insertion material for a magnesium secondary battery [1, 2], because magnesium can form an intermetallic binary phase Mg_3Sb_2. The stable alloy reaction shows high magnesium storage performance and high cycling stability.

The diffusion coefficient of Mg-insertion in Sb - multi-layers has been estimated by using various electrochemical techniques. We studied the diffusion of Mg in a thin, bulk (massive) layer of Sb by using PITT, CV and potential step experiments. Such diffusion coefficients, albeit still somewhat "apparent", are much related to true diffusion coefficient in the metal or alloy. The diffusion coefficient of Mg into the Sb layers are in the range of 10^{-13}-$10^{-15}$$cm^2s^{-1}$. The D_{Mg} values was calculated by CV at about $1.28 - 1.78 \times 10^{-14}\ cm^2/s$ into a novel Bi-based anode (Bismuth oxyfluoride, BiOF) [3] and as $1.97 \times 10^{-14}\ cm^2/s$ into a CuS cathode by GITT-Method. [4]

Recently calcium stripping and plating using a $Ca(BH_4)_2$ electrolyte was reported at room temperature with a Coulombic efficiency (CE) of 95% on an Au substrate. [5] In this work the insertion/de-insertion of Ca^{2+}-ion into antimony with $Ca(BH_4)_2$/THF electrolyte was investigated. The cyclic voltammogram for Ca insertion/de-insertion into Sb-modified electrode shows a positive shift (~1 V) of the onset potential of Ca deposition compared to that at bare Au electrode. The ratio of moles of Ca to Sb agrees with the stoichiometry of Ca_2Sb alloy. The diffusion coefficient of Ca into the Sb layers are calculated to be $4.25 - 6.11 \times 10^{-15}\ cm^2/s$ cm^2s^{-1}.

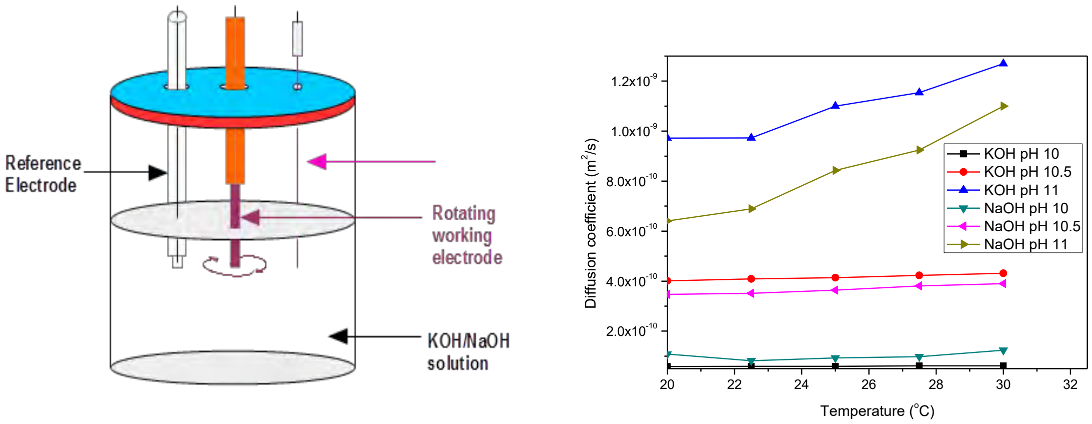
dr.praveen.official@gmail.com, philippe.mandin@univ-ubs.fr

Hydrogen [1,2] is one of the most promising energy carriers for domestic and industrial energy systems. Water electrolysis is considered as the safest and non-polluting means of producing the hydrogen. Rotating disk electrode is a hydrodynamic electrode technique that utilizes convection as the mode of mass transport. In order to determine the diffusion coefficient of hydroxide ions, Levich's theory [3] can be used. This theory makes it possible to calculate the diffusion limit current of a sample placed on a rotating disc electrode.

$$J_{lim} = 0.62 nFD^{\frac{2}{3}}\Omega^{\frac{1}{2}}\nu^{-\frac{1}{6}}C$$

With the help of the above equation value of D can be extracted. Here, the experimental set-up is a three-electrode arrangement as shown in Figure 1.A. The rotating disc electrode is placed in the centre of the beaker to avoid boundary problems and to have forced convection due to the invariant electrode by rotating it around the electrode. The counter electrode and the reference electrode are placed about two centimetres from the working electrode. NaOH and KOH solutions with different concentration are used as the electrolyte. Voltage and current data are recorded using the Nova control software and the electrochemical technique used is linear scanning voltage (LSV) voltammetry, with the potential being reset to 0 between two experiments using a second LSV. We also extracted the value of the diffusion coefficient with different temperatures as shown in Figure 1.B. It is observed that the diffusion coefficients tend to increase with temperature.



A B

Figure 1: (A) Experimental setup (B) The sensitivity of the diffusion coefficient with respect to the temperature

Novel Experimental Approach for the Direct Assessment of Nucleation Rate Constants from Cyclic Voltammetry and Chronoamperometry Data for Phase Transforming Intercalation Electrodes

Aleksandr A. Kokin,[a] Stanislav S. Fedotov,[b] Victoria A. Nikitina[b]
[a]M.V. Lomonosov Moscow State University, Leninskie Gory 1/3, Moscow, 119991, Russia

v.nikitina@skoltech.ru

Phase-transforming electrode materials with a wide miscibility gap have been extensively studied for both Li-ion ($LiFePO_4$, $Li_4Ti_5O_{12}$) and Na-ion ($Na_3V_2(PO_4)_3$) batteries. In particular, $LiFePO_4$ material has become a model system for the investigation of intercalation induced phase transformation mechanisms.[1,2] Most of the state-of-the-art research on the phase-separating intercalation materials focuses on the elucidation of phase transformation mechanisms as well as on the theoretical assessment of the nucleation barrier heights based on the evidence from structural investigation and microscopic single particle-level experiments.[3] In particular, recent reports have led to the establishment of a concept of competing mechanisms of phase boundary propagation, which can be bulk diffusion limited or surface reaction limited.[4] Yet, phase-field modeling usually used to rationalize the experimental findings rarely relies on the experimental values of nucleation and charge transfer activation barriers, deduced directly from the experimental data, which compromises the reliability of the obtained results.

Recently developed electroanalytical methods[5,6] provide the possibility to estimate the characteristic rates of nucleation, charge transfer and diffusion from the experimental electrochemical data. The proposed novel approaches enable direct comparison of phase transformation rates in various intercalation-based electrodes ($LiFePO_4$, V_2O_5, cation-rich Prussian blue analogues, $Na_3V_2(PO_4)_3$) as well as the elucidation of the rate-determining step nature. In this work, we show that the new phase nucleation appears to be a characteristic rate-determining step for a wide range of intercalation materials. We demonstrate that the nucleation rates (probabilities of critical nucleus formation) can be straightforwardly determined from the electrochemical experimental data. A simple experimental approach is proposed toward interpreting electrochemical cyclic voltammetry and chronoamperometry data for phase-transforming electrodes.[7,8] The new methodology provides for a facile assessment of the influence of various experimental factors (particle size, defect concentration, solvent nature, and surface coating) on the nucleation-controlled phase-transformation rates in intercalation materials. Experimental data analysis illustrates the validity of the applied approaches, which allows developing diagnostic criteria for distinguishing slow nucleation rate control from other possible rate-determining steps as well as obtaining quantitative estimates of the nucleation rate constants.

Iron Sulfide-Carbon Nanospindles as Sulfur Host for Li-S Batteries

Dongjiu Xie, Shilin Mei, Zdravko Kochovski and Yan Lu
Department of Electrochemical Energy Storage (EM-AEES), Helmholtz-Zentrum Berlin für Materialien und Energie (HZB), Hahn-Meitner-Platz 1,14069, Berlin, Germany.

Recently, a lot of efforts are devoted into lithium-sulfur battery system due to its high theoretical capacity (1675 mAh g^{-1}) and low cost, which could be a competitive candidate for energy storage in the future. However, it suffers from a poor cycling stability during charging-discharging, which is blamed to the notorious "shuttle effects" caused by lithium polysulfides (Li_2S_x, $4 \leq x \leq 8$) [1-2]. In our study, functional metal oxide/sulfide nanoparticles prepared by a colloidal route have been used as cathode host materials for lithium-sulfur batteries. Firstly, β-FeOOH nanospindles with a length of 250-300 nm and a diameter of 60 nm were successfully synthesized through the hydrolysis of $FeCl_3$ in cetyltrimethylammonium bromide (CTAB) solution in a large batch [3]. After coating with polydopamine and followed with annealing at high temperature, iron oxide/sulfide was designed to be encapsulated into hollow cabon nanospindle with formation of a york-shell structure(shown in Fig.1) to suppress the "shuttle effect". An improved performance has been obtained via the combination of physical adsorption of the hollow carbon nanospindle and chemical adsorption of iron sulfide. Moreover, it is revealed that the replacement of iron oxide with sulfide inside the hollow carbon spindle can improve the specific capacity and rate capability of the lithium-sulfur batteries.

