Among the recently reported catalysts, transition-metal-based alloy, metal oxides and perovskite oxides show great potential. During the OER process, those electrocatalysts would go through a surface reconstruction process at high potential, especially the transition-metal-based alloy. Transition-metal based alloy is the most potential oxygen evolution catalyst due to its oxyhydroxides surface fabricated by electrochemical oxidation induced surface evolution and multi-metallic synergistic effects. Structural evolution could be achieved by electrochemically-induced continuous oxidation. It could provide more reaction sites, more active species and better water oxidation performance.

Herein, we report a homogeneous multi-metal-site oxyhydroxide electrocatalyst (consisting of Fe doped NiOOH and Cu doped NiOOH) by *in-situ* electrochemical dealloying of multi-metal-site alloy (consisting of $FeNi_3$ and NiCu alloy). The *in-situ* structural evolution process manipulates intermediate and enhances the performance of water oxidation. After dealloying, the electrochemical dealloyed catalyst exhibits a small overpotential at large current density (250 mV at 100 mA cm^{-2}), low Tafel slope (34 mV dec^{-1}), remarkably increased ECSA (8-fold larger than before), and superior durability for 200 h at 100 mA cm^{-2}. Such electrocatalyst represents one of the best performances among all reported transition-metal based electrocatalysts, even superior to benchmark RuO_2. Operando ATR FT-IR reveals that the electrochemical dealloyed electrocatalyst could manipulate the reaction path based on direct O_2 evolution mechanism (DOEM) and facilitate the formation rate of O-O bonds. The fundamental understanding would contribute to the identification and design of the active structure of oxygen evolution electrocatalysts.

Research on Promoted Polysulfide Redox Kinetics by Graphene-Supported Carbon-Coated Ni Nanoparticles

Zhuo Yu, Bingliang Wang, Yonggang Wang*
Department of Chemistry, Fudan University
Shanghai 200433, P. R. China
ygwang@fudan.edu.cn

Although numerous efforts have been made to explore sulfur-encapsulated host materials and separator modification components (e.g., porous carbonaceous materials[1-3], metal oxides[4], and two-dimensional nanomaterials[5,6]) to physically/chemically trap sulfur species within cathodic side, they fail to facilitate intrinsically sluggish reaction kinetics of accumulated polysulfides in lithium-sulfur (Li-S) batteries. Aiming at above issue, introducing electrocatalytically active materials to cathodes or separators is regarded as an effective method to boost surface conversion kinetics of polysulfides. Nevertheless, mechanical insights of electrocatalysis are insufficient, owing to the complexity of intermediate products of the redox reactions[7]. Moreover, it should be noted that the enhanced battery performances with the introduction of electrocatalytic materials are still achieved at low sulfur mass loading (1~2 mg cm^{-2}) and excess electrolyte ($\geq$ 10 μL mg^{-1}), which is adverse to overall energy density[8-11]. Especially, it is very difficult to promote low-temperature behaviors of Li-S batteries by these reported electrocatalysts.

Herein, graphene-supported carbon-coated Ni Nanoparticles (denoted as Ni@C/graphene) was prepared by directly carbonizing the metal-organic framework/graphene oxide precursor, which was then dispersed on a commercial glass fiber membrane to form a separator with electrocatalytic activity for polysulfide conversion. *In-situ* analysis and electrochemical investigation demonstrate that the modified separator can effectively suppress shuttle effect and regulate the catalytic conversion of intercepted polysulfides, which is also confirmed by density functional theory calculation. As a result, the corresponding lithium-sulfur battery shows a high cycle stability (88% capacity retention over 100 cycles) even with a high sulfur mass loading of 8 mg cm^{-2} and lean electrolyte (6.25 μL mg^{-1}). Surprisingly, benefitting from the improved kinetics, the battery can work well at -50 ºC, which is rarely achieved by conventional Li-S batteries.

CO2 electroreduction – challenges for different products

Marta C. Figueiredo
Chemical Engineering and Chemistry Department, Eindhoven University of Technology
P.O. Box 513, 5600 MB Eindhoven, The Netherlands
m.c.costa.figueiredo@tue.nl

The electrochemical routes are within the most promising technologies for the use of carbon dioxide (CO_2) to produce chemicals. Electrochemical CO_2 reduction not only allows for direct utilization of renewable energy but also enables the production of chemicals with neutral or even negative carbon emissions [1].

A wide range of valuable fuels and chemicals can be produced via the CO_2 reduction reaction (CO2RR) [2] from hydrocarbons [3], oxygenates [4], carbonates [5] to syngas ($CO + H_2$). The production of C1 products is possible with high selectivity and reaction rate, however more complicated compounds are requiring more electrons, are lacking high selectivity and they are facing the difficulty of the C-C bond formation. Significant work still needs to be done before CO2RR is available as a technological solution at industrial level. Moreover, each some of the possible products have different properties and are at different stages of research what makes the challenges different for each of them. For formic acid formate) synthesis from CO_2 for example, high faradaic efficiencies can be found in the literature, however stability of the catalysts in prolonged electrolysis is still unsatisfying. By the other hand, the main challenge in hydrocarbons production is selectivity

In this presentation, I will focus on the different challenges for CO2RR to different products and our recent results and strategies to tackle these challenges.

Mesoporous Carbon Nitride based Catalyst for Efficient Water Oxidation

Devesh Kumar Singh and Vellaichamy Ganesan*
Department of Chemistry, Institute of Science, Banaras Hindu University, Varanasi-221005, UP, India
e-mail: velganesh@yahoo.com and velgan@bhu.ac.in

Harvesting energy from sustainable sources is of immense importance to solve the current situation of the world's energy crisis. Electrochemical water oxidation is one of those sustainable ways to produce clean fuels like hydrogen. Anodic oxidation involved in the water splitting is relatively complex and its sluggish reaction pathway requires high activation. IrO_2 and RuO_2 are treated as benchmark catalysts for the water oxidation at different conditions however, their instability and high-cost limit their consistency. In this work, we report an efficient catalyst, CoS_xO_{2-x} supported on a conducting sulfur-incorporated mesoporous carbon nitride (represented as CoS_xO_{2-x}-S-MCN) synthesized by a simple and cost-effective route. For the synthesis of CoS_xO_{2-x}-S-MCN, a unique strategy is followed in which MCM-41 mesoporous silica is used as a template to create porosity and to introduce oxygen into the material. The efficiency of the CoS_xO_{2-x}-S-MCN towards the water oxidation is analyzed and compared with other reported catalysts (including IrO_2 and RuO_2) in terms of overpotential and Tafel slope values. The careful analyses/comparisons reveal that the CoS_xO_{2-x}-S-MCN exhibits ~ 2.5 times higher activity than the RuO_2 towards the electrochemical water oxidation and thus this material could be a promising alternative to replace the IrO_2 and RuO_2 based catalysts.

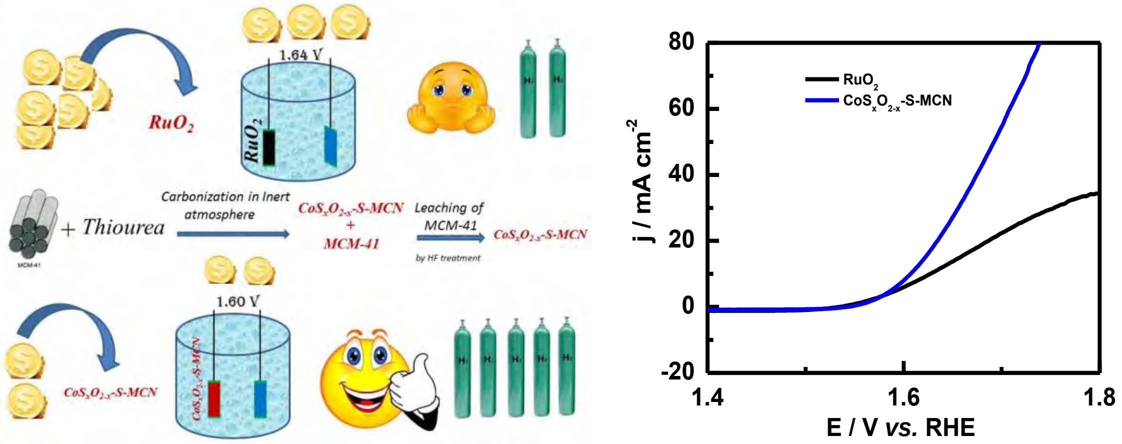

Figure: Left: Schematic representation of the higher (~ 2.5 times) water oxidation activity of CoS_xO_{2-x}-S-MCN than the RuO_2 **Right:** Linear sweep voltammetry response of RuO_2 and CoS_xO_{2-x}-S-MCN modified glassy carbon electrodes in 1.0 M KOH (scan rate: 5 mVs^{-1} and rotation rate: 1600 rpm).

Selectivity on electrocatalytic hydrogenation using well-defined PdML electrodes: C=O versus C=C saturation.

M. A. Villalba, M. T. M. Koper
Leiden Institute of Chemistry, Leiden University
P. O. Box 9502, 2300 RA Leiden, The Netherlands
m.a.villalba@lic.leidenuniv.nl

Selective hydrogenation is a key reaction in organic chemistry since the reducing agents available are scarce and their reaction is only potential-driven. Electrocatalytic Hydrogenation (ECH) reaction on the other hand, offers the advantages of a) being a clean procedure through electrogenerated species (electrons are the reducing agent generated in situ), b) tunable product distribution as function of the potential and c) adsorption geometry and energy can be modified by choosing the electrocatalyst.

Particularly, aliphatic ketones are readily reduced on Pt while on Pd the adsorption and reaction is largely hindered. However, the last one possesses the ability to easily hydrogenate unsaturated hydrocarbons and carbonyl groups in aromatic ketones too.

We will show the selectivity of the ECH in model molecules containing C=C and C=O groups using electrodeposited palladium monolayer on well-defined platinum surfaces. Supporting information was taken from similar electrochemical experiments employing molecules containing only one of the mentioned moieties. Comparatively, two low-index facets which showed the higher electroactivity were studied to investigate adsorption strength/orientation effects. Product distribution as function of the applied potential was monitored by *in situ* Online HPLC through a fraction collector.

However further research is needed to fully disclose the origin of the selectivity, the present result constitutes the fundamental knowledge for future scaling up in industries as important as pharmaceutical and fertilizers.

$Na_3Ni_2BiO_6$ with Honeycomb structure suffers from poor cycle stability when used as cathode material for sodium-ion batteries. Our strategy to improve the stability is to substitute Ni and Bi with the inactive Ti. Monoclinic $Na_3Ni_{2-x}Bi_{1-y}Ti_{x+y}O_6$ powders with different Ti content were successfully synthesized *via* sol-gel method and, 0.3 mol of Ti was determined as a maximum concentration to obtain a phase-pure compound. A solid-solution system of O3-$NaNi_{0.5}Ti_{0.5}O_2$ and O3-$Na_3Ni_2BiO_6$ is obtained when this critical concentration is not exceeded. The capacity of the first desodiation process at 0.1 C of $Na_3Ni_2BiO_6$ (~ 93 mAh g^{-1}) decreases at higher Ti concentration to ~ 77 mAh g^{-1} for $Na_3Ni_2Bi_{0.9}Ti_{0.1}O_6$ and ~ 78 mAh g^{-1} for $Na_3Ni_{0.9}Bi_{0.8}Ti_{0.3}O_6$, respectively. After 100 cycles, a better capacity retention is obtained for the Ti-containing structures. At 1.0 C, the stabilization effect of Ti is even more pronounced. Furthermore, a change in the multiple phase transformation was found. The O`3 phase, which forms in the first discharge process no longer exists after substitution with Ti. This leads to an improvement in the kinetics, which results in more stable cycling performance.

Hydrogen is one of the promising energy carriers, which can be also utilized in the various industrial field. Among some hydrogen production technologies, water electrolysis based on anion exchange membrane is getting attention due to the availability of usage of transition metal (Co, Ni, Fe, Mn) as the catalysts. Oxygen evolution reaction (OER), which is a counterpart of hydrogen evolution reaction (HER), has a higher overpotential than HER, and it causes an increasing oxidation state of metal catalysts from +2 to +3/+4. However, the active oxidation state toward OER is limited. In the case of Mn, only Mn^{3+} is known as the active site for OER due to unstable bonding between oxygen and Mn atom. To increase the OER activity, it is important to design the MnOx with dominant Mn^{3+} by oxidizing Mn^{2+} species such as $Mn(OH)_2$ and MnO.

In this study, we investigate the role of conductive carbon of catalyst layer in maximizing active site, Mn^{3+}, in OER operating potential. We observed that $Mn(OH)_2$ oxidation peak was activated by adding conductive carbon in cyclic voltammogram, and the peak potential was dependent on the amount of conductive carbon. The relationship between the amount of carbon and activated $Mn(OH)_2$ was confirmed in terms of OER overpotential and electro-conductivity estimated by band-gap. However, carbon is generally known as undergoing corrosion in the harsh OER potential. To distinguish the carbon corrosion peak from OER oxidation peak, we conducted a rotating-ring disk electrode technique and stability test.

Electroanalytical Detection of Trace Arsenic(III) in Aqueous Media Using $AgMnO_2$ Electrode

Kristina Radinović[1], Jadranka Milikić[1], Nikola Cvjetićanin[1], Tanja Barudžija[2], Biljana Šljukić[1,*]

[1] *Faculty of Physical Chemistry, University of Belgrade, Studentski trg 12-16, 11158 Belgrade, Serbia.*

(kristina.radinovic@ffh.bg.ac.rs; biljka@ffh.bg.ac.rs)

Arsenic is a heavy metal that exists in the Earth's crust and groundwaters. It occurs in organic and inorganic forms, with inorganic forms being more toxic than organics ones. Furthermore, inorganic As^{3+} is reported to be ca. 60−70 times more toxic than As^{5+} [1]. Prolonged exposure to arsenic in drinking water has a damaging effect on the human nervous system, respiratory system, skin, cardiovascular system, also increasing the risk of cancer. Consequently, the World Health Organization has limited the maximum level of arsenic in drinking water to 10 $\mu g\ L^{-1}$ [2]. Various analytical methods, such as atomic fluorescence spectroscopy [3] and inductively coupled plasma-mass spectrometry [4], have been employed for the detection of trace arsenic. However, these methods require expensive and robust instrumentation, and, as such, can only be used in a laboratory. Due to the mentioned shortcomings, replacement of these analytical methods by electrochemical ones, as portable, faster and cheaper, has been suggested [5].

Herein, Ag_xMnO_2 (x~0.2) of the hollandite-type structure was prepared by mixing equimolar aqueous solutions of $MnSO_4$ x H_2O and $(NH_4)_2S_2O_8$ with Ag wire added in the final solution. After 3 days of standing in the dark, the obtained powdery material was washed with absolute ethanol and distilled water several times, respectively, dried in a vacuum and finally heated for 4 h at 450 ºC.

This material was tested for As sensing in acidic media (1 M HCl) by anodic stripping voltammetry (ASV) Determination of As^{3+} on the $AgMnO_2$ electrode by ASV method proceeds in two steps: reduction of As^{3+} from the solution to As^0 and deposition of As^0 on the electrode, after which, due to the change in potential, As^0 is oxidized to As^{3+} and passes into solution.

Cyclic voltammogram (CV) of $AgMnO_2$ electrode illustrated its activity for detection of As^{3+} in 1 mM $NaAsO_2$ solution. Namely, CV of $AgMnO_2$ showed a well-defined peak at -0.6 V vs SCE corresponding to the electrooxidation of As. The possibility of using this electrode for detection of As^{3+} was tested in real samples using a sample of water from the river Drina spiked with As^{3+}. The response of $AgMnO_2$ electrode in the river sample (without any pre-treatment) was well defined with appearance of a clear peak corresponding to As^{3+}oxidation.

In this work, the $AgMnO_2$ electrode showed good activity for the detection of arsenic in acidic media and in the real sample indicating that this electrode can be a potentially good sensor for arsenic detection in aqueous media.

Influence of Metal-Organic Framework on the Multifunctional Catalysis of Gold Nanoparticles

***Vellaichamy Ganesan* and Dharmendra Kumar Yadav**
Department of Chemistry, Institute of Science, Banaras Hindu University, Varanasi-221005, UP, India.
e-mail: velganesh@yahoo.com and velgan@bhu.ac.in

The development of multifunctional catalysts becomes essential to satisfy the needs of the present world in the fields of renewable energy and sensing applications. Accordingly, researchers are very much focused on crystal engineering to develop new materials and reasonably utilize them through electrochemical technology. In this work, gold nanoparticles are wrapped by a zinc-based metal-organic formwork using a simple synthetic route. The crystalline nature of the resulting material, AuNPs-Zn-MOF is verified by powder X-ray diffraction patterns. X-ray photoelectron spectroscopy reveals the presence of Au^0 nanoparticles and their interaction with the zinc-based metal-organic formwork. Further, the AuNPs-Zn-MOF is employed for the electrochemical water splitting, electrocatalytic reduction of oxygen, and electrocatalytic oxidation of tyrosine. The electrocatalytic reduction of oxygen and the reductive water splitting processes are competitive to each other and these reactions were carefully analyzed based on the Tafel slope values. Reduction of oxygen proceeds through a two-electron process to produce hydrogen peroxide as the end product and the reductive water splitting follows the Volmer mechanism. Electrochemical oxidation of tyrosine is also catalyzed by the AuNPs-Zn-MOF. This phenomenon is advantageously used for the construction of an electrochemical sensor for the sensitive determination of tyrosine. The limit of detection and sensitivity of the fabricated sensor are found to be 3.03 µM and 0.12 $\mu A \mu M^{-1} cm^{-2}$, respectively. Thus, the AuNPs-Zn-MOF acts as a multifunctional catalyst that can be exploited further in the electrochemical energy conversion & storage and electrochemical sensing.

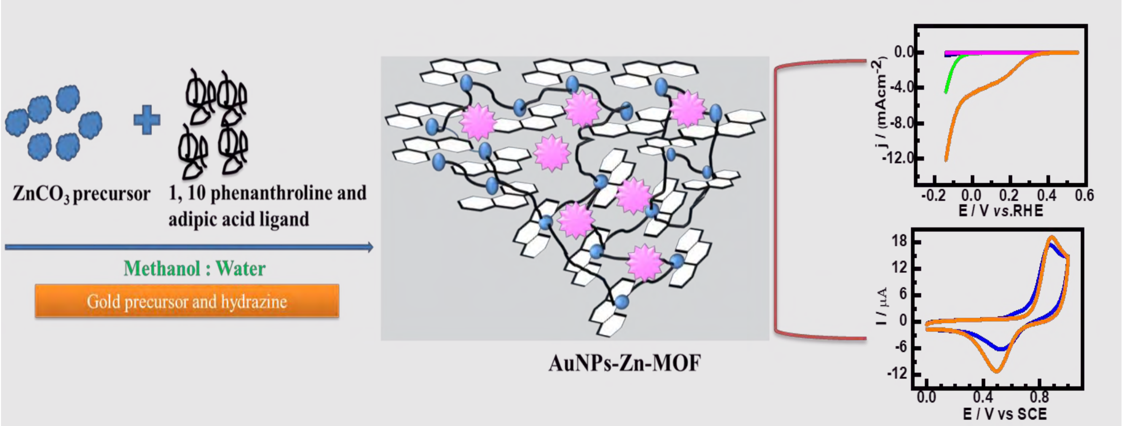

Figure: Schematic synthetic route and multifunctional catalytic activity of AuNPs-Zn-MOF.

S_8 is environmentally friendly, cheap and abundant. Its theoretical specific capacity is as high as 1675mAh g^{-1}, discharge voltage platform is 1.8V relative to Li^+/Li, and theoretical specific energy can be as high as 2600Wh kg^{-1}. S_8 is regarded as one of the ideal choice for the next generation of high energy density battery systems.According to the simulation results, the size of sulfur beam is determined, and the pore structure is reversely designed to inhibit the dissolution of polysulfide ions, and by the form of organic-inorganic compound sulfur, slow down the formation of polysulfide ions, improve the cycling performance of materials.In order to make benzonitriles with different shapes self-assemble according to a certain rule and form regular pore structure, we controlled the kinds and proportion of benzonitriles with different shapes reasonably by adjusting stirring speed, melting temperature and time; By adjusting the proportion of sulfur and benzonitrile, melting temperature and cooling rate, the in-situ SNAr and effective anchoring of sulfur and halogen are realized.

In-situ Probing of the Electrode Roughness Change during Electrodeposition in Ionic Liquids Using Electrochemical Surface Plasmon Resonance

Naoya Nishi, Kenta Ezawa, Tetsuo Sakka
Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering,
Kyoto University, Kyoto 615-8510, Japan
nishi.naoya.7e@kyoto-u.ac.jp

Ionic liquids (ILs) are promising materials for electrodeposition, because of their attractive properties such as wide electrochemical window and wide liquid temperature range. To maximize the performance of ILs for electrodeposition, studies on the interfacial structure during the electrodeposition reactions at the IL interfaces are of crucial importance. In the present study, the electrodeposition reactions at the IL|Au interface have been studied using electrochemical surface plasmon resonance (ESPR).

ESPR has shown that it can be an in-situ probe for the change in the refractive index near the IL|Au interface: both the IL side and the metal side. For the former, ESPR has been used to sensitively probe the electric double layer (EDL) structure [1,2]. ESPR revealed that the EDL structure at the IL|Au interface shows extraordinarily slow relaxation, on the order of minutes, against the potential perturbation [1,2]. This specific slow dynamics is likely to result from ionic multilayers [3-10], a well-ordered structure, spontaneously formed in the EDL of ILs. The diffusion layer of redox species at the IL|Au interface can also be probed using ESPR [11].

As for the electrodeposition, ESPR can sensitively probe the metal side of the IL|Au interface, especially the surface roughness change during the deposition/re-dissolution processes. In the present paper, we will introduce the electrodeposition of Cu and underpotential deposition (UPD) of Li on the IL|Au interface as examples [12]. For both the cases, ESPR can sensitively probe the roughness change during the multi potential cycles within which the deposition/re-dissolution of the metals repeatedly occurs. The ESPR results show the element dependence; the Cu electrodeposition and Li UPD make the Au surface flat and rough, respectively. The latter is likely caused by alloying/de-alloying of Li with Au.

Polar Conformer Formation Determining Ionic Conductivities of Linear Carbonate Electrolytes

Hochun Lee*, Hyejin Lee , Sunwook Hwang

Department of Energy Science and Engineering, DGIST
Daegu 42988, Republic of Korea
dukelee@dgist.ac.kr

The underlying nature of the ion conduction in concentrated battery electrolytes still remains elusive. An archetypal example is a long-standing puzzle why a dimethyl carbonate (DMC) solution exhibit higher ionic conductivity than other linear carbonate (LC) solutions despite the similar physicochemical properties of the LC solvents. To address this, we investigate the correlation between the conformational isomer formation and salt dissociation behavior in 0.1 M–3.0 M $LiPF_6$ DMC, ethyl methyl carbonate, and diethyl carbonate solutions using Raman spectroscopy, dielectric relaxation spectroscopy, and PFG-NMR. Importantly, we corroborate that compared to the other two LCs, DMC more readily dissociates Li-salt into free, conducting ions. The higher salt-dissociation ability of DMC was attributed to the extensive formation of polar cis-trans conformer participating in Li-ion solvation compared to non-polar cis-cis conformer, which is supported by the theoretical calculation. This study unveils the critical role of the solvent isomerism in the ion-solvation chemistry, suggesting an avenue to achieve highly conductive electrolytes for rechargeable batteries.

Active water electrolysis catalysts with Rational design of hydrogen evolution interface

Hydrogen is an ideal energy carrier with an energy density of 140 MJ kg^{-1} and water as its final product, which is considered as an ideal candidate for the replacement of fossil fuels.[1] To date, most H_2 is produced today through nickel-catalyzed conversion of CH_4 to H_2 and CO followed by a water gas shift reaction to yield H_2 and CO_2. However, this approach is based on unsustainable fossil energy and discharges greenhouse gas. Water is an ideal source for H_2 production as it is carbon-free, plentiful and almost costless. Water electrolysis, with only H_2 and O_2 as the final product, is a highly promising route in environmental benign H_2 generation.[1-2] Although the ultimate goal is to couple hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) to an integrated efficient device for whole water electrolysis, one of the most crucial issues that must be solved is the development of highly efficient and durable catalysts for water oxidation and reduction.

Here, we build a hydrogen evolution di-anionic surface on MoS_2 material to control its catalytic activity. Specifically, sulfur anions are electronically activated by heteroatom metal doping (Pd and Ru) to acquire optimized hydrogen adsorption energy. Meanwhile, –OH anions molecularly replace S sites at the interface in a controllable manner can create a reactant benign interface. The merits of the di-anion interface with –OH anion doping are: first, –OH functional groups attracts hydronium ions and water molecules closer to the inner Helmholtz plane (IHP) through hydrogen bonding, thus contributing to a reactant friendly interface; second, –OH sites work in conjunction with adjacent metal sites (M–OH) to split water in alkaline medium, thus enormously boosts the HER catalytic behavior. We show that the HER activity of the final catalyst exhibits highest kinetic performance exceeding the existed MoS_2 based material in both acidic and alkaline environments.

The recognition of the diverse cellular behaviors, such as the different metastatic potentials of the circulating tumor cells, has triggered the need to develop single cell isolation and analysis techniques, so the information for each single cell, rather than the whole population was obtained, which could help to better understand some biological behaviors. While microelectrode array and scanning electrochemical microscopy were the common approaches to electrochemically sense a single cell of interest in a cell population, 'light activated electrochemistry', a concept developed by Gooding group, offered another potential option. Light activated electrochemistry means on an unstructured semiconducting surface, a light defined where the electroactive area is. Based on this concept, a platform has been built on crystalline silicon for single cell electrochemical sensing and even single cell isolation, by simply using a laser pointer to shine to where the target cell located. Another advantage of this platform was it was compatible to work with other rare cells enrichment techniques, so it can be applied to sense and isolate rare single cells. While it is a highly interrogated system, there are opportunities to make it more accessible for the biologist for routine applications. Inspired by the previous work, here is presented a new single cell sensing and isolation platform which builds on a transparent glass slide. It shares the same advantages as the old system but it is much more robust, simpler to fabricate and more user friendly. The first step to build this improved platform was to develop a transparent semiconducting electrode that became conducting upon exposure to visible light and were compatible with high resolution fluorescence microscopy. Subsequently, surface modification of this electrode to anchor the target cells such that they could be electrochemically sensed or release individually, has been developed. The fabrication and performance of this new single cell study platform will be illustrated in the presentation.

Metallic nanofoams are recently presenting an interest in electrocatalysis and electrochemical sensing. Application to carbon dioxide reduction [1] and glucose detection [2] have been described for silver, copper, gold and platinum foams. These materials are obtained using the dynamic hydrogen template electrodeposition. Their enhanced electrocatalytic activity is explained by the large surface, the porosity at different length scales and the existence of nanometric features such as dendrites and needles.

In this presentation, we described the use of silver foams for nitrite reduction. Although nitrite is used as food preservative, its presence in high concentrations both in human body and in the environment is dangerous. Therefore, the detection and eventually the conversion of nitrite into harmless compounds is desired. Amongst other metals, polycrystalline silver has been well characterized as catalyst for nitrite conversion [3]. It has been shown that, on the silver surface, nitrous acid (HNO_2) is converted to nitric oxide (NO) which is subsequently converted to nitrous oxide (N_2O). For the first time, silver foam is used here as electrode material for catalyzing this reaction. We have employed differential electrochemical mass spectrometry as analytical technique for the on-line detection of reaction products (Figure 1). Our main finding is that the silver foam favors the reduction of solution-phase NO (issued from the decomposition of HNO_2 at acidic pH). In the low potential range (between 0.2 to -0.1 V vs RHE) the product is N_2O. As the potential is decreasing below -0.1 V vs RHE, a change in the reaction mechanism is observed. The concentration of the solution phase NO is stable while the one of N_2O is decreasing. This is interpreted as the apparition of the reduction of HNO_2 to NO that is now subsequently converted to hydrogenated species such as NH_4^+ or NH_3OH^+ that are not detectable by DEMS.