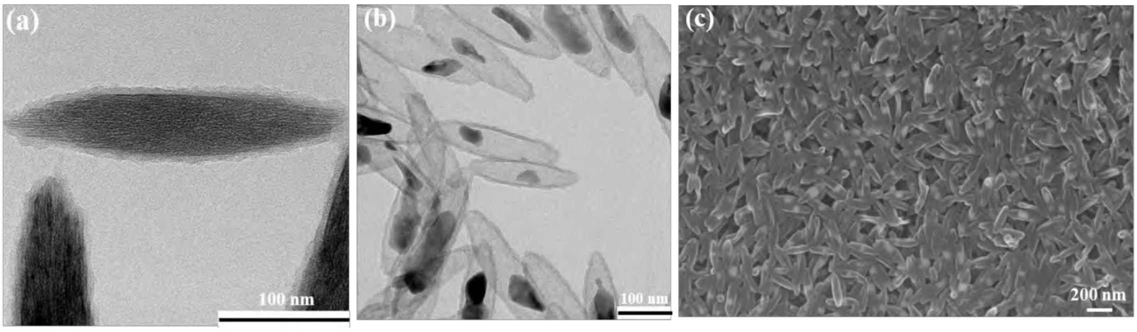

Fig. 1: TEM and SEM images of polydopamine coated FeOOH nanospindles (a), Fe_3O_4-carbon yolk-shell nanospindles (b) after etching 2 h with HCl solution (2 M) and FeS-carbon yolk-shell nanospindles (c).

aysu.yarman@yahoo.de

Molecularly imprinted polymers (MIPs) are one of the most frequently studied alternative recognition elements in chromatography and sensorics. They are prepared by polymerizing the target analyte (so-called template) and functional monomers (in the presence or absence of cross-linkers). Subsequent removal of the template from the polymer network results in the formation of cavities with a molecular memory, which is complementary in size, shape and functionality to the template [1].

Depending on the analyte of interest, three main approaches have been presented in literature for the electrochemical readout of MIP sensors [1]. Herein we present examples for each approach.

i) Electroactive analytes: For both low- and high-molecular weight targets, faradaic current is measured, which is based on the direct redox transformation of the analyte at the electrode. The analytical performance of MIPs for the anticancer drug tamoxifen and the enzyme hexameric tyrosine-coordinated heme protein will be demonstrated [2,3].

ii) Catalytically active analytes: In the second approach redox active products of enzymes, catalytically active MIPs or enzyme-labelled tracers can be directly measured. In this regard, MIPs for the Alzheimer´s disease biomarker butrylcholinesterase and the melanoma biomarker tyrosinase will be illustrated here [4,5].

iii) Redox-inactive analytes: The most frequently studied method relies on the modulation of diffusional permeability of the polymer MIP-layer by target binding of a redox marker. MIPs for the peptide drug daptomycin and the anticancer drug tamoxifen will be presented [3,6].

In this presentation the potential and challenges of electrochemical readout of MIP sensors will be summarized: Electrochemical methods are straightforward for the preparation of MIPs and analyte determination. However, up to now there has been no commercial example yet.

Electroosmotic pump for implantable drug delivery system

Taejwa Park, Junyeong Kang, Enhua Zhu, Woonsup Shin*

Department of Chemistry, BioMedical Engineering, Sogang University, Korea
** shinws@sogang.ac.kr*

An implantable infusion pump is surgically implanted in the abdomen to deliver a drug to a target area through a catheter. It is beneficial for severe chronic and cancer pain patients. For the acute pain, morphine delivers directly to the intrathecal space, where the main neuro signals pass by. The amount of 1/100th or 1/300th amount of the drug has the same efficacy of the delivery through intravenous or oral. The programmed intrathecal delivery significantly increases the patient's quality of life by reducing the side effects of the medication since the drug does not circulate through the whole body. The electroosmotic pump (EOP) consists of two electrodes separated by a porous membrane, having no magnetic component, and ideal for the implantable device. We could demonstrate that the device is MRI compatible even during the run. The sub μL/min flow rate, low-power consumption, and long-term stability confirm the pump is suitable for the implantable drug delivery.

Electrooxidation of Hydrogen Peroxide on a Pt-Metallized 4-Mercaptopyridine Self-Assembled Monolayer on Au(111)

Mathias Piescheck, Areeg Abdelrahman, Johannes M. Hermann,
Heiko Müller, Timo Jacob, Ludwig A. Kibler
Institut für Elektrochemie, Universität Ulm
Albert-Einstein-Allee 47, 89069 Ulm, Germany
mathias.piescheck@uni-ulm.de

A systematic investigation of the hydrogen peroxide oxidation reaction (HPOR) on an Au(111) single crystal modified with a Pt metallized 4,4'-dithiodipyridine self-assembled monolayer (SAM) in phosphate buffer (pH = 7.3) has been conducted. While the voltammetric behavior of bare Au shows considerable electrocatalytic activity towards the HPOR, the inhibition of the oxidation reaction after modification with the SAM implies that adsorbed 4-mercaptopyridine molecules do not catalyze the HPOR. However, SAM-modified Au(111) shows a catalytic activity for the HPOR after a single metallization step fabricating Pt islands on-top. Hydrogen peroxide (HP) may then either react at the Pt nanoislands similar to metal nanoparticles deposited on insulating SAMs[1][2] or on the reactivated Au sites, made accessible by disordered structural changes of the SAM induced by the metallization[3] (**Figure *1***). The shape of the voltammetric profiles for the HPOR on repeatedly metallized SAMs suggests that the contribution of Au to the total current density gradually diminishes with increasing Pt coverage while the contribution of the Pt nanoislands increases. The electrochemical behavior is dominated by Pt already at a coverage of 0.5 ML.

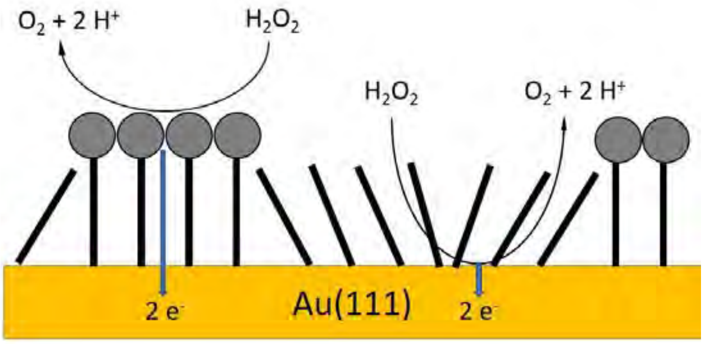

Figure 1: HPOR on a Pt island (grey circles represent Pt atoms) and on the uncovered Au(111) surface. Black bars represent the SAM of 4-mercaptopyridine molecules.

Composites Based on Three-dimensional Graphene and Transition Metal Dichalcogenides as the Electrode Materials in Supercapacitors

Masoud Foroutan, Elżbieta Frąckowiak
Poznan University of Technology, Institute of Chemistry and Technical Electrochemistry,
60-965, Poznan, Berdychowo 4, Poland
masoud.foroutankoudahi@doctorate.put.poznan.pl

Supercapacitors are capable of delivering high power density but moderate energy density at the same time. In light of this fact, researchers are endeavoring to intensify the energy density of supercapacitors without deteriorating their power capabilities through designing components with more sophisticated structures. Among various adopted approaches for improving supercapacitors' energy density, integrating high conductivity components such as carbonaceous materials, with faradaic materials, e.g., metal oxides/hydroxides/sulfides, is of paramount importance. Considering different carbonaceous structures, three-dimensional porous architecture based on graphene (3DG) is promising due to various physical and electrochemical features such as structural interconnectivities, lightweight, high active surface area, and unique porosity. Due to excellent mechanical stability, 3DG can serve as a promising substrate for depositing other materials. Among redox-active metallic materials, transition metal dichalcogenides (TMDs) have attracted widespread attention since most of them have a low cost and a high theoretical capacitance. Utilizing both 3DG and TMDs can improve the electrochemical performance of supercapacitors. Here, we demonstrate that combining 3DG with different spinel-type TMDs will give electrode materials that can deliver better electrochemical parameters compared to each single component. 3DG contains a wide range of pores with different diameters from nanometer to micrometer. Therefore, the redox-active material can be easily embedded inside the pores of the substrate. In this state, we may increase the energy density of the electrode material but at the sacrifice of losing its power density. Owing to this fact, electrode material based on 3DG and Co_3S_4 was constructed with different ratios to evaluate the proper proportion of substrate and the redox-active material. In the same line and in separate procedures, the electrode materials based on 3DG, as the substrate, as well as Ni_3S_4 and MnS_2 were synthesized. The prepared electrode materials were characterized by the various textural/structural methods: scanning electron microscopy (SEM), X-ray diffraction (XRD), and Raman spectroscopy. For electrochemical characterization, electrode materials with 1 cm diameter and fairly 1 mm thickness were cut and symmetrically served as both positive and negative electrodes inside a Swagelok cell without adding any binder or conductive additive. Whatman paper was cut in a diameter of 12 mm and used as the separator. Before running the electrochemical experiments, the electrode material and the separator were immersed in aqueous electrolyte (6 M KOH) for 24 hr to exchange the water in the pores with KOH. Cyclic voltammetry, galvanostatic charge-discharge, and electrochemical impedance spectroscopy experiments were carried out on a Biologic potentiostat/galvanostat instrument. The electrochemical tests were performed in the applied potential range of 0 - 1 V.