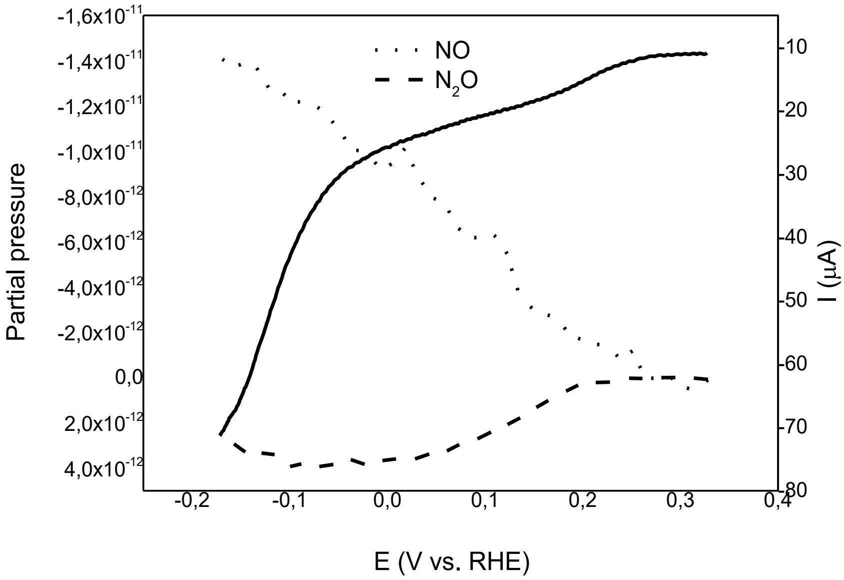

Figure 1. DEMS analysis of nitrite reduction catalyzed by **silver foam**. Black curve is the forward scan of cyclic voltammetry, dot line is the signal of m/z = 16, dash line is the signal of m/z = 46 (10 mM $NaNO_2$ containing isotope ^{15}N was used).

With our increasing demand for carbon free renewable energy, the development of high energy density and safe batteries is key. Lithium (Li) metal has been identified as the ultimate negative electrode due to its particularly high gravimetric capacity (3.86 A.h.g^{-1})(*1*) and very low potential (-3.04 V *vs.* SHE, Standard Hydrogen Electrode) which are the two levers to increase the energy density in a battery. However, Li is known to form dendrites during cycling which eventually short-circuit the device and lead to a hazard issue (fire, explosion). One strategy aims then at developing all-solid-state Li batteries, which would prevent dendrite formation using solid electrolyte and increase both battery safety and cycle life.

Solid-state electrolytes fall into two major classes; polymers and inorganic ceramics. Solid polymer electrolytes (SPEs) have advantages in terms of their mechanical properties, however poor ionic conductivity (typically 10^{-5} S.cm^{-1} at room temperature, RT) hinders their application.(*2*) Conversely, ceramic electrolytes (CE) have greater thermo-stability and ionic conductivity (around 10^{-4} to 10^{-3} S.cm^{-1} at RT for NaSICON/garnet structures),(*3*) but suffer from mechanical issues (brittleness).

Composite electrolytes have therefore come to light as a possible solution comprising the mechanical properties of SPEs and the high ionic conductivity of ceramics. The addition of highly Li$^+$ conducting CE (*e.g.* NASICON, garnet…) to a polymer should reach conductivities higher than the neat polymer electrolyte. However, results are varied, including some groups that observe a decrease in the overall conductivity upon dispersion of a CE in a SPE matrix.(*4*) Investigation are thus needed to understand the reason hindering the development of composite electrolyte. A possibility for the decrease in conductivity of the composite electrolyte could be due to the high Li$^+$ charge-transfer resistance at the SPE/CE interface.(*5*)

We propose a deep characterization of the interfacial SPE/CE processes by electrochemical impedance spectroscopy. Different model layered systems based on symmetrical cells made using reversible Li (Li/SPE/Li or Li/SPE/CE/SPE/Li) or blocking stainless steel (SS) (SS/SPE/SS, SS/ SPE/CE/SPE /SS, see Figure 1) electrodes are reported to probe specifically the ionic charge transfer resistance, R_{ict}, and capacitance at the CE/SPE interface, C_i, and its impact on the effective transport properties.

Abstract

Oxygen reduction reaction (ORR) is an important reaction in proton exchange membrane fuel cell technology (PEMFC). Because of its excellent ORR performance, platinum is widely used in fuel cell oxygen reduction catalysis. However, platinum's high cost and insufficient resources limit its application in fuel cells. It is important to design a low-cost, high-efficiency catalyst to replace platinum. Using the cyano-modified mesoporous silica hard template (CN-SBA-15), through the anchoring of the cyano-group, a highly active, active site dispersed Fe-N/C ORR catalyst was prepared. Experimental results show that the use of cyano-functionalized templates with different loadings can improve the performance of the catalyst, which is mainly due to the high dispersion of the active sites of the prepared catalyst. Under acidic conditions, the onset potential of the catalyst with the best performance was 0.88 V vs. RHE, and the half-wave potential ($E_{1/2}$) was 0.70 V vs. RHE. At the same time, after 10,000 stability tests, only a half-wave potential attenuation of 20mV was observed, which indicates that it has excellent stability.

Lithium-rich layered oxides are promising cathode candidates to build 500 Wh kg^{-1} Li-ion batteries (LIBs) yet suffer from low initial Coulombic efficiency, rapid capacity fade, and poor rate capability. To address these obstacles, heterostructured spinel/ layered oxide ($Li_{1.15}Ni_{0.20}Mn_{0.87}O_2$) nanofibers were synthesized. The synergistic effect of nanofiber morphology and spinel/layer heterostructure enhances structure/surface stability as well as lithium diffusivity coefficient, leading to improved initial Coulombic efficiency (≈100%), cyclability (258 mAh g^{-1} after 70 cycles), and rate performance (150 mAh g^{-1} at 5C). In-situ techniques combined with first-principle calculations reveal that the spinel can stabilize the layered structure via suppressing layered structural variation as well as oxygen overoxidation and maintaining oxygen vacancy. The results would pave ways for the design of 1D heterostructure composite cathodes to develop high energy/power density LIBs.

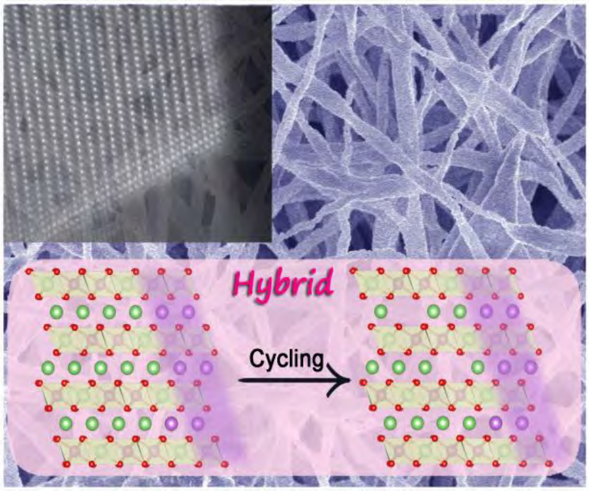

Fig.1 SEM and HAADF images of 1D spinel/layered heterostructured LLRO and illustration of stability during cycling.

Electrochemical and DFT Study of Carbon- and Heteroatom-bridged Diarylnitroxides: a Possibility to Tune Redox-properties

Dmitry Dulov, Oleg Levitskiy, Tatiana Magdesieva
Lomonosov Moscow State University, Chemistry Dept.,
Leninskie Gory 1/3, Moscow 119991, Russia
dulov.dmitry@gmail.com

Poor ecologic situation and restricted mineral resources dictate a necessity for gradual replacement of inorganic metal-containing materials for biodegradable and recyclable organic compounds. Stable organic radicals are perspective systems to investigate since they can form several redox-states and exhibit fast electrode kinetics. Importantly, organic molecules provide wide possibilities for targeted structural modification, to obtain the properties required. In this context, diarylnitroxides seem perspective candidates. Recently we demonstrated that “twisted” donor-acceptor diarylnitroxides are smart tunable molecules capable to stabilize three redox states.[1] Herein, the opposite structural “instrument” of the molecular design is applied, i.e., partial planarization of the nitroxide molecule via insertion of carbon or heteroatomic linker connecting two phenyl rings. Prior to synthesis, the influence of such structural modification on the redox potential values was estimated, to choose the most promising structures and save material and time resources.

Quantum-chemical estimation of the oxidation potential values of novel nitroxides was performed using a combination of the “Priroda” program package at the PBE/L2 level of theory with continuum solvation model (in the form of the two-step procedure) which provides a low-cost and reliable methodology for calculation of the standard redox potentials for nitroxides in acetonitrile solution.[2] It was shown, that the introduction of a carbon-bridge (containing 1-3 methylene units between various positions of the rings) has only minor influence on the oxidation potential values (E^{Ox} are varied in the range of 0.6 – 0.75 V vs Ag/AgCl/KCl) whereas the synthetic procedure becomes more time-consuming. In contrast, insertion of the SO_2-linker between the rings gives the promising structure with the DFT-estimated oxidation potential value much more anodic than that previously measured for other nitroxides, both of aryl and alkyl type (E^{Ox} = 1.24 V vs. Ag/AgCl/KCl).

The SO_2-bridged nitroxide was synthesized and investigated using cyclic voltammetry. It was shown, that the radical is stable in solution and exhibits completely reversible oxidation at 1.33 V (vs. Ag/AgCl/KCl). This is the maximal anodic potential value achieved for reversibly oxidized nitroxides to date. One can expect that new compound might be of interest as cathodic redox material providing much higher potential gap as compared to the previously reported compounds.

e-mail address: reza.khakpour73@gmail.com

The average temperature of the earth is being rapidly increased which can endanger human survival. It is occurred due to the high demand for fossil fuels to supply energy for citizens. One of the suggested methods to efficiently convert fuels into energy is fuel cells. The low performance and durability of available electrocatalysts toward direct ethanol fuel cell (DEFC) provide a challenging research area to either modify previous catalysts or discover new catalysts. Our recent Excremental evidence indicated that Ag-Ni porous coordination polymer (ANP) has a high-level capability to support platinum nanoparticles [1]. In the present research, the ANP was synthesized by the hydrothermal method, afterward, the palladium nanoparticles were deposited on the surface of the ANP (Pd-ANP). As a characterization test, field emission scanning electron microscopy (FE-SEM) has been taken to evaluate the morphology of the structure. To discover the performance and durability of synthesized electrocatalyst for the oxidation of ethanol, the cyclic voltammetry (CV) technique was exerted. Moreover, the Pd-ANP electrode was compared with the electrode contain palladium nanoparticles supported by carbon past electrode (Pd electrode). Additionally, a CV test was performed on the Pd-ANP electrode along 50 cycles to investigate the stability of the electrocatalyst. Electrochemical cyclic voltammetry demonstrated that forward peaks current density of Pd-ANP electrode and Pd electrode (without ANP supporter) are 5.178 $mAcm^{-2}$ (-0.246 E / V vs Ag/AgCl) and 1.782 $mAcm^{-2}$ (0.0836 E / V vs Ag/AgCl) respectively. It resulted that ANP supporter bolstered the activity of palladium nanoparticles toward electrooxidation of ethanol by almost 290%. Besides, the onset potential was decreased from the Pd electrode (-0.225 V V vs Ag/AgCl) in comparison with the Pd-ANP electrode (-0.594 V vs Ag/AgCl). The result indicates that ANP promisingly affects the kinetics of ethanol electrooxidation reactions.

Influence of the carbon support in the electrochemical reduction of carbon dioxide using copper-based catalysts

Fabiola Martínez, Carlos Jiménez, María Isabel Cerrillo, Rafael Camarillo, Isaac Asencio and Jesusa Rincón
Universidad de Castilla-La Mancha, Faculty of Environmental Sciences and Biochemistry, Department of Chemical Engineering
Avenida Carlos III, s/n, 45071 Toledo, SPAIN
fabiola.martinez@uclm.es

Carbon dioxide anthropogenic emissions are nowadays one of the most important concerns of our society to try to mitigate the Climate Change. Electrochemical catalytic reduction appears as a promising technology for recycling CO_2 to fuels or other valuable products. One of the most important challenges of this technology is the development of catalysts that can obtain high efficiencies in the reduction of carbon dioxide. In this sense, copper nanoparticles deposited on some type of carbon support are frequently used as electrocatalysts as they have demonstrated high reduction efficiencies. In this work, copper nanoparticles have been deposited using supercritical fluid deposition (SFD) technique (Figure 1) on three different carbon supports: carbon black (CB), carbon nanotubes (CNT) and reduced graphene oxide (rGO). SFD is an environmentally friendly technology that has demonstrated good results in the synthesis of nanomaterials [1,2].

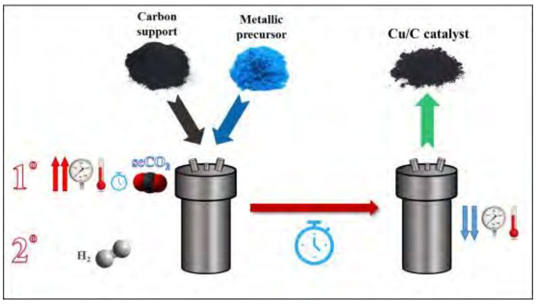

Figure 1. Scheme of the SFD technique for the deposition of copper nanoparticles

Different techniques have been analyzed to characterize the catalysts synthesized to try to understand the influence of the carbon support in the results obtained: TEM, DRX, XPS, ICP, FTIR and BET. Results show that SFD technique allows obtaining catalysts with a homogeneous copper nanoparticles distribution in the different carbon supports with deposition yields close to 90% in every case. Furthermore, most of the copper nanoparticles crystallite size is between 10 and 20 nm.

Finally, the activity of these catalysts (Cu/CB, Cu/CNT and Cu/rGO) has been determined for the electrochemical reduction of carbon dioxide in gas phase in a PEM type electrochemical cell (25 cm^2 geometric area). Every assay has been carried out in continuous mode at 0.05 SL CO_2/min of carbon dioxide circulating through the cathodic compartment of the cell. The anolyte used was a $KHCO_3$ 0.1 M aqueous solution. Temperature was fixed at 60 ºC and current density applied was 16 mA/cm^2 with four replicates for each catalyst studied.

The highest CO_2 conversion rate was obtained for the Cu/CNT catalyst. Nevertheless, products distribution was very similar in every case with CO, formic acid and methane as the main products obtained. Nevertheless, Cu/CNT and Cu/CB catalysts promote the formation of CO, whereas formic acid is the main reaction product with Cu/rGO. These results point out that the interaction between the copper nanoparticles and the carbon support plays an important role in the CO_2 electrocatalytic reduction process.

Influence of Carbon Felt Surface Oxidation on Vanadium Redox Flow Battery Behavior

Justyna Piwek, Elzbieta Frackowiak
Poznan University of Technology
Pl. M. Sklodowskiej-Curie 5, 60-965, Poznan, Poland
justyna.piwek@put.poznan.pl

Carbon fibers are commonly used as materials for the flow-through electrode coupled with vanadium redox pairs because of their relatively low cost, broad potential window, porosity and resistance in supporting electrolyte, i.e., acidic solution [1]. Their role is very important especially when vanadium redox flow batteries (VRFB) are considered. The key recognition of VRFB systems is the possibility to separate the energy and power values and to tailor VRFB for specific application. The energy is dependent on the size of the electrolyte storage tanks, while the power capability is determined by the size of electrochemical cells stack. This feature gives VRFB a brilliant future in energy storage systems for grid application [2].

Beside many advantages of RFB system, some side reactions (carbon corrosion and oxygen evolution on the positive side and hydrogen evolution on the negative) still lead to the significant RFB performance losses over time. Therefore, there is still a particular need to develop a material with good electrical conductivity and proper activity to improve overall RFB properties [3].

The research objective relates to broadly-defined comparison of the cost-effective carbon material treatments coupled with insightful *post-mortem* and *in-situ* physico-chemical analysis. For these studies, Rayon based graphitized carbon Sigracell® GFD 4.6 EA from SGL Carbon (Germany) was used.
In order to address the growing need of environmental friendliness using mild approaches, a new oxidation method will be adapted using neutral alkali salts such as potassium nitrate (KNO_3). Herein, a simple molten salt method is studied to prepare carbon felt electrode with novel properties. Various reaction conditions have been investigated and correlation of the activation time and temperature on VRFB behaviour will be presented.

All the electrodes were tested in three electrode cells and redox flow battery system. Moreover, physico-chemical properties such as: surface functionality, wettability and surface texture/structure have been monitored using X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, elemental analysis and contact angle measurements.

It seems that application of molten salts as an activation agent can be the new route for carbon felt treatment necessary for efficient vanadium redox reactions.

The production of solar fuels with devices based on metal-semiconductor junctions is a promising future technology of the renewable energy economy. The semiconductor part of these hybrid devices can provide an efficient absorption of solar light while the metal facilitates fast reaction kinetics. However, to fulfill these two functionalities the device requires a laterally patterned surface.

We show that lateral structuring of silicon-based electrodes with well-defined gold arrays in addition exhibits cooperative effects, i.e. strongly altered catalytic activities compared to bare gold surfaces [1]. We demonstrate this with the hydrogen evolution reaction (HER). In particular, we show that the alkaline HER rate scales with the interfacial area between the gold catalyst and the silicon oxide support [2]. A rate enhancement of an order of magnitude for the largest interfacial area is observed. We present evidence that the lateral structuring changes locally the electric field, thus giving rise to a bifunctional mechanism. The local field enhancement increases the reaction rate of alkaline HER at the interface compared to the rate at the metal bulk. The enhancement is not restricted to gold/silicon oxide boundaries. Rather, structured electrodes based on platinum catalysts exhibit also higher reaction rates than bulk Pt films. Such laterally structured silicon photoelectrodes can exhibit reaction rates for alkaline HER that are similar to the HER activity in acidic media [2].

Supercapacitors are primarily employed as energy sources for hybrid electric vehicles, back up systems, etc. owing to their high power density and life span[1]. However, meeting the energy demands require high energy densities, which can be achieved by improving the specific capacitance or widening the potential window. Besides, the quest for new anode and cathode materials have always been quintessential to improve the supercapacitor properties. In comparison to most commonly employed carbonaceous materials, metal oxides/sulfides are superior in their electrochemical performance due to the additional faradaic reactions. In this regard, the present work aims at the synthesis of $NiCo_2S_4$ as positive and iron oxide as negative electrode with nanoflower-like morphology by facile, scalable and highly economical electrodeposition route. Both the electrodes have been studied for their morphological (Fig. 1a and b), electrochemical (Fig. 1c) and structural properties. The appropriateness of $NiCo_2S_4$ [2] and iron oxide[3] as electrode materials is realized by their corresponding cyclic voltammetry (CV) and charge-discharge analyses, also exhibiting excellent cyclic stability. Thereafter, an all-electrodeposited $NiCo_2S_4$//Iron oxide asymmetric supercapacitor is fabricated with 3M KOH as the electrolyte (Fig. 1d). Thus fabricated device exhibited good energy and power density values while yielding excellent stability performance (to be discussed later). The present study shows that the electrodes synthesized by the economic electrodeposition method are highly efficient and are suitable for next-generation supercapacitor devices.

anetta.g.platek@doctorate.put.poznan.pl

Lithium sulfate aqueous solution finds its application as electrolyte in electrochemical capacitors (ECs) mostly by its versatile advantages [1-2], such as:

- neutral pH,
- good electrical conductivity (for 1 mol L^{-1} Li_2SO_4 - 72 mS cm^{-1}),
- suitable ion size matching to carbon porous structure,
- reversible and satisfactory capacitive performance (95% of coulombic efficiency and 65% of energetic one when charged/discharged within the voltage range of 0-1.6 V at 0.1 A g^{-1}),
- ability to operate at high voltage (up to 1.6 V) and good long-term stability (120,000 cycles recorded during 250 days of constant operation to obtain 20% capacitance fade).

We do believe that besides many advantages, sulfate-based ECs might be further improved. Our research is focused on expanding sulfate-based ECs properties, by studying the influence of various cations (Li^+, Na^+, K^+, Rb^+ and Cs^+) on the overall electrochemical performance and ageing phenomena.

After applying constant voltage hold (*floating*) test on EC with 1 mol L^{-1} sulfate-based electrolyte, deterioration of both electrodes (namely specific surface area (SSA)) has been observed contrary to nitrate-based ECs [3]. Thus, it suggests that both electrodes participate in the ageing process. Moreover, pH tends to be a crucial factor for a long-term stability of the device. In addition, considering binding energy of cations to aromatic ring, the higher binding energy ($Li^+ >> Cs^+$), the lower SSA change. Apparently, the ion size itself does not affect textural changes of electrode after ageing test remarkably. When ions penetrate the electrode porosity, local dehydration process might occur; however, it cannot be discussed based on a full device studies and *post mortem* analysis of electrode texture, as each cation is characterized by different hydration enthalpy. Hence, three-electrode investigations are required. Large cations (Rb^+ and Cs^+) favorably lose their solvation shell, as it might be done with a low energetic cost. Small cations (Li^+ and Na^+) exhibit strong interaction with surrounding water molecules. Counter electrodes SSA fade trend resembles the following order of cations in the electrolytic solution $Li^+ < Na^+ < Rb^+ = Cs^+$. It suggests that ECs based on 1 mol L^{-1} Rb_2SO_4 and Cs_2SO_4 get aged similarly. Thus, binding energy does not play such an important role considering change of SSA of electrodes, contrary to the ions' size. It is assumed that Rb^+ and Cs^+ are too big to penetrate porosity reversibly and pore clogging effect might occur, while these cations are trapped inside micropore structure. In order to enhance system with rubidium or caesium sulfate, one need to use carbon with wider micropores (1-2 nm range) or even more developed mesoporosity. Additionally, ECs lifetime has been compared (up to C/C_0=80%) among all studied electrolytes. These results indicate that proposing a novel sulfate-based electrolyte composition, extension of operational time can be achieved (up to 650h of *floating* test).

We do correlate these findings with pH influence on SO_4^{2-} anion stability. Furthermore, time of operation of ECs with Me_2SO_4 electrolyte (where Me=Na^+, K^+, Rb^+, Cs^+) seems to be in a linear trend with cation properties, e.g., binding energy, cation diameter, hydration enthalpy. Interestingly, Li_2SO_4 does not follow this tendency at all.

Insights into sulfate-based ECs have been, herein, presented. Cation influence on the overall electrolyte performance has been described and advancement of the system has been proposed.

Novel Approach for Lifespan Extension of Electrochemical Capacitors

Justyna Piwek, Anetta Platek-Mielczarek, Elzbieta Frackowiak, Krzysztof Fic
Poznan University of Technology
Pl. M. Sklodowskiej-Curie 5, 60-965, Poznan, Poland
justyna.piwek@put.poznan.pl

Water-based electrochemical capacitors (ECs) are nowadays intensively studied mainly due to their environmental benign and cost-effective technology. Nevertheless, their cycle-life at the higher voltages is limited because of thermodynamic water decomposition at U>1.23. Therefore, there is a particular necessity to develop long-lasting ECs operating in aqueous medium at high voltages [1].

Our previous studies allowed the capacitors failure reasons to be fully recognized in capacitive ($LiNO_3$-based) and redox (KI-based) systems. It has been proven that the oxidation of the positive electrode is one of the main problems which causes capacitance fade of aqueous medium carbon/carbon ECs. Moreover, solid-state deposit (namely Li_2CO_3) has been found for both electrodes after the ageing test [2].

Currently, our scientific scope concerns the study of capacitors with nitrate-based electrolytes operating with activated carbon electrodes. This research reports on the successful attempts of symmetric aqueous electrochemical capacitor life-span extension.

Various electrolyte concentrations were selected in order to observe its influence on capacitor operation. Long-term performance has been simulated using a constant voltage-holding test. The carbon-based electrodes after the ageing tests have been analysed and compared with pristine materials using various physicochemical techniques, such as: N_2 adsorption/desorption at 77K, XPS and elemental analysis. A modified electrochemical protocol was adapted in order to extend capacitor life-time operation. This approach allowed the properties of the negative electrode to be used. It has been proven that ECs cycle life strongly depends on the electrolyte concentration. All the systems were aged to the same relative capacitance level, i.e., C/C_0=80 %. On this basis, it has been estimated that maximally +83% of capacitor operation time extension is achieved for 0.2 mol·L^{-1} $LiNO_3$.

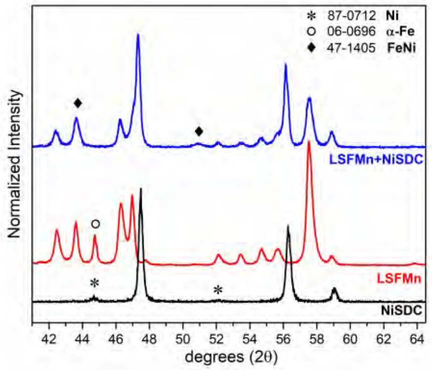
Anode deactivation over prolonged SOFC operation represents a major issue towards stable and reliable energy production from hydrocarbon-containing fuels[1][2]. In this respect, Ni-YSZ replacement with oxide-based anodes, less prone to coking, is commonly regarded as a viable solution[3]. Nevertheless, most studied oxides cannot compete with Ni-based state-of-the-art anodes in terms of conductivity and catalytic activity. A novel MIEC anodic composite based on $La_{0.6}Sr_{0.4}Fe_{0.8}Mn_{0.2}O_{3-\delta}$ (LSFMn) perovskite and $Ce_{0.85}Sm_{0.15}O_{2-\delta}$ containing 5 wt.% of Ni (NiSDC) was tested in methane fuel. In reducing conditions, LSFMn undergoes phase transformation to Ruddlesden-Popper structure, exsolving Fe^0 nanoparticles and retaining proper conductivity[4]. The small amount of Ni, well-dispersed on the SDC matrix, forms a Fe-Ni alloy with the exsolved iron from the perovskite Fig.(1). While Fe-Ni alloy activates CH_4, SDC provides enough O^{2-} ions to electrochemically oxidize any cracking products. LSGM-based electrolyte supported cells were tested in wet, dry methane and methane-based gas mixtures. Endurance cell tests at 850 °C in dry CH_4 were performed. A remarkable cell stability for over 40h was registered both in open circuit voltage and *in operando* Fig.(2). SEM and Raman Spectroscopy analyses carried out after endurance tests do not reveal any anode fouling.



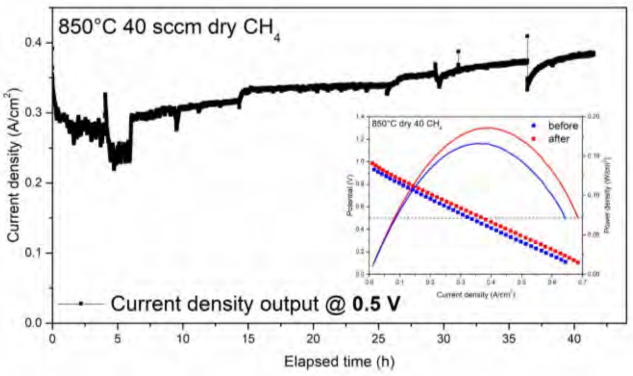


Fig. 1 – XRD patterns of reduced anodic components. From LSFMn and NiSDC co-reduction FeNi alloy formation is visible.

Fig. 2 – Endurance test in dry methane at 850 °C, current density versus time at 0.5 V. IN the inset I-V curve and power densities before and after the test are reported.

Bio-inspired Supercapacitor an ecofriendly device for green supercapacitor

Pietro Forcellese, Federico Poli, Mohammad Said El Halimi, Francesca Soavi
Alma Mater Studiorum University of Bologna, 40132 Bologna, Italy
francesca.soavi@unibo.it

The huge and continuously growing demand for electrochemical energy storage systems is forcing the scientific community to think about their impact on the environment. Technologies that should enable a transition to a sustainable society feature pollutants components and require a tremendous amount of energy for their production process. Supercapacitors represent a niche of the total energy storage market but are not exempt from this criticism [1,2]. Indeed, the main components of modern carbon-based Electrical Double Layer Capacitor (EDLC), such as the electrolyte solvent Acetonitrile, are known to be flammable, toxic to human health and dangerous to the environment. The binder is not immune from this kind of judgment, indeed, Polyvinylidene difluoride (PVDF) belongs to the larger family of the Per- and polyfluoroalkyl substances, also known as PFAS. It is arising the concern about their impact on the health and their capability to bio-accumulate [3,4]. The solvent needed for the processing of the electrodes, N-Methyl-2-Pyrrolidone (NMP) is also known to be toxic and irritant. The usage of this solvent represents a further drawback in terms of the device cost. Moreover, its processing requires a tremendous amount of energy for being dried [5-8]. Water processable binder and non-toxic electrolyte represent a solution to the majority of these problems [9-12]. A further step through green and sustainable supercapacitors is the exploitation of a living system to enhance the performance of EDLC devices.

Here we report the systematic study of an EDLC based on anthracite that exploits the activity of a biofilm to enhance its performance. A water processable Alginate based binder has been used and cation exchange (Sodium with Calcium) has been performed to enable its use in aqueous electrolytes [13]. Waste water was used as electrolyte. Different combinations of active carbon, binder, and electrolyte have been tested. The most performing one has been selected to build an EDLC. The growth of the biofilm has been monitored and the effect of its presence on the performance of the EDLC measured. This work highlights that sustainable and green devices have performance comparable with classical fluorinated polymer and organic electrolyte based EDLC. Furthermore. Our findings aim at paving the way towards a novel concept of “Bio-Supercapacitor” that exploits bacteria as active components for energy storage.

Novel water processable binder for high potential Li-ion battery cathodes

Alessandro Brilloni, Federico Poli, Giovanni Emanuele Spina, Francesca Soavi

Department of Chemistry "Giacomo Ciamician", Alma Mater Studiorum Universita' di Bologna,
Via Selmi 2 -40126 Bologna, Italy
alessandro.brilloni2@unibo.it

The growing energy demand in all the world is requiring for more sustainable energy production methods while the environmental and economic sustainability of these methods are of tremendous importance. Electrochemical energy storage systems are a key element for the implementation of sustainable energy systems and the transition from an economy based on fossil fuels to a low environmental impact society.
Lithium-ion batteries (LIBs) are the most well established battery technology with an exponentially growing market. However, LIBs require further improvement. In order to achieve higher energy density, the most effective strategy is to use high potential cathodes like $Li_xNi_{0.76}Mn_{0.14}Co_{0.10}O_2$ (NMC).
Nonetheless, the environmental impact of battery production methods is of extreme importance. Today LIBs are fabricated with F-based polymers as binders, such as poly(vinylidene difluoride) (PVdF) which need N-methyl-2-pyrrolidone (NMP) as solvent/dispersant, both very toxic for humans and environment. This process also requires expensive atmosphere-controlled environment.
Here we present a novel water processable binder based on the biodegradable biopolymer Pullulan (Pu). Pu is used to process high potential NMC cathodes in ambient atmosphere. The electrochemical results of Pu/NMC cathodes are here reported and discussed and compared with those achieved with PVdF/NMC electrodes.

Organic/inorganic hybrid electrode materials for lithium batteries

Yong Lu, Licheng Miao, Jun Chen*
Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University, Tianjin 300071, China
** Corresponding author: chenabc@nankai.edu.cn*

Organic carbonyl compounds have attracted much attention in recent years because of their low cost, high abundance, flexible structural designability and environmental friendliness. However, pure small organic carbonyl materials are easily dissolved in aprotic electrolyte, leading to inferior cycling stability, low Coulombic efficiency and undesired shutting problems. We here report a dissolution-recrystallization method to prepare flexible, binder-free and free-standing hybrid film of sodium 1,4-dioxonaphthalene-2-sulfonate and multiwalled carbon nanotubes (NQS/MWNTs) as high-performance cathode for lithium batteries. The hybrid films exhibit a high initial reduction potential at 2.97 V, a high material utilization of 75%, a high capacity retention of 96% after 50 cycles at 0.2 C and good rate performance (capacity retention of 64% at 2.0 C compared with that at 0.2 C), which result from the high polarity and small size of NQS, electron withdrawing property of $-SO_3Na$ group, and three-dimensional intertwined conductive network formed by MWNTs. Moreover, the reversible redox mechanism of NQS/MWNTs during discharge/charge processes was revealed by in situ infrared spectroscopy, which indicates that the C=O groups are active sites. This study paves the way to develop well-designed organic/inorganic hybrid materials with high electrochemical performance for practical lithium battery applications in the future.

Toward First-Principles Modelling of Charged Oxide-Electrolyte Interfaces

Chao Zhang
Department of Chemistry – Ångström Laboratory, Uppsala University
Lägerhyddsvägen 1, 75121 Uppsala, Sweden
e-mail address: chao.zhang@kemi.uu.se

Oxide-electrolyte interfaces are universally present in energy storage device, nanofluidic chemical processor, drug delivery nanoparticles and containments treatment in ground water. The surface charge of all these interfaces is controlled by the pH of the electrolyte solution and this leads to the formation of the electric double layer (EDL) by deprotonation of adsorbed water molecules or protonation of the oxide surfaces. Despite of the rapid development of experimental techniques, the missing of microscopic understanding imposes a knowledge gap. In this regard, modelling and simulation of EDL can provide complementary information of the structure, dynamics and energetics of charged interfaces. Here, I will report our recent methodological progress on the atomistic modelling of dielectric properties of charged oxide-electrolyte interfaces.

Reduction of faradaic contributions in carbon/carbon cells using a “water-in-salt” electrolyte

Emmanuel Pameté Yambou* and François Béguin
Institute of Chemistry and Technical Electrochemistry, Poznan University of Technology,
Berdychowo4, 60-965 Poznan, Poland
**emmanuel.yambou@doctorate.put.poznan.pl*

Environmentally friendly aqueous alkali sulfate electrolytes with pH close to neutrality have been recently proposed for carbon/carbon supercapacitors (SCs) demonstrating enhanced voltages up to U = 1.6 V [1]. The enhanced voltages in SCs using neutral aqueous electrolytes exceeding the electrochemical stability window of water (1.23 V) is due to the increased local pH inside the porosity of negative carbon electrode due to the electrochemical reduction water producing OH^- anions and causing important di-hydrogen evolution over-potential [2]. However, it has now been established that carbon/carbon cell in 1 mol L^{-1} Li_2SO_4 keeps good state-of-health under potentiostatic floating only up to 1.5 V, beyond this voltage oxidation of positive carbon electrode occurs owing to the generation of oxygenated functionalities demonstrated by the CO and CO_2 evolution as side products [3]. Besides, reduction of water at the negative electrode generating hydrogen gas presents another challenge at high voltages contributing to pressure increase inside the cell and consequently resulting deterioration of SC performance during long-term aging/cycling [4].

In this work, we implement LiTFSI in water at two different concentrations (1 mol kg^{-1} and 21 mol kg^{-1}, pH = 6.1) in carbon/carbon supercapacitors to demonstrate the influence of electrolyte concentration on the electrochemical performance of the cell. Three-electrode cell investigations show that the hydrogen adsorption under negative polarization of carbon electrode in 21 mol kg^{-1} aqueous LiTFSI is dramatically reduced in comparison to 1 mol kg^{-1} LiTFSI. Two electrode cell data demonstrates nearly rectangular CV characteristics similar to an electrical double-layer capacitor for carbon/carbon cell in 21 mol kg^{-1} LiTFSI. Thanks to the reduced faradaic contribution at the concentration of 21 mol kg^{-1} LiTFSI owing to the negligible hydrogen adsorption and desorption at the negative carbon electrode, the cell demonstrates low self-discharge of $\Delta U = 0.178$ V. Further analyses of self-discharge data suggest the shift of activation controlled mechanisms to diffusion controlled mechanisms with the increase of concentration from 1 mol kg^{-1} LiTFSI to 21 mol kg^{-1} LiTFSI. Thermo-programmed desorption performed on the carbon electrodes in 21 mol kg^{-1} LiTFSI suggest a sudden mass loss at around 450 °C owing to the decomposition of LiTFSI trapped inside the electrode porosity.

The electrochemical carbon dioxide reduction reaction (CRR) in aqueous media is a promising approach to closing the carbon cycle. After Hori *et al.* reported that Cu metal electrodes selectively reduced CO_2 to various organics [CO, CH_4, C_2H_4, EtOH, Pr^nOH][1], numerous studies have described Cu-based electrocatalysts for CRR. The electrocatalytic activity of Cu-based catalysts has been generally evaluated using synthetic pure CO_2 gas (> 99.99%). However, low-purity CO_2 emitted from factories will become the substrate in the real application of CRR, and thus, a certain amount of impurities are inevitably contaminated. Among various contaminations, oxygen contamination in CO_2 gas would become a significant problem because oxygen is more easily reduced than CO_2. However, there is no systematic study on the effect of contaminant oxygen on the CRR catalyzed by Cu-based catalysts.

Herein, we investigated the effect of oxygen contamination on CRR on a gas diffusion electrode carrying copper nanoparticles (Fig.1). The CO_2 gases containing oxygen (0%, 1%, 2%, 3%, 4% and 5 %) were used as the model substrate. CRR activity was evaluated under a potentiostatic condition (-3.0 V vs. Ag/AgCl without IR collection). In the absence of oxygen (i.e., pure CO_2 gas), the total faradaic efficiencies(FEs) of hydrocarbons (methane and ethylene) reached up to 24 %. Then, the total FE of hydrocarbons decreased to 3.6 % by the addition of 1 vol% oxygen in pure CO_2 gas. Interestingly, the production of hydrocarbons was more largely suppressed than CO or HCOOH production in the presence of oxygen contamination. In the poster presentation, we will discuss the detailed mechanism for the suppression of the evolution of hydrocarbons in the presence of oxygen.

Pullulan as green components for supercapacitors

Giovanni Emanuele Spina, Federico Poli, Alessandro Brilloni, Daniele Marchese, Francesca Soavi.
Alma Mater Studiorum University of Bologna, 40132 Bologna, Italy
francesca.soavi@unibo.it

The increasing market of storage systems such as supercapacitors and batteries is leading the research towards new sustainable materials, to reduce their environmental and economic impact [1]. The utilization of water-processable, biodegradable electrodes and separators is a viable approach to develop green and easy-to-dispose devices. Natural polymers processed by aqueous solutions are a very promising alternative to fluorinated polymers like polyvinylidene difluoride that also requires the use of the toxic N-Methyl-2-pyrrolidone solvent [2,3]. Electrospinning is an emerging technology for the preparation of non-woven free-standing fiber mats to be used as electrode materials and separators in supercapacitors. Enabling the utilization of novel bio-derived polymer as primer giving also the possibility to use environmentally friendly solvents.

Here, we report about a systematic study on electrospun no-woven separators for high voltage carbon-based electrical double layer supercapacitors (EDLCs). Two natural polymer-based electrospun separators have been tested in three different organic electrolytes. In particular, for all the combinations of separator/electrolyte, it has been studied the stability and the resistive contribution.at different operating temperature trough Electrochemical Impedance Spectroscopy (EIS). Natural polymer-based water processable binders have been studied too. Out study demonstrates for the first time that pullulan can be used to produce high mass loading electrodes (> 10 mg cm^{-2}) at low binder content (10%) for ionic-liquid based EDLCs. 3.2 V- Pullulan-ionic liquid EDLCs featured specific energy and power of 7.2 Wh kg^{-1} and 3.7 kW kg^{-1} along with good cycling stability over 5000 cycles.

The exact role of defect structure on transition-metal compound for electrocatalytic oxygen evolution reaction (OER) is a very dynamic process and unclear. Despite of the poor intrinsic activity of pure Co_3O_4, various modification strategies have been developed to enhance the OER activity, such as defect engineering with introduction of oxygen vacancy (V_O). However, the role of defect in catalyst materials has not yet been fully identified. V_O-rich Co_3O_4 has been widely reported as advanced OER electrocatalysts, the mechanism of which was preliminarily attributed to the enhanced electronic conductivity and more low-valence Co (Co^{2+}) formed. In addition, the chemical environment of defective Co_3O_4 is more dynamically changeable during electrocatalysis with applied potential. Studying the structure-activity relationship of defective electrocatalysts under *operando* conditions is crucial for understanding their intrinsic reaction mechanism and dynamic behavior of defect sites. Co_3O_4 with rich V_O has been reported to efficiently catalyze OER. We constructed pure spinel Co_3O_4 (as model catalyst) and V_O-rich Co_3O_4 to study the defect mechanism and investigate the dynamic behavior of defect sites during the electrocatalytic OER process by various *operando* characterizations. *Operando* EIS and CV implied that the V_O could facilitate the pre-oxidation of the low-valence Co (Co^{2+}, part of which was induced by the V_O to balance the charge) at relatively lower applied potential. This observation confirmed that the V_O could initialize the surface reconstruction of V_O-Co_3O_4 prior to march during OER process. The *quasi-operando* XPS and *operando* XAFS results further demonstrated the oxygen vacancies were filled with OH^* firstly for V_O-Co_3O_4 and facilitated pre-oxidation of low-valence Co, and promoted reconstruction/deprotonation of intermediate Co-O-OH. This result provides insight into the defect mechanism in Co_3O_4 for OER in a dynamic way by observing the surface dynamic evolution process of defective electrocatalysts and identifying the real active sites during the electrocatalysis process. The current finding would motivate the community to focus more on the dynamic behavior of defect electrocatalysts.

baglio@itae.cnr.it

A new way to produce and store electrical energy is necessary to address future energy demands and reduce polluting emissions. Rechargeable alkaline metal–air batteries are envisaged as commercially viable energy storage devices due to their high theoretical energy densities respect to lithium-ion batteries. However, they do not still offer adequate practical energy density and life cycle due to critical problems arising from the positive electrode, such as slow kinetics of the oxygen reduction (ORR) and oxygen evolution (OER) reactions. In the last few years, research was focused on the development of highly efficient oxygen reduction/evolution catalysts based on transition metals, such as Co, Fe, Mn, La, etc, in the form of mixed oxides (perovskites, spinels, etc.), or advanced carbon materials. Co-based catalysts have been thoroughly investigated for the ORR/OER, and, usually, Co_3O_4 is the most employed formulation. However, the electrical conductivity of bare Co_3O_4 is not appropriate for the application in most of these devices. Other transition metals (Ni, Fe, Mn, etc.) can partially replace Co atoms in the Co_3O_4 spinel structure, improving its electronic conductivity while promoting oxygen evolution. Another approach is to combine these oxides with carbon nanostructures, in particular graphitic ones, in order to maintain suitable stability under cycling operation. Recently, carbon nanofibers (CNF) synthesized by electrospinning, modified with a spinel Co_3O_4 [1] or a combination of cobalt oxide and metallic cobalt (CoO-Co/CNF) [2] or loaded with Nickel-cobaltite [3], were investigated in our laboratories as bifunctional air electrodes showing good reversibility and stability. In this work, Fe partially replaces Co atoms in the Co_3O_4 spinel structure, leading to a $FeCo_2O_4$/CNF, by using the same electrospinning preparation procedure previously reported. The $FeCo_2O_4$/CNF catalyst is physico-chemically studied in terms of structure, morphology and surface properties; these features are correlated to the electrochemical behavior for the oxygen reduction (ORR) and oxygen evolution (OER) reactions in comparison with previously developed Co_3O_4/CNF [1] and state-of-the-art materials. An outstanding onset potential towards the OER of 1.40 V vs. RHE is observed, which is 140 and 250 mV lower compared to the pure spinel (Co_3O_4/CNF) and Pt/Vulcan, respectively. A remarkable reversibility ($\Delta E = E_{OER} - E_{ORR}$) value of 495 mV is obtained, due to a good activity also for the ORR. To assess the stability of the catalysts for rechargeable alkaline metal-air batteries, cycling operation and chronopotentiometric experiments are carried out, showing promising results.

Ammonia is an important raw material of various chemical products, including resins and fertilizers. The present industrial technology for ammonia synthesis, Haber-bosch process, needs a grand scale because it requires high pressures and temperature. Recently, an aqueous electrochemical reduction of dinitrogen to ammonia has attracted much attention as an on-demand technology for ammonia synthesis because it can operate under ambient conditions. An active electrocatalyst to split the stable N-N bonds in dinitrogen is required for efficient electrochemical devices. Choi *et al.* theoretically predicted that single early-transition-metal (ETM) atoms (such as Mo, V, and Ti) doped into *sp2* carbons serve as the active catalytic sites for dinitrogen reduction reaction due to the efficient π back-donation to N-N bonds. 1) However, single ETM atoms easily aggregate to oxides or hydroxides in aqueous solutions. Recently, our group has demonstrated that covalent triazine frameworks (CTFs) could support a wide variety of metals via coordination bonds. Interestingly, the metal-doped CTFs (M-CTFs) exhibited electrocatalytic functions depending on the metal species2)-4). Therefore, we expect that the CTFs can stably immobilize single ETMs and catalyze dinitrogen reduction reaction.

In the present work, we attempt to synthesize efficient electrocatalysts composed of M-CTFs for the dinitrogen reduction reaction. First, we selected effective metal active centers using density functional calculations (DFT). Then, we evaluated the dinitrogen reduction activity of the synthesized M-CTFs using gas diffusion electrodes (GDEs), as shown in Figure 1. In the poster, we will present the detailed results of DFT and electrochemical dinitrogen reduction activity of M-CTFs.

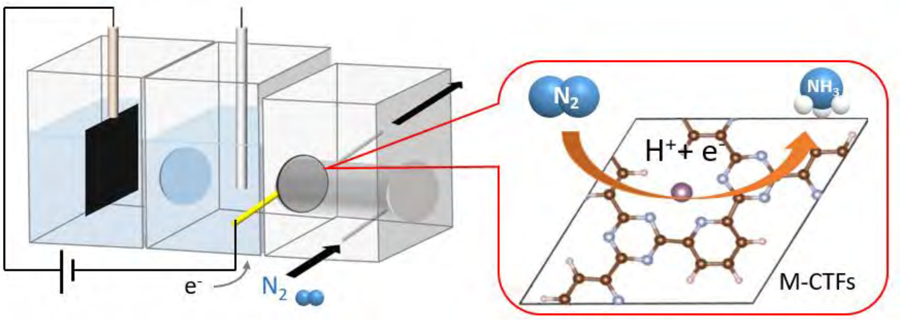

Fig.1 Schematic illustration of the electrochemical setup for the GDE carrying M-CTFs.

e-mail: antonia.stoyanova@iees.bas.bg

Supercapacitors are electrochemical energy storage devices that achieve high power density and fast charge-discharge rates. In a traditional supercapacitor, an ion-permeable and electrically insulating separator film is sandwiched between two electrodes flooded with a liquid electrolyte. Since liquid electrolyte leakage is a severe issue, especially when the material is environmentally hazardous, efforts are focused on replace the liquid electrolytes with solid electrolytes. The polymer electrolytes are ideal candidates for next generation solid supercapacitors, which are not only safer, but also offer high performance, light weight, and flexible forms [1].

A method of polymerization and chemical modification was applied for synthesis of a series of novel pyrrolidinium - containing homo- or copolymers and their turning into polymeric ionic electrolyte. The polymer electrolyte was impregnated the active layer of the activated carbon supercapacitor electrodes and the resulting thin polymer electrolyte layers on both electrode surfaces are integrated into a single thin layer minimizing interfacial resistance. The electrochemical characteristic of the assembled supercapacitor cells and also of systems consisting of carbon electrode and mixtures of ionic liquid and PIL (with varying composition) were evaluated using galvanostatic charge/discharge tests and cycling voltammetry. The effect of polymer composition and operation temperature on the supercapacitor performances was also studied.

It has been found that the use of PIL in supercapacitors leads to stabilization of its capacity, as well as to increased efficiency of the charge-discharge process. Further studies are needed to improve their electrochemical characteristics.

Influence of Ionomer Content on Oxygen Transport Resistance and Performance in PEMFC

Xinye Sun, Hongmei Yu, Li Zhou, Xueqiang Gao, Zhigang Shao
Fuel Cell System and Engineering Laboratory, Dalian Institute of Chemical Physics, Chinese Academy of Sciences
457 Zhongshan Road, Dalian, China
sunxinye@dicp.ac.cn

Proton exchange membrane fuel cell (PEMFC) is considered to be an ideal clean energy technology. However, its commercial application is still limited by cost and performance under high current densities. Previous research has shown that the performance loss of the MEA with low Pt loading mainly comes from the oxygen transport resistance at the cathode reaction site. Despite the ionomer content in catalyst layer has been accepted as one of the impact factors, few research focused on the in-situ measurements of oxygen transport resistance and further analysis. In this study, different ionomer content cathode catalyst layers with I/C varying from 0.3 to 0.9 were made. Oxygen transport resistance was characterized through limiting current density, the total oxygen transport resistance, Fick diffusion resistance, and local oxygen transport resistance were all calculated. Results show that ionomer content has strong influence on both Fick diffusion resistance and local transport resistance. Reasons of the influence can be attributed to the change of pore structure and the increase in thickness of ultra-thin ionomer film at the surface of platinum particles. Based on the results, ionomer content in low Pt loading catalyst layers should be minimized to reduce oxygen transport resistance and improve the performance at high current densities.

Influence of DNA surface density on a sensitivity of tetracycline measurements

Marcin Jaskółowski and Agnieszka Więckowska

University of Warsaw, Faculty of Chemistry
1 Pasteur Street, 02-093 Warsaw, Poland
m.jaskolowski2@uw.edu.pl

Biosensors are small devices employing biochemical molecular recognition properties as the basis for a selective analysis. Such devices consist of a biological recognition element with a physical transducer [1]. In recent years, biosensors became popular in monitoring biological and synthetic processes in the field of food analysis and in the area of human monitoring and diagnostics [2]. DNA biosensors are based on nucleic acid recognition layers which can be easily synthetize and unlike enzyme or antibodies biosensors, DNA biosensors can be regenerated for multiple uses [3].

In this project we present a study on detection limit of tetracycline, widely used in animal breeding [4], using a DNA biosensor with different surface densities of DNA probe. In order to attach to the gold surface, DNA chain has to be modified with a short thiol. Thiolated DNA is capable of forming self-assembled monolayers onto gold transducers by covalent linkage to the surface via functional alkanethiol-based monolayers [5]. We used electrochemical techniques including impedance spectroscopy to characterize layer of biological probe on the electrode surface. During the interaction between DNA aptamer on the surface and tetracycline, the charge transfer resistance between the solution and the electrode surface changes, which allows to determine tetracycline concertation in solution. Surface plasmon resonance spectroscopy was used for real time observation of antibiotics interactions and determination of layers thickness.

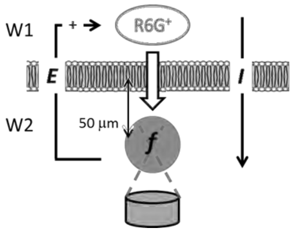
Dynamic behavior analysis of ion transport through a bilayer lipid membrane by an electrochemical method combined with fluorometry

Terumasa Omatsu, Kisho Hori, Naoto Ishida, Kohji Maeda, Yumi Yoshida
Faculty of Molecular Chemistry and Engineering, Kyoto Institute of Technology
Hashigami-cho, Matsugasaki, Sakyo-ku, Kyoto, JAPAN
d9871001@edu.kit.ac.jp

Analyzing ion transport through an artificial bilayer lipid membranes (BLMs) is essential for understanding biomembrane phenomena (such as neurotransmission and respiration) and delivery of ionic drugs into a cell.

The mechanism of ion transport through a biomembrane was conventionally studied by electrochemical methods such as the patch clamp method[1] and voltammetry[2,3], which provide a dynamic and highly sensitive analysis of ion transport through membranes. In the electrochemical methods, it is not easy to identify the transported ion from the transmembrane current. For example, a cation transfers through a membrane from an aqueous phase with more positive potential to another aqueous phase with less positive potential, yielding a positive current in the electrochemical measurement. However, the transport of an anion through the membrane in the opposite direction also gives a similar positive current. Besides, electrochemical methods cannot detect the coupled transports of cations and anions or the anti-transports of two ionic species with the same charge as electric current.



E: the applied potential
I: the transmembrane current
f: fluorescent intensity

Fig. 1 Schematic of the experimental set-up.

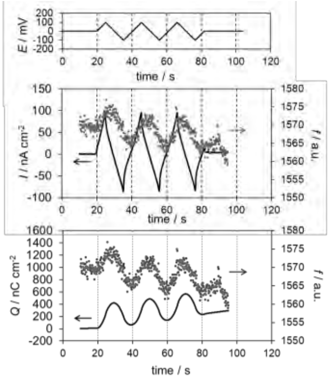


Fig. 2 Transmembrane current, *I*, Transmembrane charge, *Q*, and fluorescent intensity, *f*, recorded synchronously with membrane potential, *E*.

The combination of the electrochemical method with fluorometry solves the disadvantage of the electrochemical method, e.g. difficulty in characterization of the ion transported through a BLM in the presence of other ions. In the present work, the ion transport through a BLM caused by both a fluorescent cation (rhodamine 6G$^+$, R6G$^+$) and a relatively hydrophobic anion (BF_4^-) was examined by utilizing the electrochemical method combined with fluorometry, in which the transmembrane current and fluorescent intensity in the local area close to the planar BLM were simultaneously measured as a function of the applied membrane potential[4].

Fig. 2 indicates *I* and *f*, which were recorded simultaneously during scanning *E* between −100 mV and 100 mV. In the presence of R6G$^+$, the amplitude of *f* appeared synchronously with *E*, and the amplitude of *I* also increased. To compare *I* to *f* more precisely, we converted *I* to the total charge of the transported ions, *Q*, by integrating *I*. The positive *Q* increased for positive *E* of W1 as compared with W2. The results mean either R6G$^+$ transport from W1 to W2 or BF_4^- transport in the opposite direction. *f* increased with the increase in positive *Q*, and then we characterized the increases in *Q* and *f* as the R6G$^+$ transport from W1 to W2 through the BLM.

Using this method, the influence of a coexisting anion on R6G$^+$ transport through a BLM was examined and it was found that the R6G$^+$ transport was facilitated by the addition of hydrophilic anions such as BF_4^-.

Reasonable design and synthesis of Fe/N/C based catalysts is one of the most promising way for developing precious metal-free oxygen reduction reaction (ORR) catalysts. Here, nitrogen and sulfur doped catalyst were synthesized (Fe-N-C-S) using ferric chloride hexahydrate as Fe source, Potassium thiocynate as Sulfur source and Polyvinylpyrrolidone (PVP) as Carbon and nitrogen source. The obtained catalyst shows three dimensional macroporous structure. This method has the advantage of using Potassium thiocynate as Sulfur source during the synthesis process, which resulted in high doping of sulfur (about 5.4 %). The optimal catalyst shows high ORR activity with a half wave potential of 0.880 V, vs RHE and limiting current density of 6.5 mA cm^{-2}. The synthesized Fe-N-C-S catalyst showed stability in both acidic and basic media.

Copper-cobalt oxides, $CuCo_2O_4$ have attracted a great deal of research interests in a wide range of applications such as oxygen evolution reaction, oxygen reduction reaction, hydrogen evolution reaction, alcohols oxidation, H_2O_2 decomposition, urea oxidation, and energy storage. These are cost-effective and low-toxic and their controllable composition, electronic structure, valence states or redox characteristics, morphology, and high catalytic property have made them suitable as universal catalysts. However, their low intrinsic electrical conductivity still overshadows their practical application to some degree. In addition, the conventional preparation procedures of copper-cobalt oxide result in relatively low catalytic activity or large OER overpotential for catalytic reactions. In the present report, nanostructured copper–cobalt oxide ($Cu_xCo_{3-x}O_4$, CCO) electrodes are grown directly on conducting substrates via electrochemical deposition; then, various factors (e.g., oxygen vacancies, electrochemically active surface area, and electrical conductivity) affecting their electrocatalytic activity for overall water splitting are studied. The observed oxygen evolution reactions (OERs) performance decreases when increasing the annealing temperature due to the nanostructure deformation and agglomeration and the decreased number of oxygen vacancies, electrochemically active surface area, and electrical conductivity.