Inspired by natural photosynthesis, great effort has been directed to the design and fabrication of semi-artificial bio-photoelectrochemical devices able to harvest solar energy. Photosystem 1 (PS1), one of the key enzymes that drive photosynthesis, has been increasingly investigated for this aim due to its strong reductive force upon light-induced charge separation processes.

In our previous work, the use of an Os-complex modified redox polymer to wire PS1 with the electrode surface has enabled efficient generation of photocurrents [1]. While O_2 was used as terminal electron acceptor to scavenge the photo-generated electrons, superoxide radicals were formed leading to the generation of partially reduced reactive oxygen species in the surroundings of the immobilized protein complexes, resulting in the inactivation of PS1. In consequence, only a limited long-term stability was observed for the bioelectrode under illumination.

An in-depth evaluation of the PS1/redox polymer-based biocathode was performed by means of scanning photoelectrochemical microscopy, revealing pathways for the generation of oxygen radicals [2]. Thus, in order to prevent the deleterious effects of generated reactive oxygen species, the operation of biophotocathodes under anaerobic conditions is indispensable. The careful selection of an electron scavenger capable of efficient electron extraction even in the absence of O_2 made the operation of the PS1-based photoelectrode with an extensively improved long-term stability possible [3].

Nonaqueous Zinc-organic Battery with Ultra-long life and Wide Operating Temperature

Nan Wang, Yonggang Wang*
Department of Chemistry, Fudan University
Shanghai 200433, P. R. China
ygwang@fudan.edu.cn

Zinc (Zn) metal is an attractive anode material for next generation batteries due to their high theoretical gravimetric and volumetric capacities, abundance, nontoxicity, and cost-effectiveness. [1-3] Rechargeable Zn metal batteries using a mild aqueous electrolyte, which showing promising electrochemical performance, are extracting extensive attention of researchers. [4, 5] This directly drove the recent renaissance of rechargeable Zn battery development, such as Zn//MnO_2, [6, 7] Zn//V_2O_5, [8, 9] Zn//hexacyanoferrate. [10, 11] Unfortunately, the inescapable H_2 evolution and dendrite formation on Zn anode join hands with the structure collapse of host materials in cathode setting an intrinsic limit on the cycle life and the practical of the Zn metal rechargeable batteries.

Herein, we have successfully demonstrated a promising nonaqueous Zn-organic battery, in which the phenanthrenequinone macrocyclic trimer (PQ-MCT) and Zn foil serve as cathode and anode, respectively, while N, N-dimethylformamide (DMF) solution containing ZnTFMS (ZnTFMS/DMF) serves as electrolyte. Its operation depends on the reversible coordination reaction (C=O/C-O-0.5Zn conversion) in cathode and the Zn plating/striping in anode, in parallel with Zn^{2+} transfer in between, showing a rock-chair mechanism. It is found that the formation of Zn^{2+}-DMF complex enable Zn^{2+} uniformly transported to the surface of Zn electrode, facilitating dendrite-free Zn platting. In addition, the aprotic nature of the electrolyte eliminates the issue of undesired H_2 evolution on Zn surface, increasing the reversibility of platting/stripping. Therefore, Zinc anode shows high cycle stability in such electrolyte. Furthermore, owing the insolubility in DMF solution and the high reversibility of coordination reaction, PQ-MCT can serve as a robust cathode with fast kinetics. As a result, such Zn//PQ-MCT full battery exhibits super-long life (20000 cycles) and high power/energy densities. Finally, benefiting from the low freezing point and high boiling point, this full battery even can be operated in wide temperature range of 220 ℃ (from -70 ℃ to 150 ℃).

Cathodic oxygen reduction reaction (ORR) governs overall proton exchange membrane fuel cell (PEMFC) performance. Among all the catalysts available, the Pt-based catalyst is well deserved the best oxygen reduction catalyst, which makes them practically irreplaceable at present. However, a vast amount of platinum (Pt) is required due to the sluggish ORR kinetics, especially in harsh acidic media, which casts a blight on their economic competitiveness and sustainable development. This constraints are pressing incentives for exploring catalysts with high Pt utilization. The most mature alternatives is Pt alloy nanoparticles with substantial enhancement in activity and significant reduction in Pt loading[1]. The electronic structure of surface Pt atoms can be tailored by the so-called geometric effect and ligand effect, which are mainly originating from the lattice mismatch and heterometallic interaction. Here, we synthesized a hollow structured PtFe composite catalysts by acid leaching. The usage of Pt could be reduced without compromising the ORR activity comparing to pure Pt catalysts. Based on a series of control experiments analysis, high-resolution electron microscope image, and CO stripping data[2], we can identify the true active site of this complex catalysts, which possess non-uniform particles after high temperature calcination and acid leaching. The largest contribution to catalytic activity is from the small-sized hollow particles, where the improved ORR activity was due to the weakened oxygen-binding strength induced by the electronic structure of the segregated Pt-skin surface.

The electric double layer (EDL) is a region occurring at the interface between two phases, most commonly an electrode and an electrolyte. Differential capacitance has central role in the theories of EDL. First of all, it is one of the few observables that can be directly compared to experimental measurements. Additionally, it describes the magnitude of electrolyte response to the change in applied potential. Finally, the differential capacitance is in the heart of modern technologies such as supercapacitors and batteries [1]. While the basic theory behind the interface between dilute electrolytes and electrodes has been established, the EDL occurring between metal surfaces and concentrated electrolytes, such as ionic liquids, represents a challenge for theory [2,3]. Using a computational approach, the capacitance-potential curve, $C(U)$, for such systems can be derived from molecular dynamics (MD) simulations. Although a differential capacitance for various ionic liquids accessed via MD simulations has been reported in the literature [4,5], retrieving a C(U) curve from the MD trajectories is not trivial. Usually, it implies a differentiation of the charge-potential curve. Independently on MD methodology implemented (i.e., simulation with a constant charge or constant potential applied), the curve fitting is a crucial step, as the resulting differential capacitance strongly depends on the fitting method used and must be manipulated with care.

The present work focuses on the MD simulation data treatment in the process of C(U) curve fitting, however, always taking into account the position of surface charge plane [6]. We consider various simulations techniques and approaches for the treatment of simulation data. We demonstrate that the shape of the capacitance curve is largely determined by the electronic structure, which agrees with previous experimental results [7]. A more detailed analysis provides insights towards potentially useful combinations of electrode and electrolyte, capable of yielding significantly higher capacitances that are required for advanced electrochemical devices.

Glucose Sensing Electrode Fabrication using Unnatural Amino Acid Incorporated and Ferrocene Conjugated GDH

Quan Yuzhong[1], Woonsup Shin[2]
Department of Biomedical Engineering, Sogang University, Seoul 121-742, Korea.
[1]qyz0524@sogang.ac.kr; [2]shinws@sogang.ac.kr

Electrochemical enzymatic glucose sensors measure glucose concentration through a current generated by an enzyme specifically oxidizing glucose. However, the cofactor in which this reaction occurs is buried inside the macromolecule of the enzyme, the efficiency of electrons transferred to the electrode surface is very low. Therefore, the method of coating the electrode surface using various linkers to crosslinking the glucose oxidizing enzyme and the redox polymer that assists electron transfer is frequently applied. In this study, we use the modified enzyme to fabricate the glucose sensor which is possible to direct electron transfer, without using a separate mediator and cross-linking process. An azide group was introduced on the surface of glucose dehydrogenase through the genetic incorporation of an unnatural amino acid, then a small molecule of ferrocene containing alkyne combines on the surface of GDH through the “click” reaction. The electrode was simply prepared by drop-coating the modified enzyme on the screen printed carbon electrode, dried in room temperature. We measured the glucose in a range of 0.1~1.0 mM in PBS solution, used the electrode prepared above as working electrode, Pt wire as counter, Ag/AgCl as reference. The results proved that the direct electron transfer efficiency was clearly improved compared to the electrode using an enzyme of a natural structure with no modification. Enzyme activity in each process was also observed and compared to that of natural structures.