The configuration and electrochemical performance of Li-Na hybrid batteries

Qiu Zhang, Yong Lu, Licheng Miao, Jun Chen*
Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University, Tianjin 300071, China

Due to the low cost, wide distribution, low electrochemical potential (-2.73 V vs. standard hydrogen electrode) and high theoretical specific capacity (1166 mA h g^{-1}), Na metal anode attracts attentions in the applications of high-energy and low-cost energy storage systems. However, Na has high reactivity with the electrolyte, leading to the formation of a solid electrolyte interface (SEI) layer between Na and electrolyte. During the repeated Na plating/stripping, Na metal anode shows uneven deposition and a huge volume change, rendering the breaking and re-forming of SEI. The consumed Na metal anode and electrolyte lead to low coulombic efficiency (CE) and battery failure. Meanwhile, uneven Na plating results in the growth of dendritic Na, leading to internal short circuit and safety concerns. Thus, it is important to restrict the dendritic growth and improve the CE of Na metal anode.

The electrochemical performance and mechanism of Li and Na metal anode in ether-based electrolyte were investigated. Due to its lower reduction potential, Li^+ cannot be reduced and forms Li^+ electrostatic shield layer to guide Na plating. We also observed the dynamic plating process via in-situ optical microscope that proves the unique Na plating pattern. In addition, Na metal anode shows higher reversibility with an average CE of 99.2% and faster plating kinetics than Li metal anode. We utilized density functional theory calculation to understand the solvation/desolvation of metal-ions, and proved the fast desolvation kinetics of Na^+. Moreover, $LiFePO_4$ cathode was used to construct an advantage-complementary Li-Na hybrid battery system (LNHB). During the discharge/charge processes, Li^+ and Na^+ play roles in insertion/extraction into/from the cathode and stripping/plating of the anode, respectively. The LNHB with the high reversibility, stability and fast kinetics of Na metal anode shows low voltage hysteresis and long-term cycling.

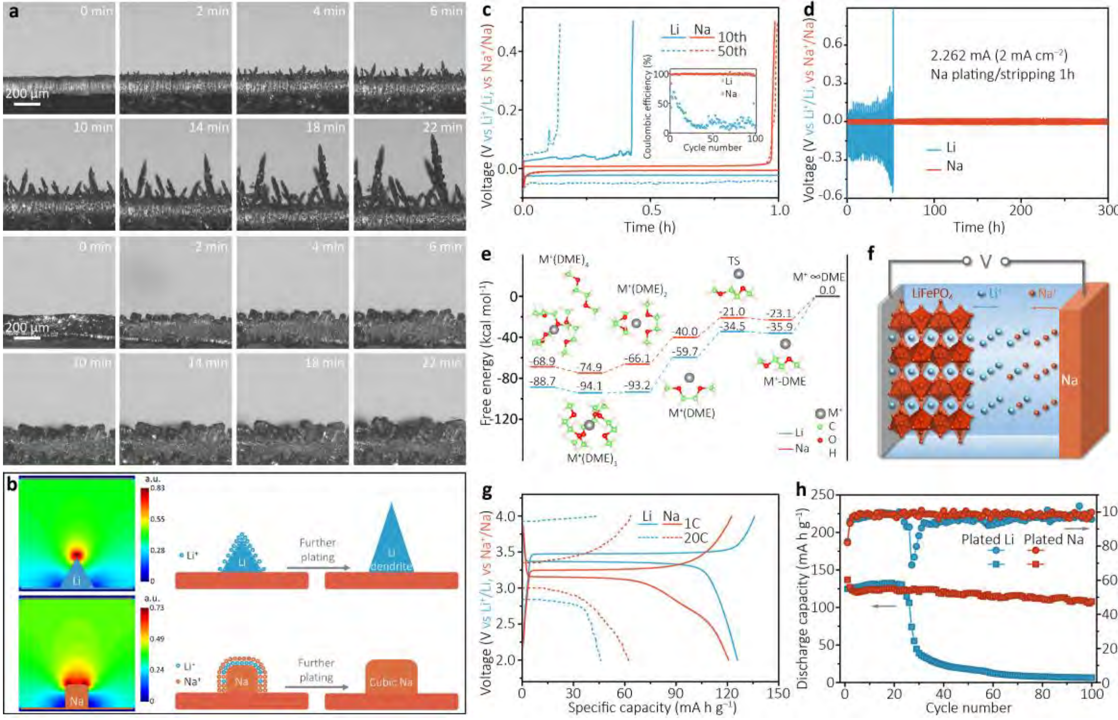

Fig. 1 (a) In situ optical observations of Li/Na plating. (b) The simulated electric field intensity distribution and schematic illustration of Li/Na plating patterns. In this work, we design an improved strategy to create an ORR catalyst by using sustainable bio waste materials (peanut shells) as source of carbon, nitrogen and sulphur. This method is proceeded by; chemical activation with KOH, intrinsically doped with nitrogen as well as sulphur, while extrinsically doped with iron in order to get a catalyst with enhanced ORR catalytic performance. The SEM images revealed 3D hierarchically graphitic micro and mesoporous structure with high surface area of about 1020.3597 m²/g. The EDX, mapping and XPS confirms the formation of Fe-N-C/S catalyst. The synthesized Fe-N-C /S displays excellent ORR activity with a half wave potential of (0.87 V versus RHE), limiting current density 5.31 mA cm^{-2} and onset potential of 1.13 V in 0.1 M KOH solution. This work will be surely helpful for the design and synthesis of biomass resource as facile route to change renewable bio waste materials to a valuable electro catalyst for Zn-air batteries.

Key words: biowaste, peanut shells, oxygen reduction reaction and Sulphur.

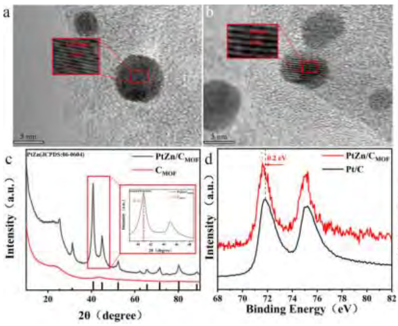
Highly dispersed PtZn intermetallic for efficient oxygen reduction catalysts

Tuo Zhao,Ergui Luo,Junjie Ge*,Wei Xing*
Changchun Institute of Applied Chemistry, Changchun, Jilin, 130022 (P. R. China)
School of Applied Chemistry and Engineering, University of Science and Technology of China Hefei, Anhui, 230026 (P. R. China)
tonyzhao@ciac.ac.cn

Abstract：This work develops a Zn-based MOF as catalyst support and provides a facile strategy to prepare atomically dispersed intermetallic alloys with highly activity and durability.



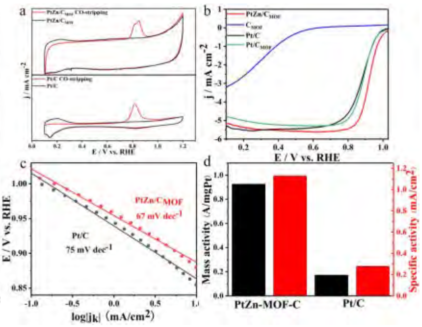


Figure 1. structure and composition of PtZn/C$_{MOF}$. **Figure2.** electrochemical performance of PtZn/C$_{MOF}$ and Pt/C.

Figure 1:

(a,b): lattice fringes of 0.221nm and 0.345nm are smaller than those(0.226nm, 0.351nm) of PtZn (111) and (220) facet, indicating the presence of lattice compression.

(c): XRD pattern of PtZn/C$_{MOF}$ agrees well with the intermetallic L1_0-PtZn PDF card(PDF#06-0604) without any impurity peak, indicating that the ordered L1_0-PtZn intermetallic alloy has been successfully formed. Slight peak position shifts to positive angle compared with standard pattern further demonstrate that the existence of compression strain makes lattice spacings smaller.

(d): Pt core levels(71.7eV of Pt4f) shows a 0.2eV negative shift to lower binding energies compared with Pt/C(71.9eV of Pt 4f).

Figure 2:

(a):The ECSA values for PtZn/C$_{MOF}$ and Pt/C are 81.9 and 60.1 m^2/g$_{Pt}$ respectively, demonstrating the higher ECSA and more active ORR potency for PtZn/C$_{MOF}$.

(b): The half wave potential E½ of PtZn/C$_{MOF}$(0.922V) is 42mV higher than commercial Pt/C(0.880V) observed from the linear sweep voltammetry (LSV) in a O_2-saturated 0.1 M $HClO_4$ solution.

Commented [1]: ？？？

(c): Tafel plot of PtZn/C$_{MOF}$(67mV/dec) derived from LSV exhibits smaller slope than Pt/C(75mV/dec), manifesting the enhanced kinetics for ORR.

(d): PtZn/C$_{MOF}$ delivers higher mass(0.926A/mg$_{Pt}$) and specific activities(1.13mA/cm^2) of Pt at 0.9 V versus RHE, which are respectively 5.4 and 4.0 times higher than those(0.172 A/mg$_{Pt}$ and 0.28 mA/cm^2) of the Pt/C reference.

Conclusion：

we adopt a facile one-step heat-treatment approach to obtain a series of highly dispersed PtZn intermetallic ORR catalysts based on a porous Zn-rich MOF. Small PtZn particles (mean size:3.95nm) enable large electrochemically active surface area(81.9 m^2/g$_{Pt}$) and high atomic utilization. The ligand effects and compressive strain optimize the Pt electron structure and binding strength between Pt and oxygen intermediates. These advantages result in better ORR performance (0.926 A/mg$_{Pt}$ of mass activity and 1.13mA/cm^2 of specific activity), which are respectively 5.4 and 4.0 times higher than those of commercial Pt/C(0.172 A/mg$_{Pt}$ and 0.28 mA/cm^2).

Electronic conductivity modification of $Na_3V_2(PO_4)_3$ cathode material using graphitic carbon shell for enhanced electrochemical performance

NASICON structured sodium vanadium phosphate Na3V2(PO4)3 is a promising cathode material for rechargeable sodium ion batteries. The high specific capacity ~176.44mAhg-1 [1] and structural stability of Na3V2(PO4)3 are important characteristics for its application in sodium ionbatteries. We optimized nanostructured Na3V2(PO4)3 synthesis process and pristine and carbon coated Na3V2(PO4)3 material are prepared. Carbon coated Na3V2(PO4)3 was synthesized by varying carbon source molar fraction during sol-gel synthesis process. The refinement of X-ray diffraction measurements suggests the rhombohedral NASICON structure with R-3c space group. The measured lattice parameters are in agreement with the reported values [2]. The carbon presence has been confirmed using Fourier Transform Infrared (FTIR), Raman spectroscopic and thermogravimetric analysis (TGA) measurements. We will discuss the impact of electronic conductivity as a function of carbon fraction and its graphitic content in shell geometries with Na3V2(PO4)3 core, as explained in Fig. 1, on charge/discharge characteristics in hybrid coin cell structures, where lithium 'Li' metal has been used as anode material..

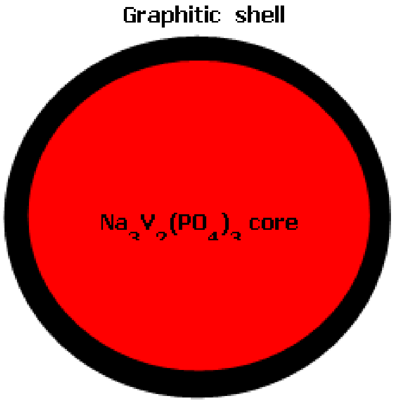

Figure 1. Schematic representation of graphitic carbon shell with $Na_3V_2(PO_4)_3$ core structure.

Monoclinic beta-phase gallium oxide (*β*-Ga_2O_3) is a wide bandgap semiconductor (4.5-4.8 eV)[1] that possess the unusual combination of high visible transparency and high mobility *n*-type conduction, a class of materials called transparent conducting oxides (TCOs). There is considerable interest in this material for deep-UV sensing, high-frequency power electronics, and transparent sensor devices. *β*-Ga_2O_3 is also interesting from a fundamental perspective as its surfaces are different from those of other *n*-type TCOs such as ZnO, SnO_2, In_2O_3, and CdO.[2] The surfaces of the latter exhibit downward band bending and electron accumulation due to the presence of donor-like surface states, while *β*-Ga_2O_3 surfaces are characterized by upward band bending and electron depletion.[2]

Using electrochemical cyclic voltammetric and spontaneous methods, aryldiazonium ion, iodonium ion and phosphonic acid-derived organic films were successfully formed on the (-201) and (010) surfaces of *β*-Ga_2O_3. 2-4 nm multilayers of nitrophenyl (NP), methylphenyl (MP), and phenyl-based films were deposited using aryldiazonium salt and iodonium salt electrochemistry[3,4] whereas, monolayer octadecylphosphonic acid (ODPA) films were spontaneously formed by submerging the substrate in solution.[5]

Synchrotron X-ray photoelectron spectroscopy showed that all aryl modifications increased the upwards band bending by 0.5 eV at the Ga_2O_3 surfaces. Reduction of the nitro functionality was also induced by the synchrotron irradiation to form AP-like moieties and these layers further increased the upwards band bending by a further 0.1 eV. This corresponds to even more electron depletion at the surface which is highly unexpected. ODPA modification resulted in a decrease of the upwards band bending by 0.2 eV.

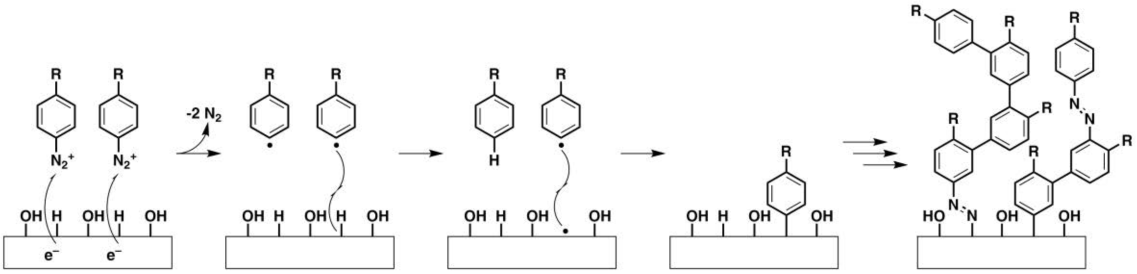

Figure: Electrochemical formation of aryl multilayers on *β*-Ga_2O_3 surfaces

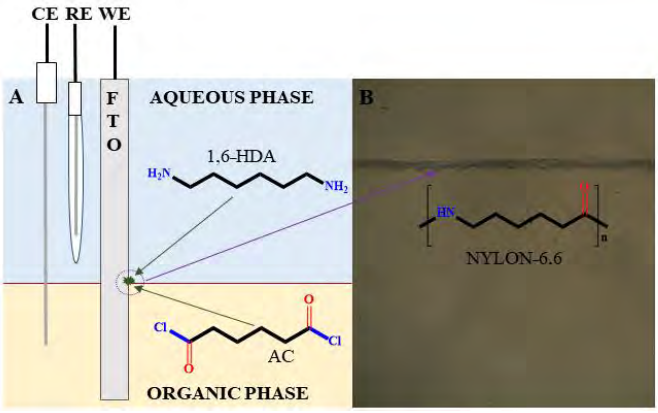
Electrochemically Assisted Polyamide Deposition at Three Phase Junction

Karolina Sipa, Karolina Kowalewska, Andrzej Leniart, Sławomira Skrzypek, Łukasz Półtorak
University of Lodz, Faculty of Chemistry, Department of Inorganic and Analytical Chemistry,
Tamka 12, 91–403 Łódź, Poland
karolina.sipa@chemia.uni.lodz.pl

A three phase junction[1] formed between solid electrode placed between solutions of the organic phase and the aqueous phase is employed for localized and electrochemically assisted nylon–6,6 deposition. The fluorine doped tin oxide (FTO) conductive support (serving as the working electrode – WE) is immersed into the cell filled with two immiscible liquids. The aqueous phase (being on the top) contains 1,6–hexamethylenediamine (1,6–HDA) whereas the organic phase (being on the bottom) is a solution of adipoyl chloride (AC) dissolved in a 1,2–dichloroethane. The interfacial polycondensation reaction between these two reagents occurs spontaneously at the liquid–liquid interface at elevated pH and is inhibited when diamine is fully protonated.[2] This means that the local pH change can be used to control interfacial polycondensation reaction.

In this respect we have designed the electrochemical set–up shown in scheme 1A. Electrochemical processing is optimized together with a number of experimental conditions. The pH of the aqueous phase was adjusted in the range from 3.0 to 8.5 by the addition of 0.1M HNO_3 to a solution of 50 mM 1,6–HDA. Next we have studied the effect of the applied cathodic potential. Local pH increase was controlled by electrochemically formed OH^- ions at the WE surface only on the water side of the liquid–liquid interface. At pH > pK_a the diamine species deprotonates and are available to react with adipoyl chloride species from the organic phase. This reaction occurs only at the three phase junction and gives a polyamide strap formed at the WE in the very localized position (scheme 1B). We found that its dimensionality can be controlled by the experimental time, applied potential and pH of aqueous phase.[3]



Scheme 1. (A) A schematic representation of the electrochemical set–up used to decorate three phase junction system. (B) The optical microscope image of nylon–6,6 strap formed at the FTO electrode.

The control experiment was carried out in the same phase arrangement without the use of electrochemistry. The reaction of polyamide deposition does not occur spontaneously, no formation of nylon strap was observed even for elongated experimental times. An analysis of the obtained nylon–6,6 strap as further performed using IR spectroscopy, atomic force microscopy and scanning electron microscopy. This protocol will be extended to a number of polyamide based materials that can be applied in corrosion studies, sensing and smart materials development.

A New Approach to Electrochemical Impedance Spectroscopy Fitting for Organic Semiconductors

Gabriela P. Kissling, Evelyne Knapp, Kurt P. Pernstich
Institute of Computational Physics, Zurich University of Applied Sciences
Technikumstrasse 9, CH-8400 Winterthur, Switzerland
gabriela.kisslingkemp@zhaw.ch

More and more, electrochemistry is becoming an everyman's tool. Researchers working in a variety of fields, such as biology, synthetic chemistry, or physics are starting to appreciate the relative low cost and versatility of electrochemical methods. With this emerging mass appeal, the amount of mistakes made in data collection and analysis is also increasing. In electrochemical impedance spectroscopy (EIS), where data analysis is especially complex, this can lead to significant misinterpretation of the results. After all, the knowledge required to design a representative equivalent circuit, comprising all the relevant components but avoiding misleading additions, is complex and can be a challenge even for experienced researchers. In addition, equivalent circuits only have limited flexibility and can struggle to represent less ideal electrochemical systems accurately.

We are developing a physics based EIS model for the analysis of organic semiconductor materials using COMSOL Multiphysics® software [1]. The design of the model will be guided by experimental results obtained for N,N′-di(1-naphthyl)-N,N′-diphenyl-(1,1′-biphenyl)-4,4′-diamine (NPB) and will endeavour to better understand the energy levels in organic semiconductor materials. While the scope of this model is relatively narrow, we believe that the general approach can be readily expanded and contribute to a better understanding of the physical properties in a range of organic semiconductors.

The poster will present some of our initial work and contrast results obtained using the physics based EIS analysis approach with standard equivalent circuit models in terms of ease of use, accuracy and computing time. The advantages and disadvantages of the two model systems will be discussed.

Polymediators and Polyelectrolytes in Organic Electrosynthesis

N. Mohebbati, A.Prudlik, R. Francke
University of Rostock,
Albert-Einsteinstr. 3a, 18059 Rostock
Nayereh.Mohebbati@uni-rostock.de

Although organic electrosynthesis is generally considered to be a green method, the necessity for excess amounts of supporting electrolyte constitutes a severe drawback. Furthermore, the employment of redox mediators results in an additional separation problem.[1] In this context, we have developed a polymer-based approach which allows for simultaneous separation and recycling of mediator and supporting electrolyte in a single step (see Figure, right) using membrane filtration. For this purpose, 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) and tetraalkylammonium groups were attached to a polymethacrylate backbone, resulting in well-soluble and task specific homopolymers **1** and **2** (see Figure, left).[2][3] Reversible redox behaviour was observed for the polymediator using cyclic voltammetry. The successful conversion of several test substrate using catalytic amounts of **1** demonstrated that such polymers can be applied for oxidation of alcohols under mild conditions. Furthermore, recyclability was demonstrated in preparative-scale electrolysis.[2]

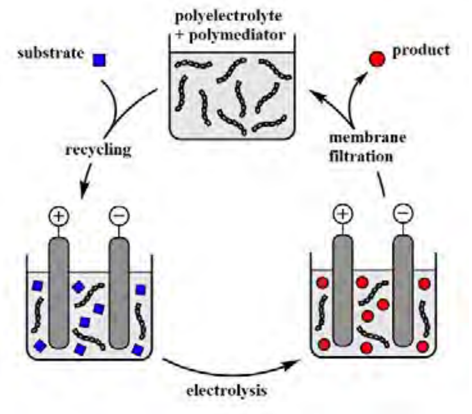
2



Since the electrolysis current is usually limited by diffusion of the redox-active species to the electrode, we are currently studying the influence of the molecular weight on current density for type **1** polymers. Our efforts are focused on finding a useful operating range in which an efficient membrane process, high current densities and optimum ionic conductivity can be achieved. RAFT polymerization allowed for the synthesis of polymers with well-defined molecular weight distribution between 3 and 100 kDa. We found that the redox-activity was increased with decreasing molecular weight, whereas the retention in the membrane filtration follows the opposite trend. Similarly, it is important to study the relationship between the ionic conductivity and molecular weight for type 2 polymers. A close investigation on polyelectrolytes' performance demonstrated that ionic conductivity is independent from the chain length.

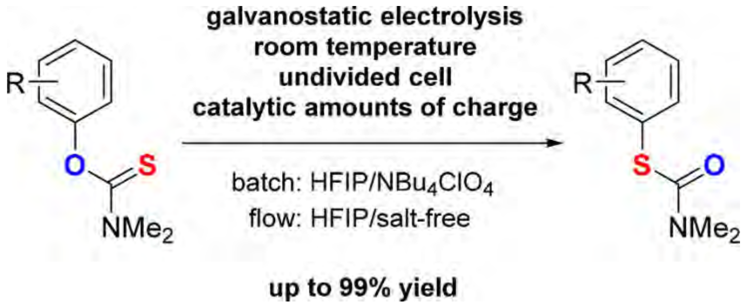
The Electrochemical Newman-Kwart Rearrangement under Microflow Conditions

A. Prudlik, T. Broese, A. F. Rösel, M. Májek, R. Francke
University of Rostock
Albert-Einstein-Straße 3a, 18059 Rostock
adrian.prudlik@uni-rostock.de



A common pathway for the synthesis of thiophenols is the three-step transformation of phenols via the Newman-Kwart rearrangement (NKR) of an *O*-aryl thiocarbamate to the corresponding *S*-aryl compound as a key step.[1,2] This rearrangement is thermally induced at temperatures up to 300°C. Via an electrochemical pathway we achieved this rearrangement at room temperature.[3] A mechanistic study revealed an electrochemically catalyzed pathway, in which anodic oxidation leads to a cation radical rearrangement,[4] thereby triggering a chain process in solution.[3] Furthermore, we investigated the effects of different substituents on the yield and side-reactions and identified the factors that govern the reactivity of specific substrates.[5]

In addition, we developed a procedure for an undivided microflow-reactor (see Figure, right), which allows for electrolysis without added supporting electrolyte. Since full conversion with quantitative selectivity is achieved, only a separation between the product and the solvent is needed. In the present contribution, the most important aspects of the electrochemical NKR under microflow conditions will be discussed.

Determination of the pK_a of neutral molecular compounds in imidazolium-based ionic liquids

Arturo García-Mendoza, Julio C. Aguilar
Departamento de Química Analítica, Facultad de Química, UNAM
Ciudad Universitaria, 04510, México, Ciudad de México.
arturogm@unam.mx

Room temperature ionic liquids (RTIL) are one of the main alternatives to molecular solvents conventionally used for electrochemical applications such as electrosynthesis, energy conversion and storage devices, or electroanalysis [1]. In any of these applications, chemistry in solution in RTILs requires specific knowledge of the equilibrium processes because they partially define the success or failure of a given reaction. For this reason, it is imperative to know and control chemical parameters under imposed chemical equilibrium conditions, such as acidity levels via the pH parameter.

In this work, a study is presented to explain the acid - base phenomenon that occurs in certain RTILs in terms of the Brönsted - Lowry theory. With the information obtained, the changes in reactivity observed in some test compounds such as pyridine (Pyr) and N, N-dimethylethylamine (DEMEA) are explained.

A series of spectrophotometric and electrochemical assays were performed by potentiometry, cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) at four different imidazolium RTILs: $[C_2mim][NTf_2]$, $[C_3mim][NTf_2]$, $[C_2mmim][NTf_2]$ and $[C_2Him][NTf_2]$; where C_2mm = 1-ethyl-3-methylimidazolium, C_3mm = 1-propyl-3-methylimidazolium, C_2mmim = 1-ethyl-2,3-dimethylimidazolium, C_2Him = 1-ethylimidazolium and NTf_2 = bis(trifluoromethanesulfonyl)imide. These RTILs were dried for 24 hours at 90 °C before use. Spectrophotometric assays were used to evaluate the effect of triflic acid (HOTf) on the protonation of a neutral molecular indicator (In) in solution in the RTILs [2,3]. For the electrochemical potentiometric assays, the open circuit potential (OCP) was determined, during a series of acid-base titrations, using as working electrode (WE) a modified interface $W^0|WO_{3(s)}$; Pt^0 was used as auxiliary electrode (AE) and several interfaces of the type $Ag^0|AgCl_{(s)}$, constructed and characterized previously by our research group [4], were used as reference electrodes (RE). Electrochemical assays by CV were used for dynamic determination of the pK_a for the conjugate acid-base pair (HA^+/A) of the test compounds [5,6]. For determination, a cell was used in a three-electrode configuration, using a modified Pt^0-Pt^0 interface as WE. All measurements were made under an inert and dry N_2 atmosphere and EIS was used to determine and compensate for the ohmic drop.

The spectrophotometric assays were used to determine the Hammett acidity parameter (H_0^0) and the pK_a value for the conjugate acid-base pair (HIn^+/In). On the other hand, the pK_a for the conjugate acid-base pairs of the test compounds (HA^+/A) was determinate by potentiometric titrations, using the OCP data obtained from the tungsten sensor, by fitting them to a family of Gunnar Grand functions and a complete titration function without segmentation. These values were also confirmed by CV. Finally, data were corroborated by the correlation of acidity scales with parameter H_0^0, showing differences of less than 2%.

Activity and Stability Study of Iron Porphyrin Covalently Bound on the Surface for Oxygen Reduction Reaction Catalysis

Ting Wu, Paula A. Brooksby, Christopher M. Fitchett, Alison J. Downard*
School of Physical and Chemical Sciences, University of Canterbury
Christchurch, New Zealand
ting.wu@pg.canterbury.ac.nz

The oxygen reduction reaction (ORR) is a crucial part for fuel cell function to produce electricity on-demand. So as to improve the fuel cell efficiency, the slow kinetics of ORR on carbon electrode requires a catalyst. Non-precious metal catalysts (NPMCs) have gained increasing attention as a cheap alternative material to Pt. Among various NPMCs materials, molecular metal complex catalysts are attractive as they can be immobilized on an electrode surface. They can act as a model of pyrolysed NPMC materials, giving well-defined active sites and insights into the ORR catalytic mechanism. They also allow the possibility of structure control to achieve a leap in electrocatalyst efficiency and stability.

The stability of molecular metal complex catalysts, especially iron tetraphenylporphyrin (FeTPP), is an issue for catalyzing ORR in acid solution. Although a few studies have been done to investigate the degradation mechanism of pyrolysed NPMC materials,[1, 2] it is still not well-understood. Studying the composition change of the immobilized FeTPP film under ORR conditions can potentially lead to understanding of the degradation mechanism. Therefore, in this project, FeTPP molecule was immobilized on carbon surface via an axial ligand and also directly to the porphyrin ligand by electrografting from aryldiazonium salts. Electrochemistry, atomic force microscopy and X-ray photoelectron spectroscopy were used to investigate and compare the film structure change before and after ORR in acid aqueous solution. The potential degradation mechanism for FeTPP under ORR conditions will be proposed.

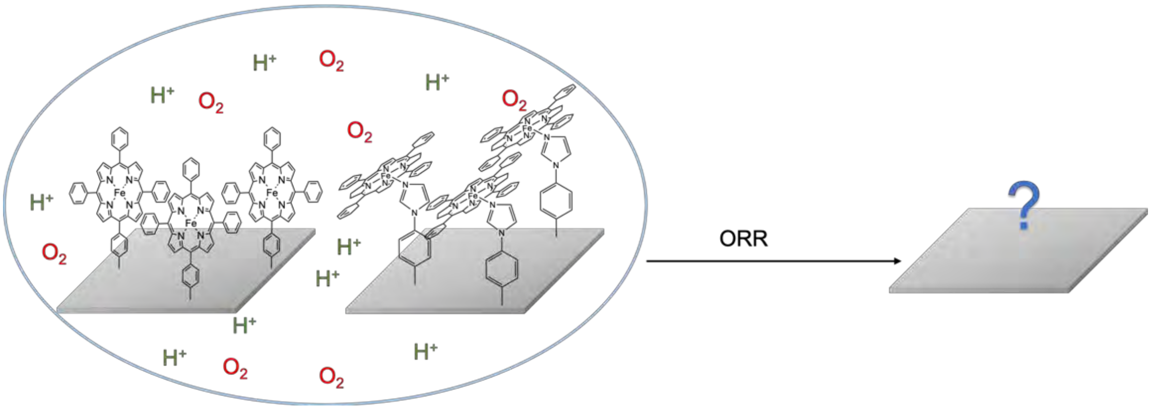

Figure 1. FeTPP film structure study as prepared and after ORR catalysis.

As the growth of global EVs market and continuous advances of IT devices' functionality, higher capacity and cycle stability of secondary batteries are being demanded. Lithium-sulfur(Li-S) battery is one of the promising next-generation batteries due to high theoretical capacity(1,672 mAh/g), natural abundance, and environmental nontoxic compare to conventional active materials of lithium-ion batteries. However, lithium polysulfide(PS) dissolution issue which causes capacity fade inevitably must be overcome for commercialization.

In this study, we introduced metal oxalates synthesized with the first transition metal series as cathode additives. They have a high polar surface area which is able to enlarge the electrocatalytic interfacial boundary enabling LiPS redox reactions to occur. Furthermore, physicochemical interactions between LiPS and metal oxalates were verified by UV-vis, X-ray Photoelectron Spectroscopy, and Electrochemical Analysis(Cyclic Voltammetry, Galvanostatic Intermittent Titration Technique, Electrochemical Impedance Spectroscopy). As a result, the modified cathode by the best candidate effectively decreased cell overpotential and improved the cycle stability by maximized electrochemical sulfur utilization.

With the population increasing, the available water resource in the world is diminishing. It has been predicted that by the year 2025, 60% of the world's population will face troubles accessing fresh water. This will affect not only the domestic sector but also the industrial and agricultural sector. The water that we use mostly come from fresh water resource, which is 2.5% of the total water on Earth. The other 97.5% is from saline water. As a solution for water scarcity, many countries like Saudi Arabia or the United Arab Emirates, use desalinated water as an alternative. Capacitive deionization (CDI) is an emerging desalination technology, which extracts the salt from water through electrostatic adsorption with an applied potential. CDI has numerous advantages. Its operation does not require high energy input since desalination can occur at low applied potentials. Moreover, it also does not require any additional chemical during the desalination process, which would lower down its cost compared to other desalination technologies. Even with its promising capabilities, CDI still has challenges in fabricating an electrode material that would have excellent performance and stability. Pseudocapacitive materials, primarily metal oxides, are potential CDI electrodes due to their excellent capacity and cyclability. In this study, different metal ratios of Ni-Mn_3O_4 was coated on activated carbon through anodic electrodeposition at constant current. The electrode surface was characterized using FESEM, XRD, BET and contact angle measurements. Its electrochemical performance was determined through CV and EIS analysis. The results from these measurements was used to pick the optimized Ni-Mn_3O_4. The chemical nature of the optimized deposit was analyzed through XPS and Raman spectroscopy. Using the fabricated electrode, it was paired with pristine AC to form an asymmetric CDI cell. At 1.2 V, it showed an excellent salt adsorption capacity of 8.54 mg g^{-1}, which is 2.5 times higher than a symmetric cell with AC. Moreover, it was able to retain 87% of its capacity after 50 adsorption-desorption cycles. Therefore, coating AC with Ni-Mn_3O_4 has successfully improved the CDI performance of pristine AC. The low cost of the metal precursors used for the electrodeposition will make it a potential material for large scale or commercial use.

Fuel cell is the energy system that converts chemical energy to electric energy, using hydrogen and oxygen. Among various type of fuel cells, proton exchange membrane fuel cell (PEMFC) operates in low temperature and its electronic density is high, thus it is known as one of the promising environmentally friendly energy systems. Since oxygen reduction reaction (ORR) in PEMFC has higher overpotential due to sluggish reaction kinetics, Pt-based metal catalysts are usually used as ORR catalyst. To enhance both ORR activity and price competitiveness, 4d transition metals (e.g. Co, Ni, Fe) have been commonly utilized by alloying with Pt. However, these transition metals are not thermodynamically stable as metallic state in the PEMFC operating condition such as pH, which causes the dissolution of transition metal and deactivation of PEMFC performance during repeated operation.

In this study, we tried to strengthen durability of the PtCo/C catalyst in PEMFC cathode. During PEMFC operation, Co^{2+} ion is dissolved from PtCo/C. To capture these Co^{2+} ion, we added N-doped carbon layer, consisting of mainly pyridinic N. We observed oxidation peak in cyclic voltammetry to confirm whether Co^{2+} is captured. Then, ORR performance was compared according to the amount of N-doped carbon. Also, accelerated stress test (AST) was conducted to evaluate the durability of catalyst with N-doped carbon.

Asymmetrical Electrode System for Large-scale Reverse Electrodialysis

Ji-Hyung Han

RED is an energy conversion system that generates electric power from a salinity gradient over ion-exchange membranes (IEMs) and is essentially pollution-free. In a large-scale one, the cathode is highly vulnerable to significant inorganic scaling due to the high pH conditions during water reduction and crossover of multivalent ions in the natural feed solution. We surmised that asymmetrical electrode system, where the geometrical area of the cathode is smaller than that of the anode, is a reasonable route to addressing the fouling issues. Because the minimized contact area between the electrode solution and feed solution by reducing the geometrical area of the cathode can decrease the amount of crossover caused by the non-ideal permselectivity of the IEM, uphill transport, and leakage, thereby decreasing the rate of precipitate formation or organic fouling. The change in the maximum power with varying area of the cathode was measured in lab-scale (100 cell pairs) and large-scale (1,000 cell pairs) RED systems to determine the minimum geometrical area of the cathode without significant power loss. It was confirmed that even though the area of the cathode corresponds to 60% of the area of an individual IEM, we can obtain the maximum power with only 3% of power loss in the large-scale RED stack. In addition, the asymmetrical electrode can be applied to a bipolar membrane (BPM)-RED system reported in our previous work. The high current density achieved by reducing the size of the cathode can induce vigorous water splitting in the BPM, which leads to more effective blocking crossover of the multivalent and hydroxide ions.

Nanostructured Cellulose Modified via Sulfonic Acid Crosslinking as a New Material for Proton Exchange Membrane

Nanostructured cellulose (nanocellulose) is an attractive material platform for proton exchange membrane, however its application for this purpose is not widely explored. The use of nanocellulose membranes in PEMFCs was pioneered by our group and previous works have demonstrated that both cellulose nanofiber (CNF) and cellulose nanocrystals (CNC) membranes can be used as PEM in hydrogen fuel cells (FC). However, membranes made of pristine nanocellulose have quite low proton conductivity and lack the stability at high temperature and humidity. The proton conductivity of unmodified CNF membrane was ~0.05 mS/cm and ~4 mS/cm for unmodified CNC membrane [Bayer, T. et al., Chem. Mater. 2016, 28, 4805–4814] and therefore requires significant improvement to be considered for FC application.

Conventional approaches for cellulosic materials modification (e.g. backbone sulfonation) can achieve better proton conductivity, but with worsening of mechanical properties, aqueous, and chemical stability. In contrast, crosslinking of nanocellulose was shown to provide improved mechanical properties and reduced swelling in water [Quellmalz et al. ACS Biomater. Sci. Eng. 2015, 1, 271−276], as well as better proton conductivity when an appropriate crosslinking agent is used (i.e. strong acid) [Seo J. A. et al. Ionics 2009 15, 555–560].

In this work we use chemical crosslinking of different forms of nanocellulose with sulfosuccinic acid (SSA) in order to improve properties needed for PEM applications. Crosslinking of cellulose nanofibers (CNF) and cellulose nanocrystals (CNC) membranes was performed in a hot-press, to form SSA-x-CNF and SSA-x-CNC membranes. Initial tests demonstrated that membranes with 10-30 μm thickness can be conveniently produced. Crosslinked membranes showed significantly decreased swelling in water, stability in boiling water, and increased through-plane proton conductivity.

Our research findings confirm the hypothesis that a properly selected crosslinking molecule can turn nanocellulose into an effective proton conductor. Mechanical properties, aqueous and chemical stability can be improved simultaneously. Investigation into the effect of crosslinking on mechanical strength, chemical stability, proton conductivity and fuel cell performance are still underway and will be reported.

A membraneless and separatorless multiphase flow battery

Lihi Amit, Matthew Suss
Faculty of Mechanical Engineering
Technion- Israel Institute of Technology, Haifa
lihiamit@campus.technion.ac.il

Storage of excess power generated via renewable sources, such as with wind turbines and solar plants, can help enable increased penetration of renewable sources into the electrical grid. Many flow battery (FB) chemistries have been investigated, and among them the zinc-bromine flow battery (ZBFB) is currently commercially deployed. The ZBFB exhibits favourable characteristics such as high open circuit voltage (OCV) of ~1.84 V, abundant and cheap reagents with bromine ~\$5/KWh and zinc ~\$2/KWh, and no requirements for precious metal catalysts. As the ZBFB operates in a closed loop form, the capacity of energy delivered during discharge is determined by the amount of electrodeposited zinc during charge. Traditionally, a membrane or separator divides an anode and cathode compartment, and the anolyte and catholyte flows. However, membraneless and separatorless cells offer simplified single flow operation and reduced cell cost. Several strategies for membraneless and separatorless cells have been investigated, namely laminar flow separations, utilization of immiscible electrolytes, use of complexing agents, and metal-based electrolytes.

Bromine complexing agents (BCA), such as quaternary ammonium bromide (QBr) salts, are example of electrolyte additives that sequester the bromine to form a separate dense polybromide phase[1], thereby enabling membraneless operation. After complexation, the concentration of active bromine in the aqueous phase is reduced by as much as two orders of magnitude. Since the sequestered bromine is phase-restricted, its diffusion towards the zinc electrode, which is the primary mechanism of self-discharge and of zinc corrosion, is significantly decreased. Such QBr are recognized also as controlling the zinc dendrite formation and growth at the zinc electrode[2]. Yet the addition of BCA comes at a cost, primarily blocking of surface reaction sites[3] and lowering the OCV[4].

We here report on a membraneless and separatorless ZBFB, which relies on a single, multiphase flow between the anode and cathode. The flow is an emulsion, consisting of a continuous, bromine-poor aqueous phase and dispersed particles of bromine-rich organic phase. We characterize the cell performance experimentally, including polarization curves, plating efficiency, and round trip energy efficiency. We elucidate key mechanisms behind the enhanced performance of this battery, demonstrating that increasing organic phase fraction allows for enhanced current capability.

Photocurrent measurement from the controlled monolayer deposition of photosynthetic reaction center proteins on a gold surface

Daniel Jun†, Sylvester Zhang*, Dan Bizzotto*

bizzotto@chem.ubc.ca

The photosynthetic reaction centre (RC) from *Rhodobacter sphaeroides* has been extensively studied for use in biohybrid solar cells. Much of the previous work has focussed on improvements of photocurrent generation, with currents reaching up to several uA. The basis behind these improvements was loading the electrode surface with many copies of the protein resulting in multilayers. The primary disadvantage with this approach is the random orientation of proteins, with some supposedly oriented properly. Rather than use this existing approach, we used RCs with Cys for covalent attachment to a gold electrode and for proper orientation. Areas of bare electrode surface and RCs bound non-specifically (i.e. not bound via the Cys) were competitively displaced by an insulating, non-redox layer of mercaptohexanol (MCH). We were able to determine through adsorption isotherm measurement that a single monolayer of RCs was produced, with the surface not covered by RCs passivated with an MCH blocking layer. The adsorbed monolayer of RCs was imaged using atomic force microscopy to detail the distribution of RCs on the gold surface for surfaces prepared with different RC deposition concentrations. Photocurrents were measured for all RC modified surfaces using a LED modulation method which enabled measurement of photocurrent in the presence of large faradaic currents at a variety of applied potentials.[1] The photocurrents generated from a monolayer composed of RCs and MCH resulted in much larger currents than without an MCH blocking layer. The rate of electron transfer generated via photoexcitation was measured with applied overpotential and a reorganization energy was determined. Our approach is different from established methods, in that instead of loading the electrode surface with multilayers, we built a single monolayer. Preparing a well-defined single monolayer is a superior approach for fundamental studies compared to maximising protein loading on the surface for consistent photocurrent generation.

Desloratadine (DESL) is a third-generation selective antihistaminic drug that functions as a H1-antagonist of histamine on cell receptor sites and is used to treat allergic symptoms without causing sedation. Severe side effects reported reinforce the need of simple, low cost, and precise methods for the determination of this drug. Voltammetric methods meet these requirements with multi-walled carbon nanotubes (MWCNTs) extensively being used to modify electrodes since, as a nanostructured material, present electrocatalytic features due to their high surface area and electron mobility [1]. The procedure of preparing and using MWCNTs as an electrode modifier is based upon their suspension/dispersion in a specific solvent before drop casting onto the electrode surface. Recently, polysaccharides were discovered that increase the water dispersive capability of carbon nanostructures [2]. In this sense, the polysaccharide carboxymethyl-botryosphaeran (CMB) was used to improve the dispersion of multi-walled carbon nanotubes (MWCNTs) in water, and this feature was applied in the modification of a glassy carbon electrode (GCE) to obtain a sensitive voltammetric sensor for the determination of DESL. CMB was obtained by the carboxymethylation of botryosphaeran, an exopolysaccharide produced by the fungus *Botryosphaeria rhodina* MAMB-05 [3]. The voltammetric measurements were performed in a three electrodes-arrangement electrochemical cell and a PGSTAT 101 potentiostat/galvanostat supported by NOVA 2.1.4 software. The supporting electrolyte of voltammetric measurements was a 0.10 mol L^{-1} KH_2PO_4 solution with the pH adjusted to 8.0 with 2.0 mol L^{-1} NaOH. The 1 mg mL^{-1} dispersion of MWCNTs in water was obtained in the presence of 1 mg mL^{-1} of CMB. An aliquot of 20 μL of this dispersion was dropped-cast into a polished-surface of a GCE and dried at room temperature. The morphology and spectroscopic behavior of the sensor were evaluated. SEM images of the unmodified and modified GCE indicated that CMB wrapped the MWCNTs allowing it to disperse into water due to the amphiphilic properties of the derivatized polysaccharide. The dispersion led to the formation of a homogeneous film on the GCE surface. The electroactive area of the modified sensor increased 53% compared to the unmodified GCE. Electrochemical impedance experiments showed that the addition of MWCNTs to GCE caused a drastic decrease (97%) in the charge transfer resistance, and after the incorporation of CMB, this resistance increased 28%. Initial exploratory studies revealed that DESL does not present an electrochemical response on the unmodified GCE in a potential scan from 0 to +1.4 V using cyclic voltammetry, but on the modified sensor, an irreversible anodic peak was observed at 1.15 V. The sensor preparation was uniform and the relative standard deviation of the DESL peak current obtained using three different modified electrodes was 1.12%. The oxidation of DESL was pH-dependent and the mechanism involves one proton and one electron. Linear sweep voltammetry was employed for the construction of the analytical curve. Different scan rates were tested, and statistically confident results were achieved using 25 mV s^{-1}. In this condition, the modified sensor presented a sensitivity of 1.018 μA L μmol^{-1} in the linear working range of 1.99–32.9 μmol L^{-1}, with a detection limit of 0.88 μmol L^{-1} of DESL. In addition, the sensor showed excellent repeatability with a relative standard deviation of only 1.02% over a sequence of 10 measurements. The selectivity was checked analyzing the influence of the presence of compounds present in the sample matrices in the current of DESL and no significant interference was observed at a ratio of 1:10 (DESL:interfering agent). The sensor was successfully applied in the analysis of pharmaceutical preparations containing DESL (tablets and oral solutions), with equivalent results compared to a validated spectrophotometric method at the 95% confidence level. The sensor was also employed in the analysis of a spiked sample in rat serum with recovery percentages ranging from 100 to 105%. The results confirmed that the MWCNTs and CMB modified GCE used in conjunction with the linear sweep voltammetry technique presented satisfactory performance in the determination of DESL in pharmaceutical and biological samples.

e-mail: dywu@xmu.edu.cn

The main problem in plasmon-mediated chemical reactions (PMCR) is how to promote the energy conversion efficiency of light energy to chemical energy. This low energy conversion efficiency is due to the ultrafast relaxation of surface plasmon resonance (SPR) and hot carriers generated from the SPR on metal nanostrucutes. In order to obtain the deep insight in the relationship of PMCR and SPR in metal surface of nanostructures, we investigate the chemical reaction processes of small organic molecules adsorbed silver electrodes. Here the laser is used to excite surface plasmon on silver nanoparticles modified silver electrodes. The small organic molecules are p-aminothiophenol (PATP) and 8-bromoadenine (8BrAd). The first molecule can be related to the hot hole oxidation process while the second molecule does the hot electron induced C-Br bond cleavage on the silver electrodes of nanostructures. The electrochemical surface-enhanced Raman spectroscopy was used to record the evolution of surface species under laser irradiations.

Our experimental results provide a pathway to connect photonic absorption and photoelectrochemical kinetics on surface SPR hot spots, which confine incident far field light to nanoscale surfaces and generate high energetic electrons and holes. From the time-dependent SERS signals and absorption spectroscopy, we can estimate the apparent rate constants of chemical reactions, such as the transformations of PATP to p,p'-dimercaptoazobenzene (DMAB) and 8BrAd to adenine adsorbed on silver electrodes of nanostructures, which can exhibit the strongest surface Raman signals. By combining the experimental results and density functional theory calculations, we provided the reaction mechanisms that describe well the role of the hot carriers driven chemical reactions. Now we use the quantum yield to estimate the energy conversion efficiency of chemical reactions due to the photogeneration of hot carriers, which involved to the SPR effect. The energy efficiency is still low close to 1%, which can be modulated by excitation wavelengths and applied potentials.

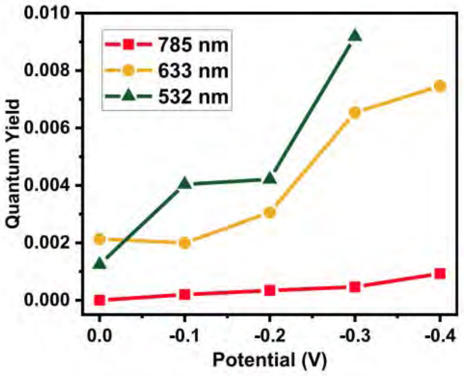

Figure 1. Quantum yield for energy conversion efficiency of PMCR in silver nanoparticles modified silver electrodes

Incorporating a Film of β-Glucan onto a Carbon Black Modified Electrode: A New Architecture for Sensing of Cyclobenzaprine

The application of nanomaterials for the development of new electrochemical platforms has received a great deal of attention due to the capacity of improvements in the signal/noise ratio, mass transport and catalytic behavior [1]. Carbon black (CB) is an example of a nanomaterial used to develop new electrochemical sensors. For improved adhesion, CB can be incorporated into a polysaccharide film, in this case, the β-glucan named botryosphaeran (BOT). Thus, the purpose of this work was to develop a novel architecture based upon a modified glassy carbon electrode (GCE) with CB onto a film of BOT (CB-BOT/GCE) for the voltammetric determination of cyclobenzaprine in pharmaceuticals, tap and lake water, and synthetic plasma. For modification of GCE, CB was first dispersed in dimethylformamide (2 mg mL^{-1}). After polishing the GCE surface, an aliquot of the CB dispersion was pipetted onto the surface of GCE concomitantly with a 3 µL solution of BOT (0.78 mg mL^{-1}) and allowed to dry for 3 h at room temperature. The modification of the GCE caused an increase in the electroactive area and electrochemical impedance spectroscopy showed an improvement of the electron transfer rate on the modified electrode surface compared to the unmodified GCE. The electrochemical behavior of cyclobenzaprine was investigated using cyclic voltammetry in a KCl solution resulting in an anodic peak at 0.97 V vs. (Ag/AgCl (3.0 mol L^{-1} KCl)). It was not possible to observe a reduction peak on the reverse scan, suggesting that cyclobenzaprine undergoes an irreversible reaction. The fabricated electrode showed a better analytical response, higher current magnitude, and lower oxidation potential for cyclobenzaprine, when compared to unmodified CGE or GCE modified only with CB or BOT. The concentration of CB in DMF was studied changing the amount of CB (1.0 – 3.0 mg mL^{-1}), with the highest current obtained using 3.0 mg mL^{-1}, but due a better repeatability of 2.0 mg mL^{-1} (relative standard deviation (RSD) = 1,64%), this concentration was chosen for subsequent analysis. NaCl solution (0.1 mol L^{-1}) was chosen as the supporting electrolyte for the determination of cyclobenzaprine. The voltammetric peak current obtained for 50 µmol L^{-1} cyclobenzaprine was observed over the scan rate range of 5 – 250 mV s^{-1}. The anodic peak current varied linearly with the scan rate, suggesting that the cyclobenzaprine redox process on the surface of CB-BOT/GCE was adsorption-controlled. The number of electrons (*n*) transferred in the oxidation of cyclobenzaprine on CB-BOT/GCE was estimated from the equation $E_p – E_{p/2} = 47.7$ mV/α*n*. The E_p and $E_{p/2}$ values were respectively, 0.98 and 0.91 V, where *n* in the oxidation of cyclobenzaprine was estimated to be 1. Following the optimization of the parameters of the square-wave voltammetry (SWV) and differential pulse voltammetry, the analytical curves were built using both techniques, due to better linear adjustment, higher sensitivity, and lower limit of detection (LOD), SWV technique was chosen for the determination of cyclobenzaprine. The anodic peak currents for cyclobenzaprine increased linearly with the concentration in the range of 2.0 to 20.6 µmol L^{-1}, following the regression equation $I/\mu A = -1.55 + 8.05 \times 10^5$ [cyclobenzaprine/mol L^{-1}] ($R^2 = 0.998$), with a LOD of 0.028 µmol L^{-1}. Lastly, the modified electrode was successfully applied for the determination of cyclobenzaprine in real samples of pharmaceutical products, whose results were statistically similar to those obtained using a volumetric method at a confidence level of 95%. The cyclobenzaprine concentration was also determined in tap and lake water, and in synthetic plasma with an average recovery of 98.2%. The results confirmed that the CB-BOT/GCE used in conjunction with the SWV technique presented a satisfactory performance in the determination of cyclobenzaprine in pharmaceutical, water, and biological samples.

In photosynthetic organisms, intracellular redox changes depending on the environment, which leads various acclimation processes in a cell. Thus, real time monitoring of intracellular redox of photosynthetic organisms is important for understanding their physiology. We have developed an electrochemical system which enable real time monitoring of intracellular redox by using a membrane permeable electron mediator: pMFc-Me_8 (Fig. 1). This method has applied to various organisms including photosynthetic microbes [1-3]. pMFc-Me_8 is comprised of 2-methacryloyloxyethyl phosphorylcholine (MPC) unit and ferrocene unit. MPC-based polymers are known to exhibit high cytocompatibility due to their protein adsorption resistance, which allows long time scale measurement of intracellular redox. Importantly, redox potential of the ferrocene unit (the mid-point potential (E_M): +0.18V vs. SHE) is adjusted to the level to that of plastoquinone (E_M: +0.1V), which enables us to monitor the redox change of photosynthetic electron transport chain *in vivo*.

In this study, we adapted this method for studying circadian clock, which is one of the photo-acclimation functions equipped in cyanobacterium *Synechococcus elongatus* PCC7942 (*S. elongatus*). The medium containing pMFc-Me_8 and *S. elongatus* cells was injected into an electrochemical cell with indium-tin-oxide (ITO) working electrode and Ag/AgCl reference electrode. The electrochemical assay revealed that intracellular redox of *S. elongatus* cell exhibited circadian rhythms under constant light conditions. When the transcription and translation of *kaiABC*, which are the essential clock genes [4], is defunctionalized, the redox rhythm disappeared. This fact indicated that the transcription and translation controlled by the KaiABC oscillator generates a circadian redox rhythm. It is noteworthy that the amplitude of the redox rhythm at a constant light condition was large enough to affect the KaiABC oscillator [5]. Based on this finding, the intracellular redox state in *S. elongatus* is supposed to actively controlled to change in a 24-h cycle under constant light conditions by the circadian clock system.

Modeling of Multi-Ion Transport in Shock Electrodialysis

Huanhuan Tian, Mohammad Alkhadra, Martin Bazant
Department of Chemical Engineering, Massachusetts Institute of Technology
77 Massachusetts Avenue, Cambridge, MA 02139
tianhh@mit.edu

Shock electrodialysis (SED) is a new water treatment method invented and developed by the Bazant lab. SED applies an over-limiting electric current through a membrane-sandwiched, slightly charged microporous material, which will induce a deionization shock and split the crossing stream into a fresh and a brine stream at the outlet. The process is continuous, and its energy requirement diminishes significantly for dilute feed solution. Desalination by SED was demonstrated early on, but it was only recently that we discovered the ability to continuously and selectively remove certain ions (mostly multivalent) from water, which indicate that SED has the potential to effectively remove trace toxic metal ions (mostly multivalent) from drinking water and industrious water at a very low cost, compared with other traditional water treatment methods which lack selectivity.

However, the selective ion removal by SED has not been well understood yet. Experimental data indicated that in most cases SED prefers to remove multivalent ions, but a counter example is the selective removal of K^+ from seawater. Moreover, the total desalination and ion removal selectivity can be dependent on various variables, such as current, feed component, surface chemistry, and geometry. Therefore, we want to develop models to help understand the multi-ion transport in SED. Though there have been simple models to roughly predict desalination of binary electrolyte system, it's the first time that multi-ion transport in SED has been modeled. In this work we have developed two models for multi-ion transport in SED: a traditional macroscopic model which solve for homogenized quantities in porous media, and a depth-averaged microscopic model for 3D planer channel. The latter one is able to include the pore-scale profiles, which may differ for different ions and lead to selective ion removal. We will use the two models to test various conditions, and evaluate the SED performance in terms of total desalination and ion removal selectivity. We will compare the results with our experiments and learn the mechanisms of selective ion removal, and then use the model to explain the experimental data and help optimize the experiments.

The demand for lithium resources is rapidly increasing with the production of lithium-ion batteries. Today's lithium is produced from brine or ore [1]. The issues of the former are long process time and large environmental burdens. The latter issue is the high cost for high purification [2]. To establish a better lithium recovery method, we have investigated lithium recovery by electrodialysis using lithium ion conductive solid electrolyte $Li_{0.29}La_{0.57}TiO_3$ (LLTO). The electrochemical impedance of electrodialysis is affected by the concentration of cations in solution. When this recovery is performed in a batch system, the lithium ion concentration of the solution changes as the recovery of lithium proceeds. Therefore, it is important to elucidate the influence of the lithium ion concentration in the solution on the electrochemical impedance. In this study, we investigate the effect of lithium ion concentration in the secondary solution on lithium recovery rate by electrodialysis using LLTO.