Elucidating the Mechanism of Li Insertion into $Fe_{1-x}S$/Carbon via in Operando Synchrotron Studies

The detailed understanding of kinetic and phase dynamics occurring in lithium-ion batteries (LIBs) is crucial for their further improvement. We previously reported that $Fe_{1-x}S$/C nanocomposite shows a promising performance as anode material for LIBs. However, the underlying lithium storage mechanism was not entirely understood during the 1st cycle. In this work, we apply *in operando* nondestructive synchrotron X-ray diffraction (SRD) and X-ray absorption spectroscopy (XAS) to directly track the complex electrochemical reaction mechanisms during the 1st (de)lithiation processes in the $Fe_{1-x}S$/C nanocomposite. The combination of *in operando* techniques enables the uncovering of the pronounced electronic changes and structural alterations on different length-scales. Additionally, the investigation of kinetics processes, morphological changes and internal resistance dynamics are discussed. These results reveal that the phase transition of $Fe_{1-x}S \rightarrow Li_2Fe_{1-x}S_2 \rightarrow Fe^0+Li_2S$ occurs during the 1st lithiation process. The redox reaction of $Fe^{2+} \rightarrow Fe^0$ is confirmed by *in operando* XAS. During the 1st (de)-lithiation process, Fe^0 and Li_2S convert to $Li_{2-y}Fe_{1-x}S_2$ and Li^+ is extracted from the Li_2S to $Li_{2-y}S$ phase. The phase transition from Li_2S to $Li_{2-y}S$ is not detected in previous findings. After the 1st de-lithiation process, amorphous $Fe_{1-x}S$ nanoparticles are embedded within the remaining Li_2S matrix[1-3].

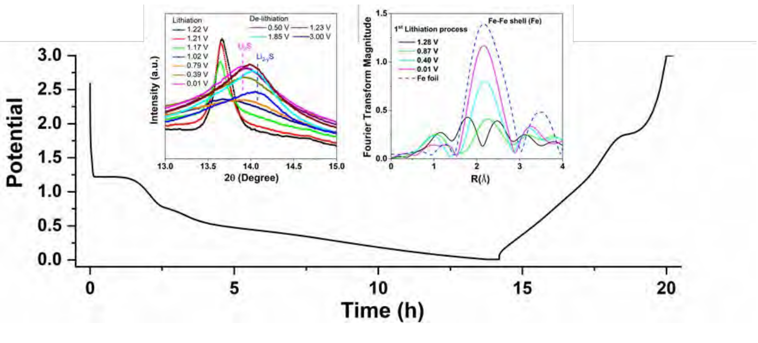

Fig. 1 In operando XRD and XAS of $Fe_{1-x}S$/C *during the 1st lithiation and de-lithiation processes.*

Recent progress in the application of ionic liquids (ILs) as electrolytes in supercapacitors, Li-ion batteries, and actuators [1] has stimulated studies of the electrical double layer (EDL) in this media [2], as the EDL structure affects the performance of all listed electrochemical devices. Due to a strong anion–cation interaction in ILs, the ionic layering near the surface is induced [3], resulting in an alternatively charged ionic structure (see Figure 1). To calculate the capacitance-potential dependence, $C(U)$, in such complex systems, advanced theoretical models are being developed along with numerous computer simulations [4,5]. In general, with the focus on the electrolyte side of the EDL, different models give two types of C(U) curves: with one (bell-shaped) or two (camel-shaped) maxima near the potential of zero charge [5,6]. In this molecular dynamics (MD) study, we show the correlation between the electrode surface corrugation in conjunction with the electrolyte atoms sizes and the shape of the $C(U)$ curve. For this reason, we chose well-studied 1-butyl-3-methylimidazolium hexafluorophosphate (BMImPF$_6$) IL and three charged gold surfaces, namely, Au(111), Au(110), and Au(100). Special attention is paid to the effect of surface crystallography on the calculated C(U) dependence in reference to the experimental data.

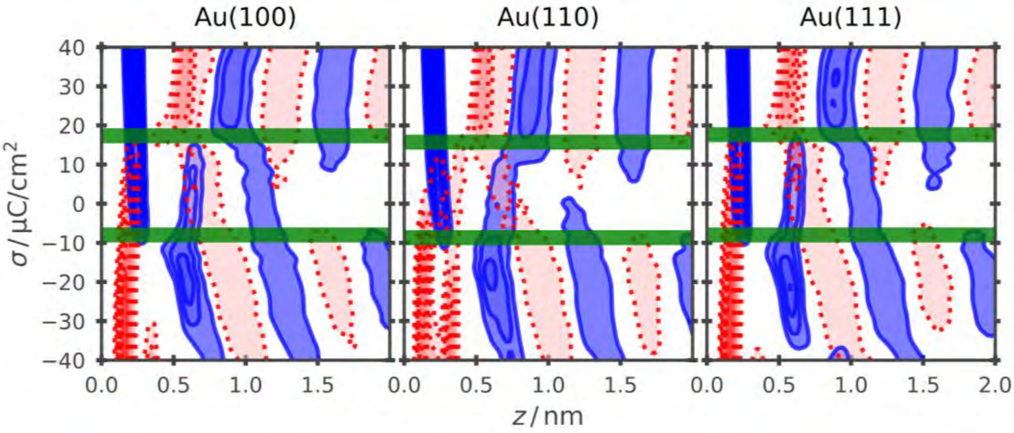

Figure 1: Ion number density contour plots on the electrode's surface. The cation (red) – anion (blue) layering structure is visible, especially at high electrode charges (in the top and bottom of green lines).

Cyclic Voltammetry is invasive on a Bioelectrochemical Systems

Sanne M. de Smit, Cees J.N. Buisman, Johannes H. Bitter, David P.B.T.B. Strik
Wageningen University and Research
Axis-Z, Bornse Weilanden 9, 6708 WG Wageningen, The Netherlands
sanne.desmit@wur.nl

In general electrochemical characterization techniques such as cyclic voltammetry (CV) and electrochemical impedance spectroscopy are regarded as non-invasive techniques. Here we show that non-invasiveness does not simply account for the application of cyclic voltammetry (CV) on a bioelectrochemical system. This finding requires a rethinking on the usefulness of CV on bioelectrochemistry. CV is widely used in bioelectrochemstry to measure biocatholytic activity, electrode composition or reaction kinetics. Although CV is considered to be an innocent technique, a recent study from Jourdin, et al. [1] showed that the cathodic current of a bioelectrochemical CO_2 reduction system increased after a CV scan was performed on the system. This finding led to the objective of our study, to study the effect of CV on microbial electrosynthesis. A bioelectrochemical system was developed with a mixed culture biofilm in which CO_2 was elongated to acetate. The effects of CV on both reactor performance and biocathode composition were studied. CV repetitively enhanced current density for up to 20 days. Additionally, a different oxidation peak was observed during the first cycle of the CV scan compared to the subsequent two cycles. This indicated that a different oxidation reaction occurred during the first cycle compared to the subsequent two cycles. To further investigate this change, the metal composition of the biocathode was studied. The concentrations of Fe, Co, Al, Ba, Mn, Mo and biomass increased in the biotic catholyte predominantly during the oxidation peak of the first CV cycle, indicating these compounds were released from the cathode. The biocatholyte concentrations of the released metals were still increased at the end of the CV, they decreased rapidly within four hours after the CV at the cathodic operation potential of -0.85 V vs SHE.

The results from this study show that CV is not simply an analysis technique, but causes changes at the biocathode. Invasiveness of CV on other bioelectrochemical systems should be investigated to understand the potential impact of this technique. Present findings are potential applicable to modify or provide in-situ maintenance on biocathodes. Moreover, our findings form a starting point for follow up studies investigating the mechanisms behind the possible catalytic effects of the performed analysis method.

Energy consumption in residential and commercial/office buildings has a significant impact on the environment, contributing significantly to greenhouse gas emissions and global warming. Not surprisingly, energy efficiency has become a priority target for the energy policies in many countries. The emerging concepts of zero and nearly-zero energy buildings call for new materials and new technologies. In this context, the interest in the development of smart electrochromic windows (ECWs), enabling the fine control of the incident solar spectrum (heat (near-infrared (NIR) region) and sunlight (visible region)) has grown significantly in the last few years [1]. Such windows rely on electrochromic devices (ECDs). ECDs undergo a reversible color change upon application of a small voltage (1-3 V). Their archetypal configuration comprises a multilayer structure: an EC film of the cathodically coloring tungsten trioxide (WO_3), an electrolyte film, an EC film of the anodically coloring nickel oxide (NiO), and two outermost transparent conductive oxide (TCO) layers, such as visible-transparent-indium tin oxide (ITO) [1], or visible- and NIR-transparent amorphous indium zinc oxide (a-IZO) [2(a)].
Aiming the production of NIR-emitting smart ECWs providing additional indoors human comfort in buildings, electrolytes doped with erbium salts and/or complexes [2 (a-b)] were reported. Herein we used the sol-gel method [2(b)] to prepare transparent and thin films resulting from the co-condensation of two urea cross-linked poly(oxyethylene)/siloxane matrices: a di-ureasil d-U(Y) [3] and a tri-ureasil t-U(Y') [4], where Y=600, 900, 2000 and Y'=400, 3000 and 5000 represent the average molecular weight of the polymers chains. The t-U(Y') materials were doped with a commercial ionic liquid, and the d-U(Y) matrices were doped with erbium complexes. For comparison purposes non-doped matrices were also prepared. ECDs incorporating optimized electrolytes were assembled and their electro-optical performance was evaluated.

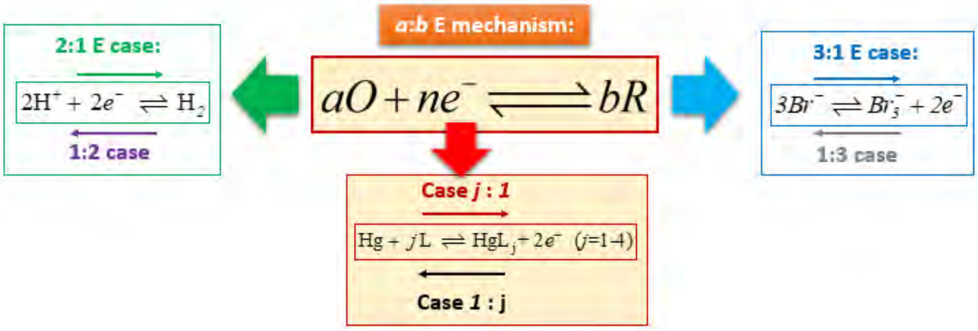
Spectroelectrochemistry of Nonunity Stoichiometry Electrode Reactions: A Theoretical Study

José María Gómez-Gil, Angela Molina, Eduardo Laborda, Juan García-Martínez

Departamento de Química Física, Facultad de Química, Regional Campus of International Excellence"Campus Mare Nostrum",Universidad de Murcia, 30100 Murcia, Spain

jm.gomezgil@um.es

Key electrochemical processes are reported to follow non-unity stoichiometries in a variety of scientific and technological fields [1]: energy storage and conversion (*eg*., halides in dye-sensitized solar cells, hydrogen production), environmental monitoring and assessment (*eg*., mercury complexes) and electrosynthesis (*eg*., dimerization of the electrode product), among others (see *Scheme* I).



Scheme I. Schematic and examples of electrochemical reactions with nonunity stoichiometry.

The full characterization of this kind of processes can be challenging considering the number of parameters to be determined, at least: the stoichiometric and diffusion coefficients of the redox species, the number of electrons transferred, and the formal potential of the couple O/R. Hence, as in other contexts [2,3], the joint analysis of simultaneous electrochemical and spectroscopic measurements can be advantageous for comprehensive and sound studies.

Attending to the above, a general theoretical treatment is developed in this work to model the spectroelectrochemical response at macroelectrodes of reversible electrode reactions with complex stoichiometry *a:b* (see *Scheme* I). The theory is applicable to any voltammetric perturbation and whatever the diffusion coefficient and bulk concentration of the redox species. Simple equations are derived for the current-potential response, surface concentrations and concentration profiles of the most common 2:1, 1:2, 3:1 and 1:3 cases. From the theoretical solutions obtained, the value of spectroelectrochemistry is assessed in the elucidation and quantitative characterization of the reaction stoichiometry. Thus, the voltabsortometric and chronoabsortometric responses are investigated both in normal and parallel modes, establishing suitable experimental approaches, diagnosis criteria and protocols for data analysis.

The aim of the present work is to assess and develop chemically modified electrodes based on a composite formed by Methylene blue (MB) and a mesoporous ordered structured (SBA-15) [1,2].
Methylene blue could be a mediator, which acts as electrocatalyst in certain redox reactions (e.g. detection of cancer markers). In addition, Methylene blue is a disinfectant and an antioxidant. It also is an antidote in case of intoxications by nitrates (NO_3^-), nitrites (NO_2^-) or chlorates (ClO_3^-) [3].
The preparation of the modified electrode was realized by drop-casting method, followed by evaporation of the solvent after deposition of a solution containing MB and SBA-15 on a glassy carbon surface. The obtained composite layer was protected by a Nafion film.
The GC/SBA-15-MB/Nafion modified electrode will be characterized by electrochemical methods of investigation (cyclic voltammetry and square wave voltammetry) in order to obtain the electrochemical parameters (ΔE, Eo', Ipa/Ipc, FWHM (full width at half maximum)). The influence of the experimental conditions (scan rate and pH) on the electrochemical behavior and the stability of the GC/SBA-15-MB/Nafion modified electrode will be investigated. Also, the morpho-structural characterization will be evaluated by Atomic force microscopy, AFM; Energy-dispersive X-ray spectroscopy, EDX and Scanning Electron Microscopy, SEM.
The GC/SBA-15-MB/Nafion modified electrode will be tested for H_2O_2 detection.

Scale-up Effect on Performance of Reversible Chlor-Alkali Electro-Absorption Cells

M. Carvela, J. Lobato, M.A. Rodrigo

Av. Camilo Jose Cela n 12, Enrique Costa Novella Building, Ciudad Real (13071) Spain
mireya.carvela@uclm.es

Nowadays, because of global warming, use of renewable energies has become of a paramount importance. Europe and other countries all around the world are putting a great effort on the introduction of the renewable energies (e.g. solar and wind energies) in the electricity grid but there are still some inconveniences that limit their implementation such as the capital costs and their intermittent nature. To overcome the last one, a storage medium or energy carrier is needed. It is in this scenario where the hydrogen technology plays a very important role as it can be stored and produced from primary energy sources [1]. Flow batteries based on hydrogen-halogen compounds have generated interest to different researchers as renewable energy storage systems [2]. Because of relatively facile chlorine redox kinetics, H2-Cl2 cells are capable of operation with lower activation loss associated to the chlorine electrode compared with the sluggish oxygen reduction reaction of the H_2-O_2 based fuel cells.

The fuel cell and the electrolyzer operation modes can be carried out in the same electrochemical cell and with the same electrodes. Thus, a reversible electrochemical cell can be operated as electrolyzer or fuel cell depending on the reagents that are fed into the electrodic compartments. It allows the use of a single equipment for the storage of energy as chemicals. Thus, in a reversible cell, the same electrodes are used in both operation modes, so they must show good performance when acting as anodes or cathodes, because they are going to perform in both roles. For hydrogen oxidation, platinum is known to be a very good electrode. For chloride oxidation, Mixed Metal Oxides (MMO) based on RuO_2 are the most widely used electrodes [3]. It is interesting to assess the performance of both types of electrodes when they are used in the reduction of chlorine and protons to produce hydrogen.

In this work, the performance of a reversible electrochemical cell for the storage of energy using the chloralkaline process was investigated. In a first stage, we checked that the anode composition (Ru/Pt ratio) influences in the performance of the reversible cell. It was found that a molar ratio Ru:Pt within the range 3-4 was good enough to obtain a good performance in both operation modes [4]. In the second stage, different models or configuration of cells are tested. Results demonstrate that design of the cell has a superb significance on the performances obtained [5]. Based on these results, we used a cell larger than the first cell we designed, in order to check the performance of the reversible cell at different scales. We observed that the results in both cells were similar, and in the scaled-up fuel cell, the influence of applied (from 25 to 80 ºC) temperature is more relevant.

These results demonstrate that working with larger cells while maintaining the efficiency of the process is possible

In Search of the Best Operation Conditions for the SO_2 Electrolysis at High Temperature (Above 100 °C)

* Sergio Díaz-Abad, Manuel A. Rodrigo, Justo Lobato

University of Castilla-La Mancha, Chemical Engineering Department. Av. Camilo Jose Cela n 12,
Enrique Costa Novella Building, Ciudad Real (13071) Spain

**Corresponding author e-mail: sergio.diazabad@uclm.es*

The Hybrid Sulphur Cycle has been identified as a highly efficient method for large-scale hydrogen production. Based on this cycle, this work is related to the step where SO_2 is electrochemically oxidized in the anode to form sulphuric acid, protons, and electrons ($E^0 = 0.17$ V vs SHE). The protons are conducted across the electrolyte separator to the cathode where they recombine with the electrons to form H_2 according to equations 1 and 2.

$$SO_2\,(aq) + 2\,H_2O \rightarrow H_2SO_4\,(aq) + 2H^+ + 2\,e^- \qquad (1)$$

$$2H^+ + 2\,e^- \rightarrow H_2(g) \qquad (2)$$

For high cycle efficiencies, operating at temperatures higher than 100°C in the electrolyzer is recommended. However, SO_2 depolarized electrolysis is currently mostly studied using Nafion membranes which limits the operating temperature to around 80°C because of the need of hydration of these membranes. That is the reason for the need of developing new materials for this application. PBI based membranes are a promising alternative for working at high temperatures due to they do not need to be humidified for its operation at high temperature, also the degradation temperature of this polymer (ca. 500°C) makes it suitable for this application.