An anode (primary side) and a cathode (secondary side) electrodes were prepared on the surface of LLTO using a platinum paste. Reference electrodes was prepared on both surfaces of the LLTO at positions apart from the anode and cathode. A DC voltage of 2.0 V was applied between the anode and cathode. Electrochemical impedances were measured by the 3-terminal method using the reference electrodes and 2-terminal method. The primary side solution was a 1.0 M aqueous lithium hydroxide solution. The secondary side solution was pure water or an aqueous lithium hydroxide solution having a concentration of 10^{-3}-1.0 M. The amount of transferred lithium was estimated by Faraday's law using the current value.

As shown in Figure 1, the migration rate of lithium depended on the concentration of lithium ions in the secondary solution and reached a maximum at 10^{-2} M. The cause of this dependence was clarified by the AC impedance method.

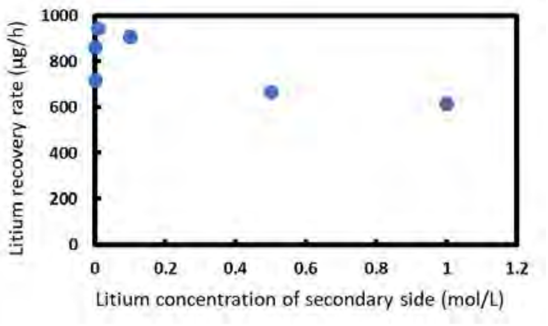

Figure 1 Lithium recovery rate at different lithium concentration in electrodialysis secondary solutions.

Comparison of kinetics and degradation mechanism of two isomers by electrochemistry

Xule Zhou, Qingqing Zhou, Zifeng Liu, Jiade Wang *
Zhejiang University of Technology
18, Chaowang Road, Hangzhou, China
jdwang@zjut.edu.cn

Dimethylphenols (DMPs) are one of the main organic compounds in the environment and annually are discharged 730,000 tons in the water environment, which are threating water quality. DMPs have six isomers, among which 2,4-Dimethylphenol (2,4-DMP) is listed as a priority by the US Environmental Protection Agency due to its high toxicity and 2,6-Dimethylphenol (2,6-DMP) also has long-term adverse effects on the aquatic environment. In this study, the differences in current density and hydroxyl radical utilization between the two isomers were compared. Besides, the intermediate products and degradation paths of two isomers were analyzed and discussed by in-situ FT-IR spectroscopy. The purpose of this study was to compare the electrolysis information of 2,4-DMP and 2,6-DMP in various aspects and revealed the influence of the position of the methyl on the benzene ring on the electrolysis conditions. It will provide a theoretical basis on the isomers pollutants of electrolytic in the future.

Fig. 1a showed that at the current density of 4.5mA cm^{-1}, the (kinetic constants) K of 2,4-DMP was 0.0049 min^{-1} and that of 2,6-DMP was 0.0166 min^{-1}, indicating that the degradation rate of 2,6-DMP was quicker than that of 2,4-DMP. Fig. 1b showed that the intensity of 2,4-DMP was higher than that of 2,6-DMP by electron spin technique (ESR) spectrometry, indicating that fewer hydroxyl groups were used in the electrochemical reaction of 2,4-DMP and the degradation rate was lower at the same current density. As shown in Fig.2, the main intermediate products of 2,4-DMP and 2,6-DMP pollutants were different. The main macromolecular intermediates of 2,4-DMP were 2-Methoxy-4-methylphenol (ethers) and a few of ketone, alcohols, carboxylic acids, while those of 2,6-DMP include 2,6-Dimethylbenzoquinone (quinones) and 5-Hexen-2-One (ketone) mainly and few of carboxylic acids. The open-loop voltage were both at 1.4V. As a result, the position of the group on the benzene ring of pollutants had significant influence on electrochemical information.

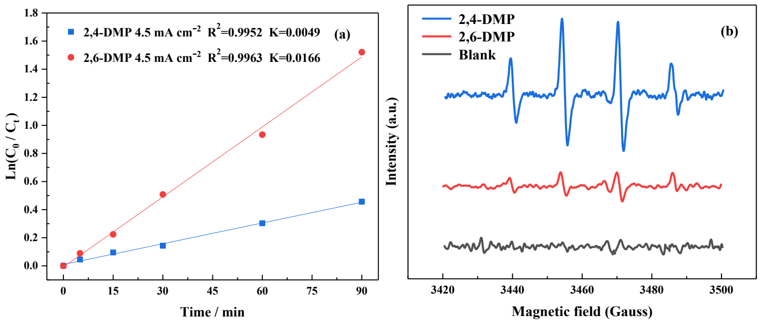

Fig. 1. Influence of pollutant structure on current density: (a) kinetic analysis, (b) •OH radicals utilization. (Ti/PbO_2 electrode, pH =5.8, Na_2SO_4 =0.1 mol L^{-1}; initial DMPs concentration =100 mg L^{-1}).

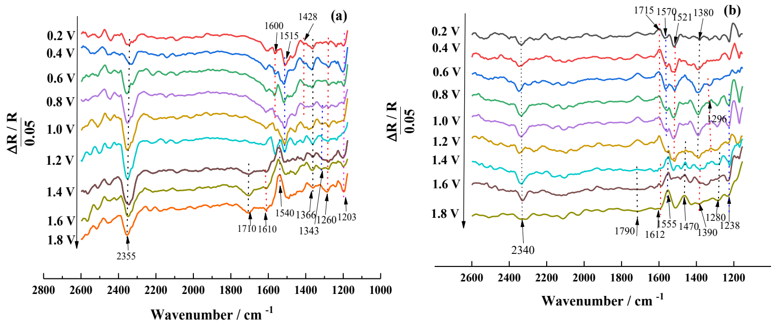

Fig.2. FTIR spectra collected for Ti/PbO_2 electrode, and the sample potential was stepped from 0.2V to 1.8V:(a) 2,4-DMP pollutant;(b) 2,6-DMP pollutant (Na_2SO_4=0.1mol L^{-1}; DMPs concentration=100 mg L^{-1}; pH =5.8;50 interferograms, p-polarised light, reference potential 0 V) .

We are studying covering the surface of the structural material of the divertor for thermonuclear fusion reactor in contact with the liquid metal with the corrosion resistant film. Here, the corrosion resistant film is a film that has compatibility with liquid metals and excellent high heat load resistance performance. In the case of the surface of the structural material facing the plasma is made of metal zirconium, if the zirconium surface is oxidized to be a corrosion-resistant film, it can have not only excellent compatibility and high heat load resistance performance, but also hydrogen-permeation prevention property. Furthermore, because zirconium oxide containing lattice defects at oxygen sites has oxygen ion conductivity, it is theoretically possible of in-situ diagnose of changes in the microstructure of the film due to changes in the conductivity characteristics measured by the AC impedance method. In this study, we measure the AC impedances of a dense oxide film prepared by the self-oxidation method in water vapor and an oxide film that has cracked by rapid thermal cycling (100 °C/h). Comparing with microstructure change observed by scanning electron microscope, we try to clarify the possibility of in-situ diagnosis by microstructure change by conductivity measurement *via* the AC impedance method.

Figure 1 shows cross-sectional SEM images of the zirconium oxide film (a: as prepared by the self-oxidation method, b: after rapid thermal cycle treatment). The zirconium oxide film prepared by the self-oxidation method was dense. By the rapid thermal cycle treatment, cracks with a width of about 1 μm and many small cracks were generated in the film parallel to the interface between the film and the Zr plate. Figure 2 shows Nyquist plots of the electrical conductivity measurement results in thickness direction of each film. After the crack was generated, the conductivity could be measured by AC impedance method, but the resistance increased 2.5 to 3.0 times of the dense film.

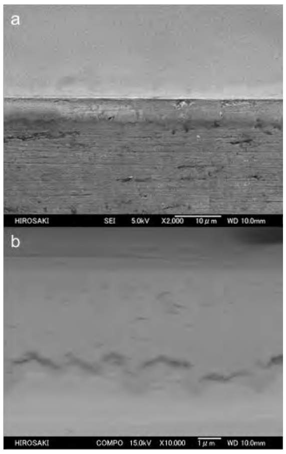

Figure 1. Cross-sectional SEM image of oxide film formed on Zr plate surface. a: as prepared film, b: after rapid thermal

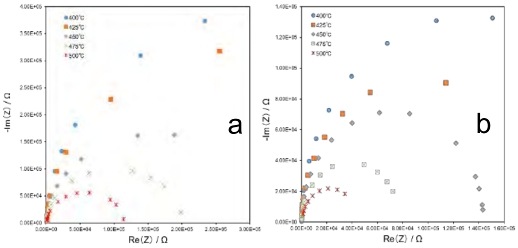

Figure 2. Electrical conductivity of oxide film by AC impedance method (Nyquist plots). a: Dense film after film formation, b: Crack-introduced film by rapid thermal cycle treatment.

Spectroelectrochemical Study of Phenol Oxidation on Platinum Electrode

Electrochemical oxidation is an effective way for the wastewater treatment due to its advantages of non-selectivity, highly controllability. Electrochemical in situ spectroscopy (FTIR), a real-time method, has been gradually used to study the mechanism of electrochemical oxidation/reduction in a molecular level. In this work, mechanism of phenol electro-oxidation was studied by cyclic voltammetry and in-situ FTIR on platinum electrode.

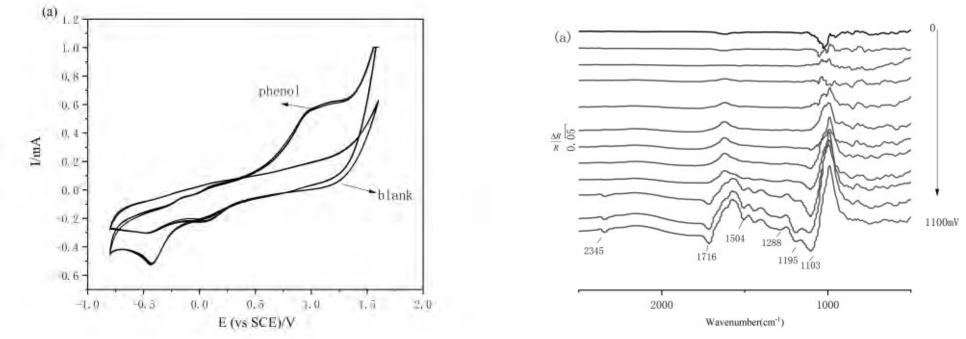

Fig. 1 Cyclic voltammetry (a) and in situ FTIR spectra (b) of phenol on Pt electrode surface

During the anode potential scanning, the oxidation of phenol appeared at 900 mV in contrast with the blank, showing that Pt electrode exhibited a high electrochemical activity for the oxidation of phenol. The bands appearing on the calculated spectrum was studied with variation of potentials (from 0 to 1.1V). The phenol degradation process was investigated and proved by several positive bands. Negative-going band appeared starting from potential 0.9 V, the intensity of which reached the most at 1.1 V. Negative-going band at 1103 cm^{-1} is assigned to the group of alcohol. Bands at 1288 cm^{-1}, 1716 cm^{-1} and 1504 cm^{-1} belong to the group of acid and carboxylate. Ketone and CO_2 were observed at 1195 cm^{-1} and 2345 cm^{-1}, respectively. Meanwhile, the result of GC-MS is consistent with the assignment of byproducts produced in FTIR experiment. All the results indicated that phenol can be thoroughly oxidized on Pt and the deduced mechanism is credible.

Additives for Low Temperature Performance of Na_2SO_4-Polyacrylamide Electrolytes

Alvin Virya and Keryn Lian
Department of Materials Science & Engineering, University of Toronto
184 College Street, Toronto, Ontario, Canada M5S 3E4
alvin.virya@utoronto.ca

Aqueous-based polymer electrolytes are key enablers for solid-state electrical double layer capacitors (EDLCs) that are inherently safe with thin and flexible form factors. Polymer electrolytes comprised of Na_2SO_4-polyacrylamide (PAM) were developed with high ionic conductivity, good chemical stability, and wide voltage window at ambient conditions. However, its ionic conductivity and ability to form EDLC were severely degraded below 0 ˚C due to the formation of crystal hydrates below the freezing point.

In this study, dimethyl sulfoxide (DMSO) was investigated as an additive, leveraging its deep eutectic properties with water, to improve the low temperature performance of Na_2SO_4-PAM. Various amount of DMSO was added into Na_2SO_4-PAM and its effects on the material and electrochemical properties under ambient and sub-zero temperature were assessed. Raman microscopy revealed electrolyte films with homogenous and chemically compatible mixture. The electrochemical performance of Na_2SO_4-PAM at ambient temperature was minimally affected by DMSO. Meanwhile, the addition of DMSO enhanced the ionic conductivity Na_2SO_4-PAM below 0 ˚C (Fig. 1a) and allowed its enabled cells with activated carbon electrodes to maintain near-rectangular CV profile at -10 ˚C (Fig. 1b). Thus far, DMSO has been demonstrated as a good additive to widen the operating temperature range of Na_2SO_4-PAM.

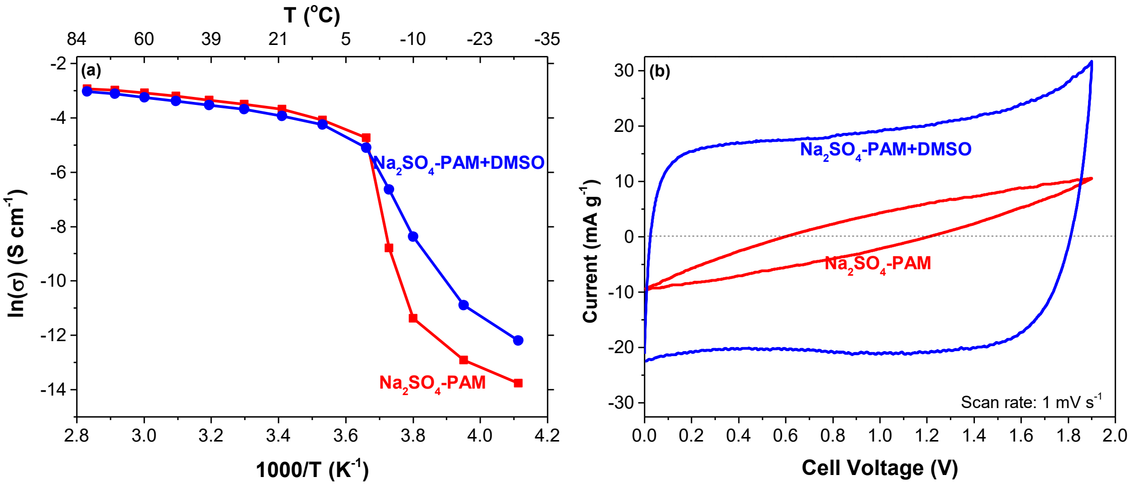

Figure 1: Comparison in performance of Na_2SO_4-PAM+DMSO vs Na_2SO_4-PAM on their (a) ionic conductivities (Arrhenius plot) and (b) CV of activated carbon devices (-10 °C, 1 mV s^{-1})

Electrochemical Properties of CVD Graphene on Copper Substrate

Piotr Ozga, Agnieszka Hara, Zbigniew Świątek, Janusz Pstruś
Institute of Metallurgy and Materials Science of the Polish Academy of Sciences,

p.ozga@imim.pl

Highly Oriented Pyrolytic Graphite (HOPG) as also real graphene sheets have surfaces with heterogeneous electrochemical properties according to the structure of sites: basal, edge, defect in the basal site etc. Each type of sites has own electrochemical activity with different Butler-Volmer terms and cyclic voltammetric profiles of a given redox pair [1]. However, there are also other important electrochemical processes as the evolution of hydrogen and electrodeposition on the graphene surface. Growth of graphene using the CVD method (so-called CVD graphene) on mono- and polycrystalline copper surfaces give the possibility to obtain large-area graphene coatings [2]. The μ-Raman Spectroscopy (μ-RS) is very sensitive on the properties of graphene layers and this method enables the possibility to characterise the following main properties of CVD graphene: (i) number of layers of graphene coating; (ii) type and density of defects, (iii) deformation/stresses in graphene coating and (iv) doping charge. Simultaneously, this method permits the determination of some deposition products as tin and tin-zinc alloys as also their changes during formation processes. The relatively large areas of sample can be analysed on the base of a set of spectra from the small areas (about 1 μm^2 in used experimental conditions). This allows the formulation of statistical description, and a graphical representation of the distribution of heterogeneity of graphene layers in micro-areas simultaneously with the description of deposition products. The surface topography and roughness of the substrates were examined using atomic force microscopy (AFM, tapping mode). The examinations of the electrodeposition processes were done using copper, tin and tin-zinc alloys on the copper substrate covered by CVD graphene. The processes of the electrodeposition of Cu, Sn and Sn-Zn layers as also hydrogen evolution from citrate solutions on graphene/copper substrate were investigated and optimal parameters were determined. The obtained results indicate a strong influence of defects in CVD graphene materials (types, density), an important role of substrate preparation (topography, roughness, oxidation) and influence of electrodeposition conditions on the properties of the graphene layers. The damages of graphene coatings by the evolution of hydrogen were analysed by μ-Raman Spectroscopy and optical microscopy (Fig.1). The electrodeposition of tin on such damaged layers appears selective deposition of tin only on the not damaged graphene layer and lack of tin on the uncover copper surface (Fig. 2). The electrodeposition of tin-zinc alloys gives similar results. The results of E-pH diagrams calculations for Cu-H_2O, Cu-SO_4^{2-}-H_2O etc. in experimental conditions were presented and electrochemical processes on graphene/copper surfaces were conducted potentiostatically for chosen and different E-pH parameters where Cu, CuO, Cu_2O, Cu_2O-B_2O_3 (in borate buffer environment) were dominant compounds. The surfaces of samples after potentiostatic experiments were investigated by AFM, μ-RS and OM. The CVD graphene protects the copper surface against oxidation except some areas contain the defects in the graphene layer.

Synergistic Effect between Pt Active Sites and Readily Oxidized Secondary Metal in Partially Disordered Pt-M Electrocatalysts for Methanol and CO Oxidation

Hsiang-Sheng Chen, Tania M. Benedetti, Jiaxin Lian, Cameron H. W. Kelly, Peter B. O'Mara, Kazeem O. Sulaiman, Robert W.J. Scott, Soshan Cheong, Christopher E. Marjo, J. Justin Gooding and Richard D. Tilley

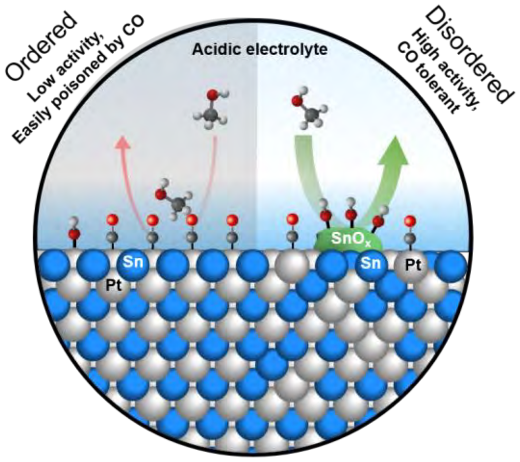
Hsiang-sheng.chen@unsw.edu.au



Synergistic effect between Pt or Pd active sites that adsorb CO and metal oxides of less noble metal that dissociate water to form OH_{ad} is commonly regarded as the reason bimetallic catalysts outperform pure-metal catalysts in processes that include CO oxidation.[1] It has been shown that alloy catalysts shorten the distance between sites for CO_{ad} and sites for OH_{ad} into sub-nano range and are effective in oxidizing CO at much lower overpotential than non-alloyed catalysts with similar compositions.[2] To answer whether the highest intimacy between atoms of Pt and secondary metal in the ordered configuration could further enhance the activity, we modify the degree of ordering of Pt_3Sn nanocubes while maintaining the exposed {100} facets to exclude the influence of exposing facets.[3] Strikingly, the 60% ordered Pt_3Sn nanocubes outperform the 95% ordered Pt_3Sn nanocubes for the methanol oxidation reaction by almost 5 times when considering the charge of the oxidation peak in the anodic direction of the cyclic voltammograms. The onset potentials of methanol oxidation and CO oxidation using the 60% ordered Pt_3Sn nanocubes is about 150 mV more negative than those using the 95% ordered Pt_3Sn nanocubes. Moreover, we demonstrate the outstanding tolerance to CO of less ordered Pt_3Sn nanocubes comparing to the 95% ordered Pt_3Sn nanocubes by saturating the electrolyte with CO during methanol oxidation. XANES spectra suggests that the d-band structures of the Pt in different degree of ordering are quite similar, whereas the XPS spectra reveal that the Sn at less ordered configuration are easier to be oxidized under the oxidative potential during methanol oxidation reaction, which provides more abundant OH_{ad} in the vicinity of Pt-CO that boosts CO oxidation. This model system shows that ordered alloys are not always more active than their disordered counterparts, and CO oxidation via the Tafel-Heyrovsky mechanism is more facile on the disordered phase of alloy catalysts.

The increasing concerns on severe environmental issues and rapid fossil fuel depletion stimulate the intensive interests in renewable and sustainable energy sources. Hydrogen energy through electrochemical water splitting is considered as one of ideal options to feed energy demand without environmental concerns. The challenge for its commercialization is to minimize the electricity consumption and cost, which requires the efficient, low-cost and durable electrocatalysts for hydrogen evolution reaction (HER) at the cathode and oxygen evolution reaction (OER) at the anode.

The catalytic performance of electrocatalysts are closely related to the intrinsic activity and the number of the accessible catalytic sites in the electrocatalysts. This presentation will focus on the exploration of earth-abundant efficient HER and OER electrocatalysts with an emphasis on the performance boosting by the synergistic engineering of catalyst structures. Several reasonable strategies will be introduced for rationally engineering the morphological structure, electronic structure, and crystalline structure of electrocatalyst to augment the accessible catalytic sites and boost their intrinsic activity, leading to the significant performance enhancement of these low-cost materials for practical applications.[1-3] These results will open opportunities for the rational design and bottom-up synthesis of cost-effective and high-performance electrocatalysts for sustainable hydrogen production through electrochemical water splitting.

Iron-Containing Porphyrins Self-Assembled on ZnO Nanoparticles as Electrocatalytic Materials for Oxygen Reduction

Jia Li, Jianguo Liu*
National Laboratory of Solid-State Microstructures, College of Engineering and Applied Sciences,
Nanjing University
22 Hankou Road, 210093, Nanjing, PR China
lijia0226@nju.edu.cn, jianguoliu@nju.edu.cns

Nonprecious metal electrocatalysts (NPMEs) have been recognized as highly promising oxygen electroreduction catalysts, but improving their activity and stability in acidic electrolyte remains critical. The use of porous materials with high specific surface area is one of the most direct and effective ways to increase their activity. Here, we integrated self-assembly technology induced by rotary evaporation with the hard-template method to synthesize Fe-N-codoped NPMEs with large specific surface areas and hierarchical pore structure. The presence of Fe^{3+} dramatically decreased the carbonization temperature of the precursors and the vaporization temperature of carbothermally reduced zinc, which is beneficial for both the in situ growth of micropores/mesopores within the carbon layers and the retention of more nitrogen-containing groups. Meanwhile, iron atoms present in the obtained Fe-N-C/ZnO electrocatalyst established FeNx ORR active sites. The obtained Fe-N-C/ZnO porous carbon material exhibited outstanding oxygen reduction reaction catalytic activity with $E_{1/2}$ of 0.78 V (vs. RHE), along with respectable electrochemical stability in a perchloric acid electrolyte (only a 7 mV negative shift after the durability test). Applied in fuel cells, the electrocatalyst loading was reduced to 2.0 mg/cm^2 because of increased mass transfer arising from the hierarchical porous structure and resulting in a power density of 700 mW/cm^2. The significantly improved activity and durability are contributed by the hierarchical porous structure and direct 4e$^-$ ORR mechanism of NPMEs.

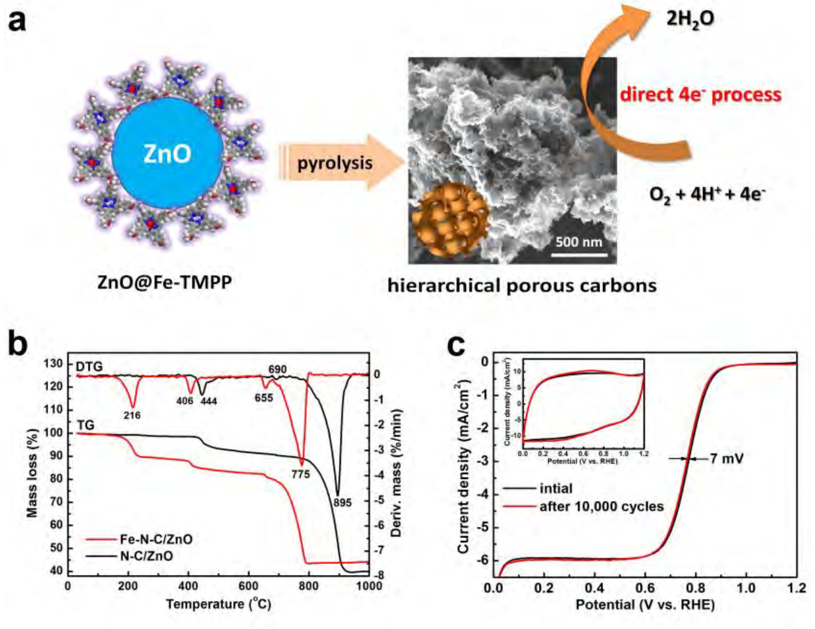

Figure 1 (a) Schematic synthetic process of porous carbon materials; (b) TG and DTG curves of precursors collected in N_2; (c) ORR polarization curves and CV curves (inset) measured before and after the durability test (0.6-1.0 V, 10,000 cycles).

A New Electrochemical Sensor Based on Oxidized Capsaicin/MWCNT/GCE for Xanthurenic Acid, Ascorbic Acid, Dopamine, Epinephrine and Uric Acid Quantification

Andresa K. A. de Almeida (1*), Leonardo Vieira da Silva(2), Nicholas D. dos Santos(1), Andresa K. A. de Almeida(1), Dave Di E.R. dos Santos(1), M. O. F. Goulart(1)
1Instituto de Química e Biotecnologia, UFAL, Maceió, Al; 2Instituto Federal de Educação, Ciência e Tecnologia de Alagoas, IFAL, 57020-600 Maceió, AL, Brazil. andresanjinho@hotmail.com.

Chemically modified electrodes have been developed and present advantages, such as low price, portability and good analytical performance for the detection of target analytes [1]. In the present case, capsaicin (CAP) was used as a redox mediator and added to multi-walled carbon nanotubes (MWCNT) modified glassy carbon electrode (GCE). The CV profile for the oxidation of CAP is displayed in figure 1A, together with the possible oxidation mechanism (Fig. 1B). The presence of the redox system (IIa/IIc) is important for the redox catalysis, which can be understood through the formation of carbocation, which undergoes hydrolysis with the formation of quinones, responsible for the reversible system [1,2] (Fig. 1B). This modified platform was applied for the determination of xanthurenic acid (XA), ascorbic acid (AA), dopamine (DA), epinephrine (EP) and uric acid (UA), one at a time, using cyclic voltammetry (Fig. 1C) and chronoamperometry, in buffered aqueous solutions, pH 7.0. The diffusion coefficients (*D*) for XA was obtained as 5.67 x 10^{-5} cm^2 s^{-1}; for AA, 1.23 x 10^{-6} cm^2 s^{-1}; for DA, 6.97 x 10^{-4} cm^2 s^{-1}; for EP, 4.00 x 10^{-5} cm^2 s^{-1} and for uric acid, 3.0 x 10^{-5} cm^2 s^{-1}The obtained analytical curves for XA, AA, DA, EP and UA showed linear ranges, between 10–95, 5–75, 5-115, 50-1150 and 5–70 μmol L^{-1}, respectively. The detection limits were 8.76, 1.95, 1.80, 7.20 and 1.56 μmol L^{-1} for XA, AA, DA, EP and UA, respectively. The catalytic constants for the oxidation of XA, AA, DA, EP and UA on the modified electrode were 5.94 × 10^4, 1.45 × 10^4, 3.12 x 10^5, 2.41 x 10^4 and 2.10 × 10^3 L mol^{-1} s^{-1}, respectively. This oxidized capsaicin-based platform is reported for the first time and is able to detect the analytes at a micromolar level.