A commercial PBI membrane supplied by Danish Power Systems USA was used for the experiments. The membranes were doped with 85 wt% phosphoric acid. As reactants for the electrolysis, MiliQ water and SO_2 were used. A platinum loading of 0.7 mg Pt/cm^2 was employed on both electrodes (anode and cathode) using 40% Pt/Vulcan carbon XC72 as catalyst by spraying a catalytic ink on the electrode surface. For the electrochemical measurements, a potentiostat/galvanostat (AUTOLAB, Netherland) equipped with Frequency Response Analysis (FRA module) was used.
The tests were performed in a 25 cm^2 SO_2 depolarized electrolysis cell based on PEMFC technology, working with SO_2 in gas phase and generating steam which will be mixed with the SO_2 flow. The performance was studied in a range of temperatures from 120°C to 150°C. Polarization curves were obtained by scanning the applied potential from 0.00 to 1.00 V (vs RHE) at a scan rate of 10 mV s^{-1}. Impedance spectroscopy was measured potentiostatically, at 0.15 and 0.55 V, with a perturbation signal of 10% with a frequency range of 10 kHz to 100 mHz
Results showed that increasing temperature has not always a beneficial effect on the performance of the electrolyzer as result of enhancement of parasitic reactions. On the other hand, when an inert gas is introduced to the cathode of the cell it results in some advantageous effects as they can remove the possible SO_2 which has crossed the membrane. Regarding this aspect, nitrogen and a mixture of nitrogen and steam where studied as feed for the cathode. Finally, the effect of the flows of water and sulfur dioxide in the anode where also studied in order to evaluate the optimum stoichiometry of the system.

ACKNOWLEDGEMENTS

Development of a Sensitive Electrochemical Paracetamol Sensor based on Nano-composite Fe_2O_3/TiO_2 Electrodes

Emmanuel Topoglidis, Christina Sofia Leva, Pavlos Nikolaou, Ioannis Koutselas
Department of Materials Sciece, School of Natural Sciences, University of Patras
Rio 26504, Greece
e-mail: etop@upatras.gr

Paracetamol's usage, a widely used analgesic and antipyretic drug, suffers from overdoses and chronic usage problems and its concomitant use with alcohol or other drugs causes toxic metabolite accumulation, hepatic toxicity and disorders, nephrotoxicity, pancreas inflammation and skin rashes. Therefore, accurate determination of paracetamol is necessary during quality control in pharmaceutical formulations and biological fluids.

Paracetamol is an electrochemically active structure which is oxidized on various electrodes, while on bare electrode this occurs at high overpotentials. Chemically modified electrodes have been used successfully in order to lower the oxidation overpotential and increase the current sensitivity without affecting the drug concentration determination.[1]

In this work, nanocomposite electrodes of hematite (α-Fe_2O_3) deposited on mesoporous TiO_2 film electrodes on ITO glass were found to be simple, low cost, sensitive, electrochemical paracetamol sensors, with improved conductivity compared to bare TiO_2 films.[2-4] The electrodes' excellent electrochemical behavior was examined by cyclic and differential pulse voltammetry, while their structure was investigated by FESEM, EDS and X-ray diffraction. Under optimized conditions these electrodes demonstrated excellent electrocatalytic activity towards paracetamol oxidation in the linear response concentration range from 2 to 40 μM (correlation coefficient 0.987) with a 1.07 μM detection limit. These sensors demonstrated good repeatability, reproducibility and stability, applicable for pharmaceutical paracetamol determination.

Electroactive sulfate reducing microorganisms and their relevance in accelerated iron corrosion

Krishnaveni Venkidusamy[a*], Hari Ananda Rao[a] and Laura Machuca Suarez[a]
[a]*Curtin Corrosion Centre (CCC), Western Australia School of Mines: Minerals, Energy and Chemical Engineering, Curtin University, Bentley, WA, 6102, Australia*
**E-mail address*: *krishna.venkidusamy@curtin.edu.au*

Sulfate-reducing microorganisms (SRM) are major metabolic groups of microorganisms causing microbially influenced corrosion (MIC) and known for their corrosivity through the formation of biogenic hydrogen sulfide (H_2S), iron sulfide (FeS), and hydrogenotrophic metabolism (1,2). Among these distinct corrosion mechanisms of MIC, electromicrobiologically influenced corrosion (EMIC) is currently recognized as being involved in the acceleration of the iron corrosion (3). Recent research has shown the importance of electroactive SRM (ESRM) and their role in possible ennoblement and accelerated corrosion of iron structures due to their special adaptations of extracellular electron uptake mechanisms through iron oxidation (4, 5). Such studies indicate that ESRM influences the cathodic reaction of iron corrosion. In the present study, we review such abilities in known corrosive bacterial genera of the families, *Desulfovibrionaceae* and *Desulfobulbaceae* to use iron structures as a sole source of electron and explore its electron uptake mechanisms in relevance to EMIC. These specialized bacterial species employ different strategies including cell-associated direct electron uptake through outer-membrane vesicles (6,7), formation, and accumulation of electrically-conductive mineral crusts (FeS) through dissimilatory sulfate reduction (2,8) and redox mediators' generation from bacterial cells (9). Nevertheless, the new electromicrobiological routes of such corrosive behavior have yet to be studied. Since the microorganisms are adapted to acquire energy from various environments, further exploring the research on extracellular electron uptake mechanisms will provide novel insights into microbial evolution and energy conversion besides its technical relevance.

How to Measure Sustainable Electrical Power Produced by Thermogalvanic Cells using Waste Heat

Leigh Aldous, M. A. Buckingham
King's College London
Department of Chemistry, Britannia House, 7 Trinity Street, London SE1 1DB, UK
leigh.aldous@kcl.ac.uk

Thermogalvanic cells can exploit a temperature gradient (*e.g.* from waste heat) to generate electrical power. This is driven by the entropy difference between two redox states (commonly observed in electrochemistry as *the temperature coefficient of the reduction potential*).[1] This is exemplified in the cartoon below, for water containing 0.2 M of $K_3[Fe(CN)_6]$ and 0.2 M of $K_4[Fe(CN)_6]$. With two electrodes sharing an electrolyte containing both redox states, redox processes and mass transfer ensure a continual flow of electricity (as long as the temperature difference persists).[2]

Numerous thermogalvanic devices (or thermocells) using novel cell designs,[3] electrolytes,[4] redox couples,[5] *etc.* are now being published, and invariably compared. But are the comparisons – and even the initial measurement and characterisation – valid?

This poster will summarise recently published work[6] where a 'round robin' type approach was made to comparing 5 common methods reported in the literature for characterising the electrical power produced by thermogalvanic cells. As summarised in the Figure below, some methods were accurate and some significantly overestimated the power capable of being sustainably produced. Normalisation of power values are also increasingly common, given the wide range of temperatures different groups apply, culminating in the popular adoption of "temperature-insensitive figure of merit for areal power density". This method of normalisation was explored, and found to be significantly temperature-sensitive; an alternative method of normalisation was also demonstrated.

Controlling proton-electron transfer in CO reduction electrocatalysts

Prof. Marcel Schreier
University of Wisconsin-Madison
1415 Engineering Drive, EH 3016
Madison, WI 53706
mschreier2@wisc.edu

CO_2-derived fuels, synthesized using renewable energy, present an attractive way towards a sustainable energy system. Impressive progress has been achieved in the production of CO and formic acid from CO_2. The selective electrosynthesis of higher order products such as ethylene and methane remains challenging, however. This can be attributed to an insufficient understanding of the complex reaction networks involved in transferring multiple protons and electrons to surface-bound intermediates.

To shed light into this fascinating maze, I will present investigations into the electrochemical reduction of CO in nonaqueous model systems, allowing the independent interrogation of the role of proton donor pKa, solvent, cation nature and molecular structure and the interaction of conjugate base anions with the electrode surface.

Our experiments explain the kinetic bifurcation between methane and ethylene production and provide an integrated mechanistic picture that explains why these pathways are either affected or not by the nature of electrolyte cations. I will show, how these results can be exploited to modulate the catalytic selectivity between methane, ethylene and parasitic hydrogen.

Ammonia Modified Graphene Oxide – Gold Nanoparticles Composite as a Sensing Platform

Mateusz Kasztelan[1,2], Grażyna Zofia Żukowska[2], Władysław Wieczorek[2], Barbara Pałys[1,3],

Graphene oxide (GO) is a novel material which is an important member of graphene family. The popularity of GO originates from the combination of pristine graphene features such as exceptional mechanic, electronic and thermal properties and advantages of oxygen surface groups. GO contains many oxygen groups in its structure, including epoxide, hydroxyl and carbonyl moieties, which help to overcome some limitations of pure graphene, such as high hydrophobicity, poor solubility in aqueous solvents and difficulties in surface functionalization [1]. Due to mentioned facts GO is commonly used as a component in many fields, for example in designing electrochemical [2,3] and SERS [4] sensors, catalysis [5], and many more.