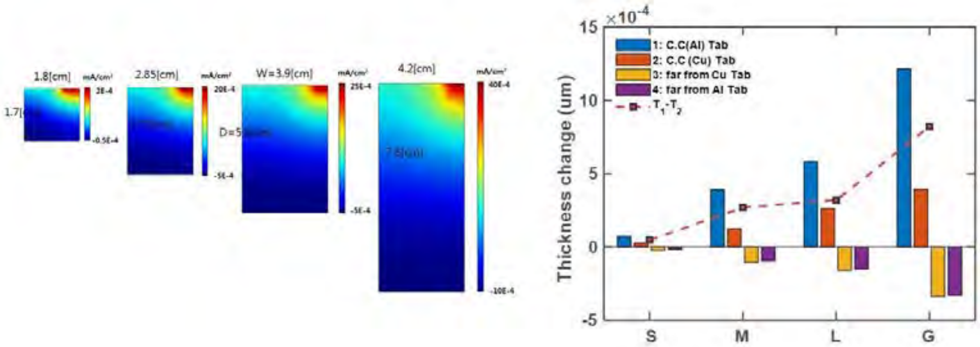
Full Cell Design Consideration for Uniform Lithium Distribution in Lithium Metal Rechargeable Battery

Goojin Jeong,[1] Hee-Kook Kang,[1] Janghyuk Moon,[2] Ye Ji Kim,[1] Sang-Gil Woo,[1] Je-Nam Lee,[1] Ji-Sang Yu[1]
[1] *Advanced Batteries Research Center, Korea Electronics Technology Institute, Seongnam, Republic of Korea.*
[2] *School of Energy System Engineering, Chung-Ang University, Seoul, Republic of Koreae-mail address*

In a Li-metal rechargeable battery, it is critical to prevent the formation of dendritic or “dead” Li and stabilize the interface between the Li-metal and the electrolyte. Electrolyte composition, surface protective layer, and/or three-dimensional Li host structure are expected to play an important role for improving Li-metal anode performance. However, how to control the nonuniformity of current distribution and the corresponding spatial difference in Li volume change in a Li-metal anode can be another big issue once the Li-metal anode is operated under large areal cell format. Therefore, new strategies for uniform Li plating and stripping throughout the large Li-metal area are required in addition to the well-studied microscopic interfacial material designs for practical application of Li-metal rechargeable battery. This work exhibits relationship between Li uniformity and cell design factors in a large areal pouch cell format, and potentially promising strategy for improving the Li uniformity by changing cell component design, for example, current collector for Li-metal anode, which was simultaneously studied by mathematical modelling and experimental methods. These findings provide new perspectives for the design of large areal Li-metal rechargeable batteries needed for the practical application.



<Fig. 1. Mathematical modelling on Li-metal thickness change after 1 cycle in various cell size format>

Expansion of the potential region for the sustained discharge of non-aqueous Li-O_2 batteries by surface modifications of the positive electrode

Kiho Nishioka [a], Shuji Nakanishi [a]
[a] *Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan*
nishioka@rcsec.chem.es.osaka-u.ac.jp

Non-aqueous Li-O_2 batteries are one of the next-generation batteries, which has a much higher theoretical energy density than the state-of-the-art Li-ion batteries. However, due to non-conductivity of Li_2O_2 formed on the cathode as the discharge product, the capacity is limited to be much smaller than the theoretical value. There are two different paths, surface and solution paths, for the Li_2O_2 formation, the latter of which is advantageous for the sustained discharge of Li-O_2 batteries.[1] It is now known that (1) positive electrode potential is a critical factor determining the reaction path, and (2) there is an optimal potential window where the solution path becomes dominant.[2] Considering the above facts, in this study, I aimed to expand the potential window for the sustained discharge by modifying the surface of the positive electrode.

Figs. 1(a) and (b) show discharge profiles at various potentials obtained for pristine carbon paper (p-CP) and surface-modified carbon paper (m-CP) positive electrode, respectively.[3] Surface modification of the CP was conducted by immersing p-CP in a hot acid (H_2SO_4:HNO_3 = 3:1) for 2 h. For the p-CP, the discharge capacity exceeded 100 mAh/g_{carbon} at 2.2 and 2.4 V, whereas it was less than 10 mAh/g_{carbon} at 1.8 and 2.0 V. This indicates that the discharge reaction occurred via surface and solution paths at lower and higher potentials, respectively. Almost no cathodic current was obtained at 2.6 V on the p-CP. On the contrary, for the m-CP, large discharge capacity in the range between 80 and 100 mAh/g_{carbon} was obtained at all potentials examined. It should be noted that a large discharge capacity was obtained even at 2.6 V (Fig. 1c). Thus, it was revealed that the potential window for the sustained discharge could be expanded by the surface modification of the CP.

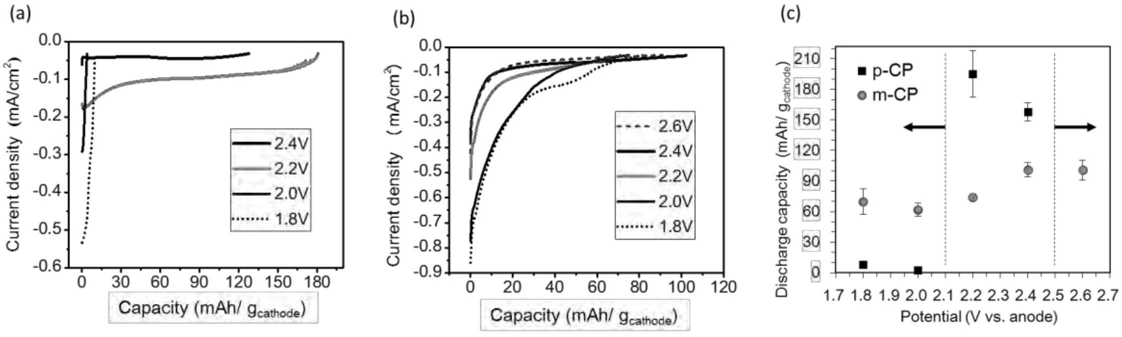


Figure. 1 Discharge profiles at various positive electrode potentials for (a) p-CP and (b) m-CP. (c) Discharge capacity vs. potential plots for p-CP and m-CP.

Mesoporous silica FDU-12 presents applications in several fields of science, including food and environmental analysis, pollutant adsorption, catalysis, drug delivery, enzymatic immobilization, nanoscience, biotechnology, and recently in the field of immunology with advances towards the research of vaccines and oral vaccines, but there are few reports about the use of this material on sensors development.(1,2) In this work, FDU-12 structures were synthesized in acidic medium using tetraethoxysilane (TEOS), Pluronic 127 (triblock polymer),1,3,5-trimethyl benzene as a porous expander, and KCl as a catalyst.(3) The materials were characterized using Thermogravimetry, SAXS, and Nitrogen Adsorption Isotherm. The specific area of two synthesized materials was evaluated using BET methods ($602m^2/g$ and $700m^2/g$) and these materials were used to prepare carbon paste modified electrodes (FDU-12/CPMEs). The experimental conditions to obtain a very reproducible carbon paste (graphite/oil ration; order of the reagent additions; homogenization method and presence of humidity) were primarily optimized for the construction of the modified electrodes, which contained 74.1% of graphite, 18% of nujol 7,9% of FDU-12 concerning the total paste content. The FDU-12/CPME behavior was evaluated using cyclic voltammetry with $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ as an electrochemical probe. The presence of the FDU-12 in the composition of the modified electrode improved the performance of the electrode: increase in the current peak levels, maintenance of the cathodic and anodic peak potentials until υ values as high as $1Vs^{-1}$ and a subtle shift on the oxidation peak potential to the less positive potential, Figure 1. The improved performance of the modified electrode resulted from the synergic effects between high surface area and good mesoporous structuration of the silica FDU-12.

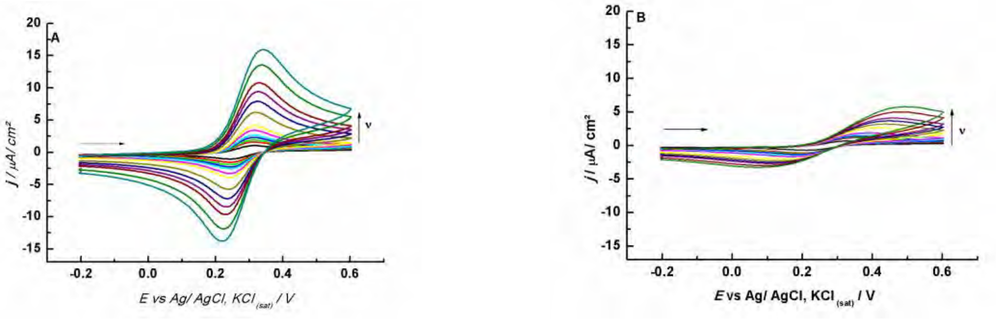

Figure 1. Cyclic voltammograms obtained with: **(A)** (FDU-12/CPME) and **(B)** CPE in 0.5mM of $[Fe(CN)_6]^{3-}$ plus 0.5mM $[Fe(CN)_6]^{4-}$ in 0.5M KCl, at υ from 10 to $1000mVs^{-1}$.

Copper nanoparticles (CuNPs) are considered as potential antimicrobial agents due to their improved stability and safety, and longer active period than that of organic nanomaterials, with multi-targeted mechanism of action [1]. Nevertheless, metal NPs can suffer from agglomeration, reducing their antibacterial activity [2]. Cu incorporation in inorganic substrates such as metal oxides or montmorillonite (MMT) plays an important role due to the possibilities of creating an antibacterial nanomaterial with slow release of Cu species in order to obtain a prolonged antibacterial activity. Therefore, CuNPs were synthesized via a rapid electrochemical method using the inorganic micro-powders as carrier. Characterization studies on the nanocomposite were done by Scanning electron microscopy (SEM), Transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). The as-prepared Cu-based nanocomposites could be employed for inhibiting the growth of biofilms.

On the investigation of the influence of surface crystallography and local packing density on the stability of thiolated DNA SAMs

Tianxiao Ma, Isaac Martens & Dan Bizzotto
University of British Columbia
2036 Main Mall Vancouver, BC, V6T 1Z4
matianxi@chem.ubc.ca

The stability of DNA self-assembled monolayer (SAMs) on gold electrode has drawn great attention in the biosensing field.[1,2] The performance and the lifespan or stability of the fabricated biosensor determine the reliability of the test results in early disease detection and point-of-care use.[3,4] The thermal stability of a mixed SAMs composed of a short alkythiol and alkythiol modified DNA prepared at OCP (open circuit potential) on a single crystal gold bead electrode were studied. These SAMs were carefully evaluated in buffer using in-situ fluorescence microscopy and electrochemical measurements. The single crystal bead electrode enabled study of a number of surface crystallographies in a self-consistent manner. For a selection of surface crystallographic regions, the stability and the functionability of the SAMs were studied after thermal treatment from 25 °C to 95 °C for 2 hours in buffer. The analysis showed that surfaces with hexagonal symmetry (111, 311, 211) were less stable than those with rectangular or square symmetry (110, 100, 210) which suggests that the characteristics of the surface should be carefully considered when using for sensor application. It was also observed that the packing density of the SAMs influences thermal stability since high DNA coverage slows the kinetics of thermal desorption which is beneficial for making more stable sensor. However it has been shown that low coverage DNA SAM has shown to be optimal for effective biosensing[5] and it seems to be challenging to make DNA SAMs with both low coverage and high thermal stability by using current SAM preparation protocols. In this study, we found that using potential assisted deposition can help to achieve DNA SAMs with both higher thermal stability than those made at OCP and with a good control of surface coverage. This study may help to explain the inconsistent results from the DNA SAMs during the experiments while the solution was heated[6] and provides valuable insights on improving the DNA biosensor preparation method in order to optimize the stability and the functionability at the same time.

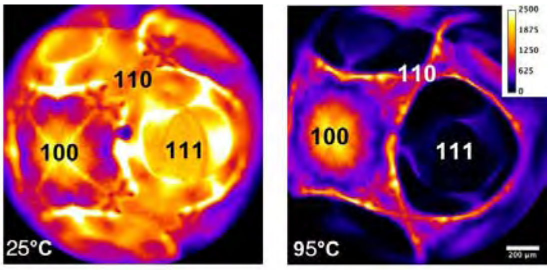

Figure 1: An example of the thermally induced changes in the fluorescence images of the single crystal gold bead electrode for a MCH/DNA SAM. The sample was prepared by 90 min in 1 mM MCH and 24 hrs in 1.0 µM DNA at 25 °C. The images were taken in buffer after the thermal treatment from 25 °C to 95 °C. The selection of crystallographic map is provided to guide interpretation of the images.

The necessity for greener energy sources has been the major driving force in fuel research during the last decades, and it has driven the production of renewable fuels, such as biodiesel, from which glycerol is generated as a co-product. Glycerol is one of the several organic molecules which can be used in the cogeneration of electricity and platform chemicals in fuel cells, or in the simultaneous generation of hydrogen gas and chemicals in an electrolysis cell, a strategy called paired electrosynthesis (1). In this context, the main goal of our work is to develop Pt-based electrocatalysts for the electro-oxidation of glycerol (EOG) in alkaline media. In this work, we study the effects of the modification by Bi (2) and Pb (3) adatoms on both polycrystalline and single crystals of the main crystallographic orientations. In both cases, we found that adding the metal ions to the electrolyte resulted in the highest improvement of catalytic activity. The experiments with single crystals showed that the EOG activity on all facets was improved, with the (110) orientation showing the highest increase in current density (figure 1). *In situ* FTIR revealed that both adatoms block the adsorption of CO on Pt and suppresses the pathways in which C-C bonds are broken, seen in a reduction of the carbonate bands (2,3). Further investigation with online HPLC confirmed this observation, evidenced by the significant enhancement in the glycerate production (figure 2). We ascribed these results to a stabilization of several reaction intermediates through an interaction between its hydroxyl groups and the positively charged adatoms (4). We are currently studying the effect of other p-block adatoms to understand how each of them influence the electrode activity and the reaction selectivity.

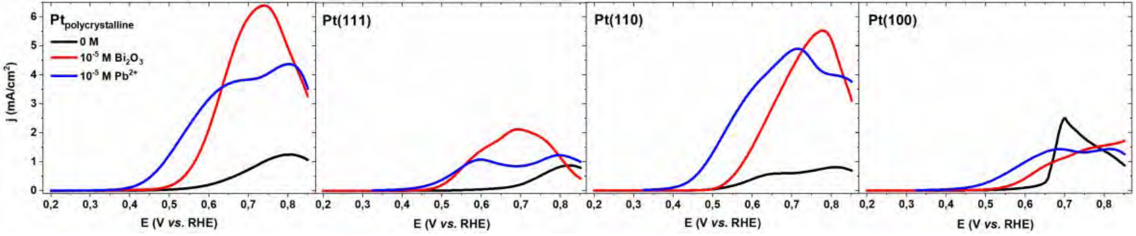

Figure 1: Effect of adding Bi (red) and Pb (blue) to the electrolyte during the EOG on Pt electrodes. Base electrolyte composition was 0.1 M NaOH + 0.1 M glycerol with addition of either 10^{-5} M Bi_2O_3 (red) or 10^{-5} M Pb^{2+} (blue). Scan rate was 10 mV/s. Adapted from (3).

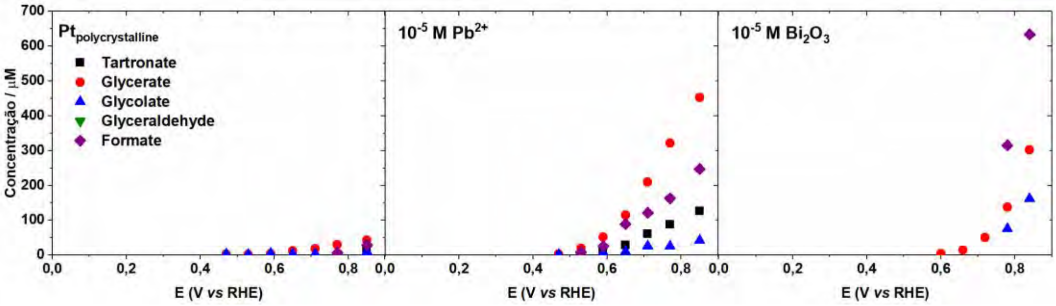

Figure 2: Distribution of the EOG oxidation products with electrode potential for polycrystalline Pt (left), Pb-Pt (center) and Bi-Pt (right) systems. Adapted from (2,3).

Edoxaban (EDX) is a novel oral anticoagulant drug, approved by the FDA in 2015 to prevent stroke in atrial fibrillation [1]. EDX act as a competitive inhibitor of factor Xa with higher selectivity compared to thrombin [2]. Here, we present a preliminary study on the electrooxidation of EDX in aqueous media. The voltammograms were recorded using a potentiostat/galvanostat Autolab PGSTAT128 (Ecochemie, Holland) interfaced to a computer and controlled by NOVA 2.1 software. The experiment was carried out in a Britton-Robinson buffer solution using a three-electrode system consisting of a carbon paste electrode (4 mm of diameter) as the working electrode, a Pt wire as the counter electrode, and SCE as the reference electrode. EDX was first dissolved in a mixture of water and acetonitrile (50:50) to prepare a stock solution. Fig. 1 shows the chemical structure of edoxaban and the cyclic voltammograms registered at different concentrations of the drug. The voltammograms show two overlapped peaks in the range of 0.8 - 1.0 V, and another with higher intensity at a more positive potential, about 1.3 V. As they all increased by increasing the concentration of EDX, and no peak was observed by adding only acetonitrile, theses peaks can be attributed to the oxidation process of EDX. The three peaks shifted towards less positive potentials by varying the pH from 5.0 to 10.0 with a visible reduction of the intensity. The effect of the scan rate (25 - 500 mV s^{-1}) was also evaluated. More analyses are being conducted to acquire more information about the electrooxidation process of EDX.

Acknowledgments. The authors thank the financial support of the INCT of Bioanalytical (CNPq/INCT), CNPQ, PPGQ/UFRGS, PROPESQ/UFRGS, as well as to CAPES for the PhD scholarship to M.O. Rocha.

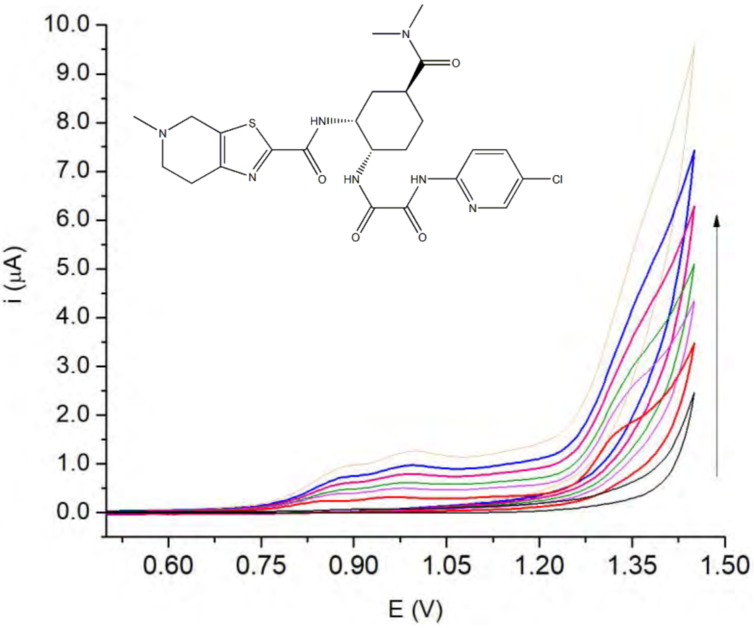

Fig. 1. Cyclic voltammograms at different concentrations of edoxaban obtained in Britton-Robinson buffer solution (pH =6.0) at a scan rate of 50 mV s^{-1}. Arrow indicates concentrations of 0, 10, 20, 30, 40, 50, and 60 μg mL^{-1}.

Gold micro/nanostructures are fascinating due to their wide range of applications in areas including electronics, catalysis, biomedicine, and chemical sensing [1]. Besides their active surface area, they exhibit optical, electronic, and chemical properties that make them promising candidates for the design and fabrication of highly effective electrochemical platforms. There are many synthetic routes to produce different shapes of gold structures [2]. Among the various procedures reported in the literature, electrodeposition is an efficient and convenient method to create gold micro/nanostructures. The size and morphology can be facile controlled by changing the concentration of the gold precursor, the electrolytic solution, the technique, applied potential, and time of experiment [3]. In this work, different gold microstructures were obtained on the surface of screen-printed carbon electrodes (SPCE) by performing constant-potential electrolysis and consecutive cyclic voltammograms. All measurements were performed using a potentiostat/galvanostat Autolab PGSTAT128 (Ecochemie, Holland) interfaced to a computer and controlled by NOVA 2.1 software. The electrolyte solution consisted of a solution of 0.1 M Na_2SO_4 and 30 mM HAuCl4, prepared with ultrapure water (Milli-Q system, 18.2 MΩ cm). Leaf-shaped gold microstructures resulted by carrying out by applying a potential of -0.6V during 600 s. However, different kinds of structures appeared after twenty consecutive cycles of voltammograms registered at 50, 100, and 200 mV s^{-1}. Fig. 1 shows the scanning electron microscopy (SEM) images. These structures significantly increased the electrode surface area of SPCE, as confirmed by comparing the electrochemical response of 1 mM ferricyanide at the electrode surface before and after the electrodeposition.

Microbial Electrosynthesis Systems (MES) use electricity and microorganisms to produce energy carriers, such as hydrogen (H_2) or methane (CH_4). In what can be called Bioelectrochemical Power-to-Gas (BEP2G) process, MES combines CO_2 sequestration, renewable energy carrier production, and energy storage. In this study, a continuous conversion of CO_2 to CH_4 in a laboratory-scale MES is achieved. The MES cell for CH_4 production was built using Plexiglass plates assembled to create two compartments divided by two layers of electrically insulating Nylon cloth with a total area of 96 cm^2 (anode-cathode interface area). The cathode compartment consisted of a stainless-steel mesh (current collector) and it was filled with 45 g of carbon felt pieces. The anode consisted of a Ti/IrO_2 mesh current collector. The cathode compartment was maintained at a constant temperature of 30°C and continuously supplied with CO_2 and a solution of nutrients. The cathode compartment was initially inoculated with 20 mL of homogenized anaerobic sludge. To further increase the CH_4 production rate, nickel was (*in-situ*) electrodeposited on the cathode carbon felt.

The introduction of Ni at 0.2 g L^{-1} into the influent exhibited a remarkable improvement in CO_2 conversion. At an applied voltage of 2.8 V, the MES with the Ni-modified carbon-felt cathode accomplished a CH_4 production rate of 2.3 L d^{-1}, which was by 30% higher than before Ni was introduced into the influent stream (1.6 L d^{-1}). Similar improvements were noted with other performance parameters, such as the Coulombic efficiency and the energy consumption, which considerably improved from 56% to 73% and 11.5 Wh L_{H2}^{-1} to 7.4 Wh L_{H2}^{-1}, respectively. Furthermore, when the dissolved Ni was removed from the influent solution, the cell performance remained unchanged, suggesting successful *in-situ* electrodeposition of Ni on carbon felt. Electrochemical characterization using the cyclic voltammetry technique confirmed Ni electrodeposition. Overall, the experiment was carried out for over 60 days without observable performance deterioration. In fact, somewhat improved performance was observed with time, likely due to the development of a stable electroactive biofilm. These results demonstrated a great potential of using *in-situ* Ni electrodeposition to improve catalytic properties of the MES biocathode. It can be concluded that bioelectrochemical conversion of CO_2 to CH_4 can be exploited as a potential technology for continuous stable BEP2G conversion combined with CO_2 sequestration.

Can perovskite oxides be used as catalysts for the concomitant production of hydrogen and fine chemicals in electrolyzers?

The increasing concern about pollution is generating opportunities for bio-based economies. Biomass-derived molecules like glycerol (G) can be utilized as feedstock for the production of value-added chemicals and high purity H_2 in low temperature electrolyzers[1]. In traditional water based electrolyzers the overpotential needed to run the device is high (around 2V), increasing the cost of H_2 production. Once water is substituted at the anode compartment by biomass derivative, the possibility of running the electrolyzer device with smaller overpotential arises as shown in Figure 1. Noble metal-based electrocatalysts are well known for the electrooxidation of small organic molecules, but its high cost and scarcity hinders the application in large scale[2]. Thus, in this work we discuss the possibilities for the application of perovskites oxides (PO) for the electrooxidation of small organic molecules. PO can be synthesized using highly abundant, cheap and non-hazardous materials. Also, they are very versatile due to their compositional (then structural) flexibility[3]. PO have been evaluated for oxygen evolution reaction (OER) with promising results in terms of activity[4]. Considering the oxidation of small alcohols, preliminary studies have shown that PO can oxidize methanol[5], ethanol[6] and glycerol[7] with smaller overpotential than needed for OER. However, the overall performance of these materials with organics are still far from those obtained with noble metals[8]. Thus, systematic studies about the use of PO in anodes for biomass conversion are necessary to link its physicochemical properties with its activity. In this context, fundamental studies involving *in situ* techniques and computational experiments are mandatory to speed up the fundamental knowledge in the field and open the door for the rational development of more active and selective materials.

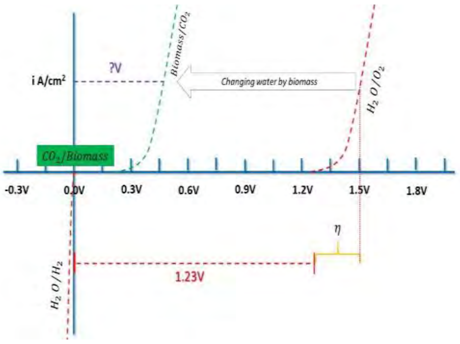

Figure 1: Most important reactions and electrochemical parameters for low temperature electrolyzers. In this method, water oxidation begins at 1.23V and the current follows a Butler-Volmer relationship between current density and potential. The potential at the anode must be equal to 1.23V + η to operate the system at a current of "i A / cm^2." However, with a pricey catalyst like Pt, the hydrogen reaction may be powered close to the reversible potential. Standard potentials for the complete oxidation of several biomass molecules have values around the green rectangle. The difference in potential between the arbitrary I-V curve of the biomass oxidation and the I-V curve of the water oxidation shows that the potential input needed for an electrolyzer is decreased to 1V.

Degradation of petroleum hydrocarbons (HC) in sediments is often limited by the availability of electron acceptors. Cable bacteria may stimulate the regeneration of sulphate in the anoxic sediment by allowing long-distance electron transport (LDET) to the oxic overlying water, thereby accelerating petroleum HC degradation. Incubations of crude-oil contaminated sediment, showed that cable bacteria accelerate alkanes degradation by +24% compared to control sediment where the growth of cable bacteria was inhibited. Similar degradation rates (+25%) were obtained via the application of graphite snorkels. The combined application of cable bacteria and snorkels yielded the highest rates of HC removal (+46%), and sulphate production via sulphide re-oxidation.

Screening data show that cable bacteria can be common in HC-polluted sediments. Cable bacteria may thus represent key and so far, overlooked players in the self-healing capacity of sediments upon HC spillage, and inspire novel biotechnological approaches for sediment remediation.