GO is a versatile and easy processing material, which can be easily modified by chemical reactions. Presence of various oxygen groups facilitates numerous modifications of GO surface. Increasing attention is devoted to fabrication hybrid nanocomposites, which include graphene oxide and metal nanoparticles [6]. Thanks to imperfect carbon plane of GO and presence of oxygen moieties it is relatively easy to promote efficient adsorption of nanoparticles on its surface. Moreover, presence of graphene oxide is additionally advantageous as it protects nanoparticles from ambient environment and thus prevents from their degradation [7,8].

In this work we have performed a modification of graphene oxide with ammonia solution. Obtained product was thoroughly examined using spectroscopic (Raman, XPS, FTIR, UV-VIS) and microscopic techniques and used as a component of hybrid composite with gold nanoparticles (AuNPs). Hybrid composites consisting AuNPs and as-prepared or modified GO were used as platforms towards electrochemical detection of H_2O_2 and SERS platforms towards optical detection of aromatic dye, rhodamine 6G.

e-mail address: nureli.abdukirem@uniroma2.it

As being the bottleneck in the design of advanced Li-ion Batteries, the development of cathode materials remains as a hottest research topic. Low cost and low toxicity make Manganese and Titanium particularly desirable materials for cathode. In this work lithium-rich cathode with the partial substitution of fluorine for oxygen and based on Lithium, Manganese and Titanium was prepared and characterized.
$Li_2Mn_{1/2}Ti_{1/2}O_2F$ (LMTF) has been synthesized using two different approaches: 1) One pot ball mill synthesis starting from the mixtures of all precursor salts according to the stoichiometric ratio (LMTF1) [1]; 2) Combination of a sol-gel first step to synthesize the mid-product $LiMn_{1/2}Ti_{1/2}O_x$ (LMT), then a ball mill step of LMT prepared by sol-gel step and LiF as precursors [2] to obtain LMTF2. The two methods have been optimized changing the ball mill time and speed. $LiMn_{1/2}Ti_{1/2}O_2$ was also synthesized using the ball mill approach as control.
All the samples have been characterized by X-ray diffraction (XRD), Thermal Analysis (TGA, DTA), and Scanning Electron Microscopy (SEM). In fig.1 XRD diffraction patterns of the samples obtained with the different procedures are reported together with the theoretical pattern, as reference. In both cases a disordered-rocksalt structure was obtained indicating the success of the both procedures in the preparation of $Li_2Mn_{1/2}Ti_{1/2}O_2F$ [1].
Furthermore the electrode preparation has been optimized in terms of binder (Polyvinylidene difluoride (PVdF) and Polytetrafluoroethylene (PTFE)) and ratio of components (active material:carbon:binder).
Electrochemical characterization was carried out in Li-ion half cells using Cyclic Voltammetry (CV), and Galvanostatic Cycling with Potential Limitation (GCPL) techniques, pointing at the possible applicability of the prepared LMTF in lithium batteries.

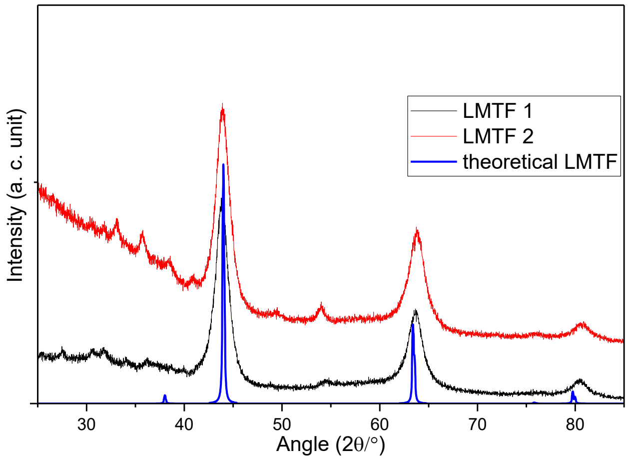

Figure 1. XRD patterns of $Li_2Mn_{1/2}Ti_{1/2}O_2F$ from different approaches

Electrochemistry of the Calcium Channel Blocker Lercanidipine at a Carbon Black Modified Glassy Carbon Electrode

Ana-Maria Chiorcea-Paquim, Isabel Garrido Fernandes and Ana Maria Oliveira-Brett
University of Coimbra, CEMMPRE, Department of Chemistry, 3004-535 Coimbra, Portugal
anachior@ipn.pt

Hypertension is one of the main risk factors of cardiovascular diseases, and occurs mainly at the aging population, causing a high number of premature deaths. The use of antihypertensive drugs is important to avoid cardiovascular illness and mortality, and the most important drugs, such as diuretics, calcium antagonists, β-blockers and others, are efficient in the blood pressure control. Lercanidipine is a third generation calcium channel blocker belonging to the dihydropyridine group of compounds, and is used to treat mild to moderate hypertension, chronic stable angina pectoris and Raynaud's syndrome.

The need for rapid, easy and low cost detection, and quantification of pharmaceutical compounds in pharmacological compositions, combined with the necessity of reducing the utilization of organic solvents due ecological considerations, are causing an increasing interest on voltammetric methods that are highly sensitive. The carbon black (CB) nanomaterial was used in many electrochemical studies, due to its interesting properties, that include high conductivity, chemical stability, large surface area, and very low cost.

The lercanidipine electrochemical behaviour at different carbon electrode materials, in a wide pH range, was studied using cyclic, square-wave and differential pulse voltammetry [1]. A comparison was made between unmodified glassy carbon electrode (GCE) and boron doped diamond electrode (BDDE), and GCE and BDDE modified with a CB nanoparticles embedded within a dihexadecylphosphate (DHP) nanostructured film (CB–DHP/GCE and CB–DHP/BDDE). The lercanidipine oxidation, for $3.4 < pH < 9.5$, was pH-dependent, diffusion-controlled, irreversible, and took place at the N1 and C4 positions from the 1,4-dihydropyridine ring. Two consecutive steps were observed, each involving the transfer of one electron and one proton. For $pH > 9.5$, both oxidation processes were pH-independent, and a $pKa = 9.40$ was determined. The lercanidipine reduction was irreversible, and the lercanidipine reduction products were also electroactive, following a reversible electron transfer reaction.

Based on the lercanidipine oxidation, and with no need for N2 purging, the lercanidipine electroanalytical determination at a nanostructured GCE modified with a CB–DHP film (CB–DHP/GCE) was achieved, showing a detection limit of 0.058 μM (3.58×10^{-5} g L^{-1}) and a quantification limit of 0.176 μM (1.08×10^{-4} g L^{-1}), more than ten times lower than previous described.

Water splitting photoanodes made of Ni/Co-layered double hydroxide (LDH) anchored at the surface of TiO_2 nanorods array (TNRA) were successfully fabricated by using a two step hydrothermal method, in order to enhance the performances during water photo-oxidation. Ni and Co were selected because of their known activity towards the oxygen evolution reaction (OER). Several experimental parameters have been tuned to maximize the OER efficiency of these NC-LDH@TNRA photoanodes: the nickel-to-cobalt ratio, the thickness and porosity of the coating, and the structure of the interface between TiO2 nanotubes and the active LDH phase. The LDH coatings have galleries containing Co and Ni cations that have been partly oxidized to higher valence states. A current density of 0.45 mA/cm^2 was measured at 1.75V (v.s RHE) in 0.1M Na_2SO_4 neutral electrolyte using a NC-LDH@TNRA photoanode with a 2:1 (Ni : Co) ratio. The OER activity was significantly increased compared to bare TNRA. Based on these results, it is expected that these nanostructured NC-LDH@TNRA photoanodes can provide a new pathway for the fabrication of efficient water photoanode materials and the development of water photo-dissociation devices.

With the rapid development of novel advanced materials for 3D printing, the applicability of these techniques has extended into various specialized fields. In electrochemistry, there is a growing interest in developing printable conductive composite filaments[1,2,3] to be used as electrode materials as an alternative to conventional carbon or metal electrodes. In this work, we chose a commercial polylactic acid/carbon nanotube (PLA/CNT) filament to manufacture electrodes employing fused deposition modeling (FDM) 3D printing process (Fig. 1A) with the goal of developing customized catalysts for the electrochemical reduction of CO_2. In addition, we employed FDM to fabricate an insulating electrode casing from unmodified PLA to ensure a defined area of the electrode/electrolyte interface (Fig. 1A). It is known from the literature that different metals lead to various products of the CO_2 electrochemical reduction.[4] Therefore, we additionally designed and manufactured a PLA cell dedicated for functionalization of electrodes by metallic electroplating (Fig. 1A) to control the product selectivity of CO_2 reduction by selecting a suitable metal ion solution (Cu^{2+}, Sn^{2+} Sn^{4+}, Zn^{2+}, Ag^{+}). Our recent work[3] has demonstrated that metallic electroplating additionally leads to a drop of the kinetic intrinsic barrier for the interfacial electron transfer. Electron transfer properties were investigated by cyclic voltammetry employing $[Ru(NH_3)_6]^{3+/2+}$ couple as the electroactive probe (Fig. 1C). For PLA/CNT electrodes functionalized by potentiostatic electroplating performed in 0.1 M $Cu(NO_3)_2$ for 32 minutes at 6 V, the separation of faradaic maxima decreased and the faradaic peak current distinctly increased. This observation confirms that the Cu layer reduces the kinetic barrier to electron transfer and also increases the total area of surface active sites available for this process. Such an improvement in electrical properties offers great potential for practical use of 3D printed electrodes modified by electroplating such as the production of hydrocarbon chemicals and fuels.

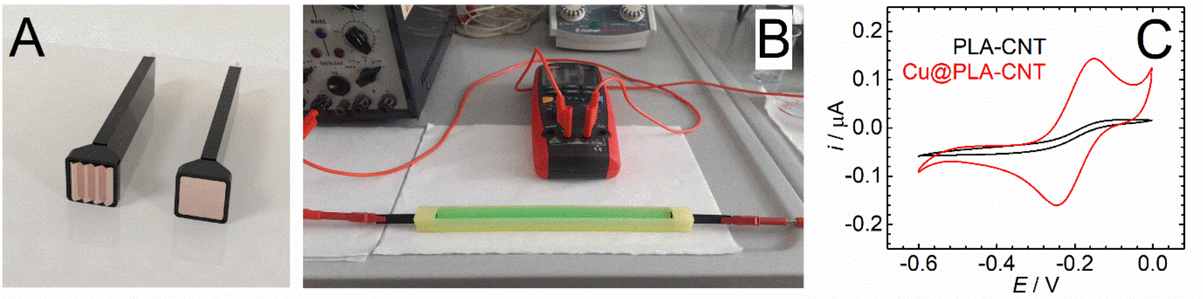

Fig. 1 (A) CAD design of 3D printed electrodes in insulating casing, (B) setup for electroplating of electrodes with controlled applied voltage and recorded resulting current, (C) cyclovoltammetric response of unmodified PLA/CNT electrode (black) and the same electrode subjected to copper electroplating for 32 min at 6 V (red).

Celestijnenlaan 200F, 3001 Leuven, Belgium
Louis.DeTaeye@imec.be

Next generation battery materials should be cheap and environmentally benign, while retaining both a high energy and power density. LMO is an interesting material as it contains only abundant materials, however, the energy density of LMO is generally limited by the relatively low capacity of 630 mAh/cm^3 and the average potential around 4V vs. Li^+/Li. The applicability and performance of LMO can be enhanced by utilizing the 3V potential range in LMO, effectively lithiating the material up to $Li_2Mn_2O_4$. Operating the material using both the 4V and 3V potential ranges, boosts the capacity to 1260 mAh/cm^3 with 630 mAh/cm^3 at 4.1V vs. Li^+/Li and an additional 630 mAh/cm^3 at 2.9V vs. Li^+/Li, leading to a net increase of 65% in energy density. This increase in energy density places the material on par with many state-of-the-art materials, such as NMC and LMNO.

There are some drawbacks. Lithiation of $Li_xMn_2O_4$ beyond x=1, leads to poor cyclability due to Jahn-Teller distortion and Mn dissolution. Improvements in the cyclability were achieved in thin films by scaling these films down to sub 100 nm thickness [1]. This was linked to suppression of the mechanical damage inflicted by Jahn-Teller distortion.

A second issue stems from electrolyte instability at the upper limit of the electrochemical window. This can be minimized by the choice of electrolyte. $LiPF_6$ in EC:DMC is a commonly used electrolyte solution due to the wide electrochemical stability window. When this electrolyte solution is used during deep discharge of LMO a peculiar decomposition reaction was observed, leading to poor cycling and rate performance. The decomposition for the given potential window (2.5V vs. Li^+/Li up to 4.25V vs. Li^+/Li) is unexpected, as the electrolyte solution is not expected to cathodically decompose above 1V vs. Li^+/Li. [2]

A comparative study of the performance of LMO utilizing both the 3V and 4V regions is conducted using different electrolyte solutions, to determine whether the reaction stems from the solvent (EC:DMC or PC) or the salt ($LiClO_4$ or $LiPF_6$) used during cycling. Based on the results, the decomposition reaction is linked to the use of the $LiPF_6$ salt and appears to be independent of the solvent used.

A reaction mechanism for this decomposition is postulated based on the formation of a blocking fluorophosphate and metal fluoride surface layer. The reaction requires the formation of a surface layer of $Li_2Mn_2O_4$ in the 3V region. XPS and ERD are combined to confirm the hypothesized mechanism.

Assessment of electrochemically driven technologies applied to the treatment of endocrine disruptors in different aqueous matrices

Alexsandro J. dos Santos, Matheus S. Kronka and Marcos R. V. Lanza

Institute of Chemistry of São Carlos, University of São Paulo, Avenida Trabalhador São-Carlense 400,
São Carlos, SP 13566-590, Brazil
e-mail address: alexsandrojhones@usp.br

Every day different organic pollutants are being discharged into water streams and even at low concentrations can cause considerable harm to environment and human health. Currently, it is estimated that more than 87,000 compounds from natural or synthetic origin can directly affect human endocrine system [1]. These compounds are known as endocrine disruptors (EDs). The conventional physical-chemical treatments applied to treat them demonstrated low efficiencies and require long depollution times of operation. The electrochemical advanced oxidation processes (EAOPs) appeared as efficient, clean and low-cost technologies. EAOPs have been successfully used due to their simplicity combined to high performance. Little information in literature has been provided about their performance with complexes aqueous mediums. Therefore, the aim of this work is to evaluate the influence of different aqueous mediums like sulfate (SO_4^{2-}), persulfate ($S_2O_8^{2-}$) and chloride (Cl^-) in the treatment of Bisphenol A, a typical EDs. A simulated matrix that mimicked a real wastewater and tap water were also tested in order to show EAOPs viability in complexes matrices. The depurations were based on anodic oxidation with H_2O_2 eletrogerated (AO-H_2O_2) using boron-doped diamond/O_2-diffusion electrochemical cell at a current density (j) of 33.3 mA cm^{-2}. The AO-H_2O_2 process consists of *in situ* electrogeneration of physically adsorbed hydroxyl radicals ($^\bullet OH$) ($E^o(^\bullet OH/H_2O)$ = 2.80 V/SHE) from water oxidation (reaction 1), where the hydrogen peroxide (H_2O_2) is yielded by the O_2 reduction on the cathode (reaction 2).

The results highlight that EDs degradation is considerably affected by the type of water matrix. This behavior can be related to the formation of different oxidants in the medium. The kinetic constant (k_1) and dissolved organic carbon removal values increased in the following order: tap water (6.67×10^{-5} s^{-1} – R^2=0.993, 42.2%) < sulfate (1.53×10^{-4} s^{-1} R^2=0.992, 52.1%) < persulfate (2.78×10^{-4}s^{-1} – R^2=0.996, 63.7%) < chloride (5.12×10^{-4}s^{-1} – R^2=0.997, 77.2%) < simulated wastewater (1.48×10^{-3} s^{-1} – R^2=0.983, 72.8%). In the sulfate medium, the greatest contribution to EDs removal was reaction 1, where $^\bullet OH$ reacts with the contaminant leading to its overall degradation to CO_2, H_2O or partial conversion. Regarding the persulfate medium, there is the formation of sulfate radical ion ($SO_4^{\bullet-}$) through reaction 3 with the H_2O_2 electrogenerated. Sulfate radical ion has high oxidation potential ($E^o(SO_4^{\bullet-}/SO_4^{2-})$ = 2.5-3.1 V/SHE)) and longer half-life (30~40 μs) than $^\bullet OH$ [2]. Active chlorine species (Cl_2, HClO and ClO^-), obtained from Cl^- oxidation, accelerates the degradation process [3], as revealed by the acquired results.

$$BDD + H_2O \rightarrow BDD(^\bullet OH) + H^+ + e^- \quad (1)$$
$$O_2(g) + 2H^+ + 2e^- \rightarrow H_2O_2 \quad (2)$$
$$S_2O_8^{2-} + H_2O_2 \rightarrow 2SO_4^{\bullet-} + 2^\bullet OH \quad (3)$$

The presence of inorganic ions acted as scavengers of oxidants in the tap water, justifying the poor degradation of EDs in this medium. Thus, before applying any type of treatment to water, the medium must be widely characterized with the aim of verifying what can influence the removal of the target pollutant.

yyxia@fudan.edu.cn

Water splitting reaction involving oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) represents the core of renewable energy conversion and storage technologies. OER is generally considered to be the rate-limiting reaction due to the four-electron transfer, sluggish kinetics, and high overpotential. In the conventional mechanism of OER, the reaction includes multiple adsorbed intermediates (i.e., O–O bond formation, the rate determined step), leading to a large overpotential, while a new identified direct O_2 evolution mechanism (DOEM), which involves direct O–O coupling, has been proved to break through the limitation. Designing catalysts based on DOEM could boost the kinetics by enhancing the formation rate of O-O bonds.