Using ion-selective electrodes and mercury microelectrodes: Towards mapping local ion gradients

Tom Philipp, Christine Kranz
Institute of Analytical and Bioanalytical Chemistry, Ulm University, Albert-Einstein-Allee 11, 89081 Ulm, Germany
tom.philipp@uni-ulm.de

The ion and electron transfer processes at interfaces between electrolyte and electrode are of pivotal importance for the overall performance of Li-ion and post-Li batteries. Due to these processes, degradation of the electrode material as well as the electrolyte takes place and an interphase is formed. This solid electrolyte interphase (SEI) at the anode and cathode electrolyte interphase (CEI), respectively, is essential for a stable and safe operation of battery systems such as Li-ion battery and other alkali ion based batteries, since it serves as a protective layer which prevents further decomposition of the electrode and electrolyte while maintaining ionic conductivity. The formation processes of these interphases are not yet fully understood and they are characterized by heterogeneities. Hence, characterization techniques providing spatially resolved information are pivotal to elucidate the heterogenous nature of the interphase as well as the role of the shuttling ion in the formation process. [1]

The combination of a scanning probe microscopy technique such as scanning electrochemical microscopy (SECM) with ion-selective electrodes (ISE), as already shown for biological samples [2,3], or mercury microelectrodes [4] allows the localized and selective detection as well as mapping of ion gradients with high spatial resolution. Due to information on kinetics, ion concentration and substrate reactivity gained from the electrochemical approach and information on local heterogeneity, topographical and morphological changes gained from the scanning probe approach, conclusions on the mechanism of the SEI/CEI formation can be drawn. Next to the fabrication and thorough characterization of micro-ISEs for battery relevant ion sensing as well as mercury microelectrodes for the detection of cations, first SECM measurements at model electrodes will be presented.

lorenzo.ripani@studio.unibo.it

Digital simulation is a powerful tool in electrochemistry to investigate complex systems in which many variables influence the current-potential response, i.e. homogeneous chemical reactions, convection and multiple electron transfers.

The electrochemical reduction of CO_2 (CO_2RR) is complicated by a variety of phenomena, i.e. homogeneous chemical reactions, hydration of CO_2, acid-base equilibria of bicarbonate and carbonate. Moreover, bicarbonate electrolyte has been experimentally proven not only to be a buffer agent, but to actively participate in the electrochemical reaction of CO_2RR, providing CO_2 and to hydrogen evolution reaction (HER) as a proton donor. Thus, understanding the changes in surface concentration of the species is crucial, as they are involved in the equations of the reaction rates.

In this study, we developed a microkinetic model of CO_2 electrochemical reduction of carbon dioxide and hydrogen evolution reaction in bicarbonate electrolyte based on our previous experimental measurements of CO_2RR and HER under well-defined mass transport condition[1].
The surface concentration obtained by microkinetic modelling have been used to calculate the reaction rates of CO_2RR based on different reaction mechanisms. Then, we tested the agreement between the current-potential curves obtained from experiments with the theoretical ones.

Microbial biofilms are known to exhibit an increased tolerance against biocides and antibiotic treatments in comparison with their planktonic counterparts. Due to their high resilience, biofilms contaminate medical implants and are difficult to eliminate, leading to serious problems for infection controls, increased contaminations and mortality of patients [1]. Novel therapies to prevent biofilm growth, include, among other strategies, coatings containing metal-based nanoparticles (NPs), which are intensively studied [2], in respect to their ability to disrupt biofilms. In presence of silver(I), a stimulation of bacterial respiration is detected with the consequent death of the microbes: this mechanism is also reported in biofilms [3].
In this contribution, silver(I) is studied biocomplateble AgNPs-fluoropolymer (Ag-CF_x) composite films, which were prepared by ion beam sputtering (IBS) deposition [4], are investigated as antimicrobial substrates. The mechanism of the silver(I) release is studied ex-situ by electrothermal atomic absorption spectroscopy (ETAAS) and in-situ by scanning electrochemical microscopy (SECM) in combination with square-wave stripping voltammetry (Fig. 1). In addition, the relation between silver(I) release and the swelling of Ag-CF_x films will be presented, combining electrochemical techniques and atomic force microscopy (AFM).

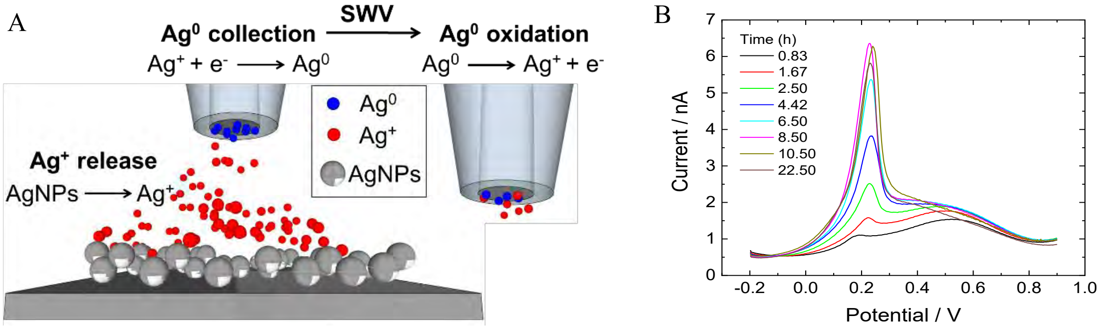

Fig. 1. (A) Scheme of silver(I) release study with SECM-SWV. (B) Square wave voltammograms at different immersion times of Ag-CF_x samples in KNO_3 0.1 M.

Using iron sulphate to form both pseudo-n-type and p-type liquid thermoelectrics: Non-hazardous and ‘second life’ thermogalvanic cells

Mark A. Buckingham, Kristine Laws, Leigh Aldous
King’s College London
7 Trinity Street, Britannia House, SE1 1DB
Mark.buckingham@kcl.ac.uk

Liquid thermoelectric (or thermogalvanic) cells use a redox-active couple to convert a temperature difference between two electrodes (ΔT) to electricity (ΔV) through the Seebeck effect, where potential difference generated as a function of temperature difference is obserevd as the Seebeck coefficient (Se) where: Se = $\Delta V/\Delta T$. High Seebeck coefficient redox couples such as the acidified $Fe^{2+/3+}$ [1] and $[Fe(CN)_6]^{3-/4-}$ [2] have been fundamentally assessed previously in our group. These systems display Se of *ca.* +1.4 and -1.4 mV K^{-1} (for the $Fe^{2+/3+}$ and $[Fe(CN)_6]^{3-/4-}$ systems respectively), where the positive and negative signs indicate that the hot electrode acts as the cathode or anode respectively.

The main drawback with thermogalvanic cells is the low overall voltage generated from these systems, to overcome this, positive and negative Se systems need to be utilized electrically in series (shown in Fig. 1). To date, the $Fe^{2+/3+}$ and $[Fe(CN)_6]^{3-/4-}$ systems have been typically utilized as combinations of positive and negative Se systems to generate higher voltage devices. However, a combination of the $Fe^{2+/3+}$ and $[Fe(CN)_6]^{3-/4-}$ systems has the potential to evolve high concentrations of toxic HCN. [3] Due to the potential toxicity of the evolved products, a benign combination of positive and negative Se systems needs to be developed to achieve high voltage devices.

Here, we demonstrate that a both positive and negative Se systems have been developed from $Fe(II)SO_4$ and $Fe(III)SO_4$ and an excess of either the $[HSO_4]^-$ or $[SO_4]^{2-}$ ions. Crucially, we also demonstrate that these systems can be mixed safely, where the resulting mixture solution is also found to maintain thermogalvanic activity as a positive Se system that can easily be electrically connected. This demonstrates a single-source, multi-functional thermogalvanic cell that even when mixed maintains thermogalvanic activity, which we coin as a ‘second-life’ thermogalvanic cell, that removes the inherent risk associated with the current state-of-the-art system.

Voronoi Diagrams and Diffusion at Random Arrays of Active Sites

Giovanni Pireddu, Irina Svir, Alexander Oleinick, Christian Amatore

CNRS, 24 rue Lhomond, 75005 Paris, France
giovanni.pireddu@ens.psl.eu

Many practical systems at micro- and nanoscale can be represented as arrays of active sites distributed randomly [1]. As shown previously these systems can be efficiently addressed theoretically by using Voronoi diagrams [2, 3] which allows facile tessellation of the system into the unit cells around each active sites. The overall current flowing in the system can then be evaluated by modelling diffusion-reaction processes inside every unit cell and summing the contributions from individual active sites. Although this approach is tempting by its simplicity and efficiency [3] one should bear in mind that Voronoi diagram representing the unit cells by polygonal prisms remains approximation and as each approximation remains valid only under certain conditions. In this work [4] we show that even for the case of diffusion limited electron transfer (ET) the actual shapes of the unit cells are more complicated and depend on the local configuration of the neighbouring active sites. This was exemplified on the small patches of the random arrays with band-like and disk-like active sites via simulations and in the case of band-like active sites confirmed by analytical derivations.

Importantly, by comparing the total array current obtained by employing Voronoi tessellation and simulation of the system without any approximations we found that they agree well (relative error ca. 5% or less). At the same time, the individual contributions from the active sites are reproduced with a much larger relative error [4]. The latter suggests that in the case of kinetic control or reaction mechanisms that are more complicated than simple ET the diffusion-reaction competition between the active sites may become even stronger eventually leading to significant deviations from the total current predicted on the basis of the Voronoi approximation. This is currently investigated in our team.

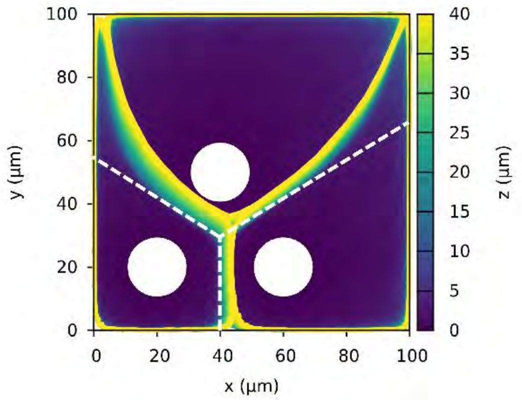

Fig. 1. Comparison between the Voronoi tessellation boundaries (white dashed lines) and the actual boundaries (coloured surface) of the unit cells. Three disk-type active sites are shown as white disks.

Microbial fuel cells (MFCs), which generate electrical energy through a bioelectrogenesis process, are considered one of the most efficient alternative technologies [1]. Two electrochemical processes occur inside the cell: at the anode the oxidation of a biodegradable organic substrate and at the cathode a reduction reaction with oxygen from the ambient, which together lead to current generation and reduction of the organic matter contents. Although considered a promising technology for the generation of electricity, due to the simultaneous generation and wastewater treatment [2], there is the need of process characterization to overcome the limitations encountered during scaling up [3]. This work presents the study of the process variables of a MFC prototype built with low-cost and recycled materials. Three 1 L MFCs were built and installed at UTA, using domestic wastewater as substrate, graphite felt cathode, and electrocatalyst obtained from recycled anodes from alkaline batteries; graphite felt anode; proton exchange membrane of treated wood and external electrical resistance of 500 Ω as shown in Fig. 1. The cells were instrumented to measure voltage, internal reactor temperatures, ambient temperature and relative humidity. Conductivity, pH, salinity, and TDS were measured on a HACH multiparameter and chemical oxygen demand (COD) with a Hanna Instruments photometer. In the first 100 hours a 72% decrease in COD and 74% decrease of pH in 3 MFCs was observed due to the metabolic activity of bacteria (Fig. 2,3). After 100 hours of acclimatization, the best performing cell (MFC3) started with recharging of new substrate. The voltage evolution during the 180-hour operation is shown in Fig 4. As conclusion, oxidation and reduction reaction exist and maximum electrical values were 0.298 V and 0.59 mA. This characterization of the factors that affect the cell will establish the bases for the construction of a wastewater treatment plant in this University.

Finding new ways for sustainable energy production and storage has been the object of intense research over last decade. In this context, Fuel Cells (FCs) have attracted much attention thanks to the use of hydrogen, which is retained to be the energy vector of the future. Commercial low temperature FCs are based on a Proton Exchange Membrane (PEM), such as Nafion®. However, the high cost of these devices, chiefly due to the use of Platinum Metal Group elements as electrocatalysts (ECs), prevents their large-scale application. Anion Exchange Membranes (AEMs) are largely investigated because the use of an alkaline pH environment opens the possibility to exploit cheaper ECs based on Fe, Ni, Ag [1]. Moreover, the alkaline environment facilitates the Oxygen Reduction Reaction at the cathode with respect to PEM working conditions [2].

Here we present a synthetic strategy to convert commercial protonic membranes into AEM. In particular, the polyfluorinated PEM Aquivion® EW=980 g/mol (Solvay) is functionalized by reaction with aqueous diamine solution to obtain sulfonamide AEM (see insert of Fig. 1). This allows to maintain the same mechanical and chemical resistance of the pristine membrane but at the same time, it increases the thermal stability thanks to the formation of sulfonamide bonds. This functionalization is carried out in an aqueous media, which is clearly advantageous from the environmental point of view. The in-plane conductivity is 1,1*10^{-1} Scm^{-1} at 80°C and with relative humidity 100%.

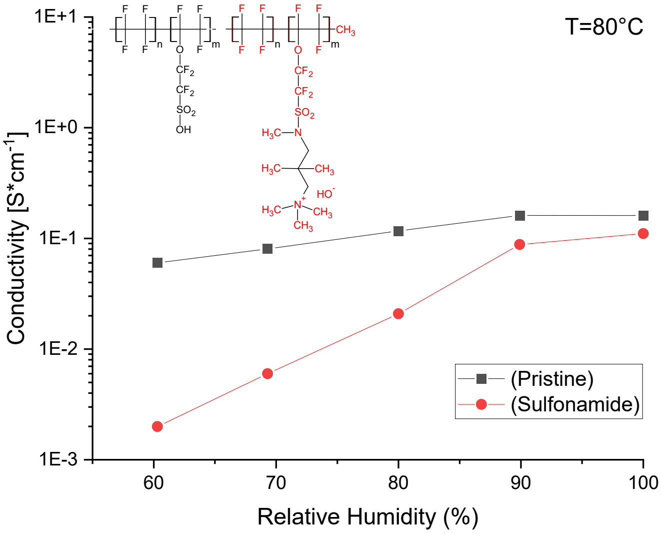

Fig. 1 - Conductivity measured as a function of the Relative Humidity for the Pristine (black) and the Sulfonamide (red) Aquivion® at 80°C. The inset shows the polymer structure of PEM (left) and AEM (right) Aquivion®.

Redox-flow batteries (RFBs) can play a crucial role in the future electricity supply to balance the time lag between the generation of electrical energy from photovoltaics or wind power and the demand for electrical energy. However, to deploy the technology on a large scale, significant cost reductions are required. For this task, a thorough understanding of the reactions and processes taking place within a redox-flow battery is crucial and this knowledge can be significantly improved by using a suitable mathematical model to describe the processes in a single cell of an RFB. However, the available mass transport correlations result in Sherwood numbers which vary over two orders of magnitude [1-5] and therefore significantly affect the accuracy of the model.

In this work the validation of a two-dimensional model for the prediction of polarization curves of an RFB is presented, focusing on the refinement of the mass transport correlation. Newly developed potential probes are used for in-situ measurements of solid and liquid phase potentials within a vanadium RFB [6, 7]. Combined with systematic variation of flow rate and state of charge, the experiments build a robust data base. After parameter estimation, the model predictions are in good agreement with the experimental data (exemplary shown in Fig 1 A). The resulting mass transport correlation is well in line with the most appropriate literature data (Fig. 1 B). Using the improved correlation, the RFB model provides more accurate predictions and better support for optimizing the cell design.

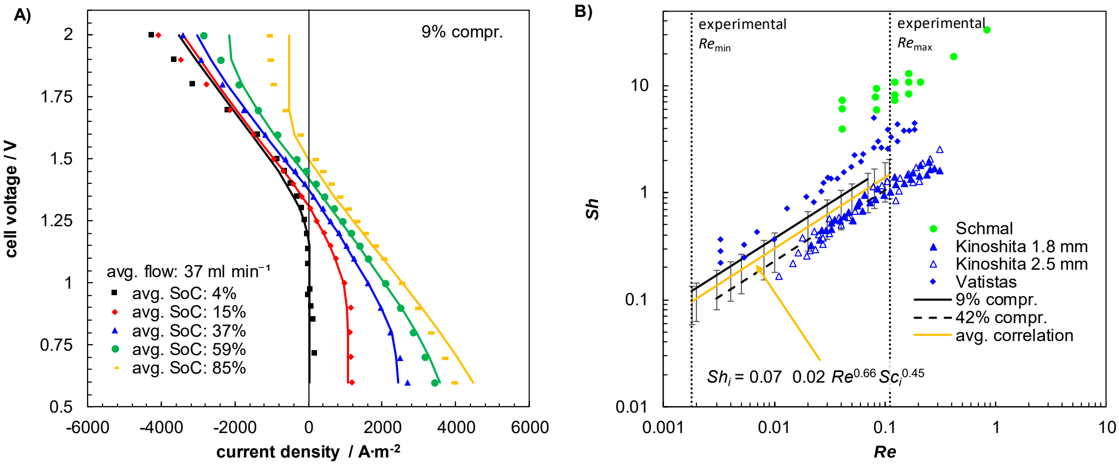

Figure 1: A) Exemplary polarization curves of a 100 cm² cell setup with GFD4.6A carbon felt and Nafion® 117 membrane for low (left) and high (right) flow rate. Flow rate and state of charge of each half-cell electrolyte are given within the figure. Compression rate of the carbon felt is 9%. Points represent experimental data, lines indicate simulations. B) Dimensionless Sherwood correlations from literature compared to results from model-based parameter estimation.

Long term oxygen sensing in 3D hydrogel scaffold cell cultures

Elżbieta Jarosińska, Zuzanna Zambrowska, Emilia Witkowska Nery
Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, 01-124, Warsaw, Poland
ejarosinska@ichf.edu.pl

The launch of a new drug is an extremely long and expensive process, lasting from 7 to 15 years with costs exceeding $1400 mln per drug[1]. The process includes: basic research; *in vitro* (with 2D cell cultures) and *in vivo* (using animals) preclinical research and in the end clinical trials. Animal models are controversial not only because of the ethical aspects, but also because of their imperfect reflection of the human body, which results in over 30% drugs withdrawals during the clinical trial phase[2].

Three dimensional cultures are an alternative providing a better understanding of complex cell–cell interactions. In contrary to simple monolayer cultures, they allow cell growth in all directions as well as secretion of signaling molecules and specific proteins in normal levels as in the human body[3]. Among many culture systems, hydrogels are the most promising platforms for cell cultures due to their transparency, good diffusion of nutrients and similarity to many soft tissues[4]. While traditional analysis is mostly based on optical methods including broadly understood microscopy techniques and measurements of fluorescence, analysis in 3D requires more advanced and expensive techniques in order to reach deep structures. This is the main reason why 3D cell cultures have not yet achieved wide implementation despite their obvious advantages over 2D cultures and more than 50 years of research. However, using electrochemistry, we are able to do real-time analysis *in vitro.* Oxygen and glucose consumption measurements provide us with a lot of information about cell viability and can be translated to toxicity during tests of new drugs.

For such systems electrodes need to withstand prolonged (at least 3-4 weeks) contact with the cell culture matrix and the surrounding medium, thus biofouling is a major issue. That is why we have tested major antifouling layers including: polymers (e.g. Nafion®, phenylenediamine, polyvinyl chloride, polysilicate matrix), hydrogels (e.g. polyhydroxyethyl methacrylate), protein (e.g. albumin), polyethylene glycol and poly-L-lactic acid. Electrodes were first coated with syringaldazine, which is easily adsorbed on carbon surfaces and provides an easy to interpret response towards pH changes[5]. It is also very stable in buffer solutions but quickly desorbs in more complex media, thus making it an excellent probe for measurement of beneficial impact of antifouling layers. Tests were first conducted on macro- glassy carbon electrodes and later on low-cost pencil based sensors (250 μm diameter) as it was shown that some layers are less stable due to the big size of the electrode surface. It was revelated that polysilicate matrix, poly-L-lactic acid, polyhydroxyethyl methacrylate are suitable candidates for antifouling layers for electrochemical sensors.

At the same time we conducted experiments directed at possibilities of oxygen sensing in hydrogels at various potentials. Initial experiments revealed that 2,9-dimethyl-1,10-phenanthroline as well as a porphyrin complexes with cobalt effectively reduce the potential value for oxygen sensing as compared with Nafion® coated sensors, in both acidic and neutral pH. While in PBS results are immediate, measurement in hydrogels results in the answer extended in time, indicating diffusion problems. Current measurements include oxygen sensing not only in hydrogels and cell culture medium but also with growing cells.

Application of a Schiff base derivative denatured cytochrome c analogue, for the analytical reporting of nitric oxide.

A Farao, P Baker; F Ajayi

SensorLab, Department of Chemistry, University of the Western Cape, PB X17, Bellville 7535, South Africa; *2427770@myuwc.ac.za*

Biointergrated sensors involve the biological electron transport between proteins and polymeric materials. Immobilization of biomolecules often compromise the activity of the enzyme. Losses have been attributed to conformational changes or interactions between the biomolecule and the solid surface. Investigations into the redox behaviour of cytochrome c revealed compromised electron transfer to metal surfaces as result of adsorption denaturation[24]. Modification of electrode surfaces by chemisorbed self-assembled monolayers (SAM) resolved this limitation. NO has been reported to coordinate strongly with the iron heme of cytochrome c to form linear nitrosyls with the Fe^{2+} metal centres. Coordination of nitric oxide to the iron centres are expected to alter the redox behaviour of the system. However, nitric oxide has been reported to exhibit trans-effects which would inhibit coordination to the iron centre. Similar findings were recorded in study to reproduce the electrochemistry of denatured cytochrome C. The poor electrochemical response of the denatured cytochrome c metal centre to nitric oxide was attributed to steric crowding surrounding the heme.

In this work, a novel Schiff base was synthesized by cross-linking naphthalene to pyrrole to produce the monomer, N,N-bis((1H-pyrrol-2-yl)methylene)naphthalene-2,3-diamine), by simple reflux chemistry. The structural analysis of the ligand-Fe complex indicated a square planar co-ordination that presented Fe in a favourable position for NO co-ordination.

A novel Schiff base was synthesized by cross-linking naphthalene to pyrrole to produce the monomer, N,N-bis((1H-pyrrol-2-yl)methylene)naphthalene-2,3-diamine). The iron ligand complex was electrodeposited onto screen printed carbon electrodes (SPCE) for electrochemical evaluation, over the potential window of -1 V and 1 V vs Ag/AgCl. The sensor demonstrated electrochemical properties analogous to that of the denatured cytochrome c system. The response of the sensor towards NO generated in situ from the NO donor, diazeniumdiolates (Z)-1-(N,N-diethylamino)-diazen-1-ium-1,2-diolate (DEANONOate), which spontaneously decomposes to nitric oxide in neutral pH. The quantitative analysis of NO was evaluated by spectroscopic and electrochemical methods, with very promising results.

Electrochemical and Physico-Chemical Properties of the Separation Materials for Lithium-Ion Batteries on the Basis of Electrospun PVDF|PTFE, PP and Glass Fibers

Semen V. Makhov, Aleksandr V. Ivanishchev
Institute of Chemistry Saratov State University
Astrakhanskaya str. 83, Saratov 410012, Russia
semen_mahov@mail.ru

Nanofibers materials produced by electrospinning method can be applied as separators in lithium-ion batteries. This method of synthesis is characterized by simplicity of hardware design, high energy efficiency and variability of conditions. The separation material based on polyvinylidene fluoride (PVDF) and its copolymer with polytetrafluoroethylene (PTFE) was obtained by capillary-less electrospinning [1]. In the present work the optimal synthesis conditions were established. The average fiber diameter was determined in the range of 100-250 nm by scanning electron microscopy (MIRA LMU Tescan) (Figure 1a). The bulk porosity of the obtained material was 71.43%, thickness 50 µm, surface density 27 $g \cdot m^{-2}$, wettability by electrolyte 800%. We studied the electrochemical behavior of a $Li_4Ti_5O_{12}$ electrode in half cells with a metallic Li counter electrode and 0.67 M $LiClO_4$ electrolyte in a mixture of propylene carbonate (PC) and dimethoxyethane (DME) (7:3), and three types of separators: based on electrospun PVDF|PTFE, commercial polypropylene (PP) and glass fibers (GF).

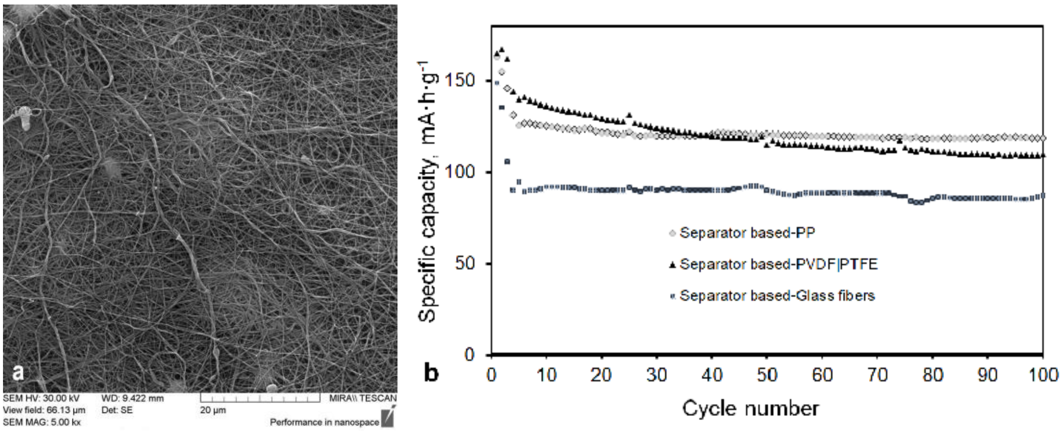

Figure 1. SEM micrographs of the PVDF|PTFE-based separator (a) and galvanostatic discharge capacity of the $Li_4Ti_5O_{12}$ electrode with electrospun PVDF|PTFE-based separator as well as conventional PP-based and GF-based separators at cycling under the specific current in the range of 0.1C – 0.5C during first three cycles and under 1C current during subsequent 100 cycles (b).

The galvanostatic charge-discharge cycling of the cells was carried out in the following range of currents: from 0.1 C to 1 C during the first four cycles and then at 1 C current up to 100 cycles. Cells with the electrospun PVDF|PTFE separator demonstrated higher C-rates with respect to the cells with conventional separators based on PP and GF: at equal currents, higher capacity values of the $Li_4Ti_5O_{12}$ electrode during long-term cycling were observed.

A decrease in the working electrode polarization and an increase in the cycling capacity in the case of the electrospun separator in comparison with the conventional separators based on PP and GF were established. The state of the electrodes and the separator in the cell was monitored by electrochemical impedance spectroscopy (EIS) method. The parameters of the electric equivalent circuit and the diffusion coefficient of lithium ions in the $Li_4Ti_5O_{12}$ electrode for the cells with each type of separator were determined and compared.

Acknowledgments. The reported study was funded by RFBR, project No 19-33-90068.

Formation of Mn-substituted $Na_{1+2x}Mn_xTi_{1-x}(PO_4)_3$ (x = 0.0 – 1.5) from Density Functional Theoretical and Cluster Expansion Analysis

Gustautas Snarskis[a] and Linas Vilčiaukas[a]
[a]*Center for Physical Sciences and Technology (FTMC)*
Saulėtekio al. 3, LT-10257 Vilnius, Lithuania
Linas.Vilciauskas@ftmc.lt

The development of novel rechargeable batteries is currently one of the most important topics in science and technology. Although Li-ion batteries are becoming the leading technology, they face a number of problems like safety and rare and expensive (Co, Li, Ni) raw materials needed for production. Na-ion batteries might be based on inexpensive and widespread materials and could be a viable alternative in applications where particularly high energy densities are not required [1]. Natrium SuperIonic Conductor (NASICON) framework compounds are attracting a lot of attention as potential electrodes from the battery research community [2]. Mn-based NASICONs are deemed as very suitable high voltage positive electrode materials for Na-ion batteries [3]. In this work, a part of the Na-Mn-Ti-PO4 phase diagram corresponding to Mn-poor and Mn-rich solid solutions of different concentrations in the NTP-123 system $Na_{(1+2x)}Mn_xTi_{(2-x)}(PO_4)_3$ $\{0 \leq x \leq 1.5\}$ was constructed using the Cluster Expansion approach and periodic density functional theory calculations [3]. Results indicate a limited thermodynamic stability window at around x = 1.0, which might provide valuable guidance for the experimental effort to prepare various Mn-substituted NASICON compounds (Fig. 1).

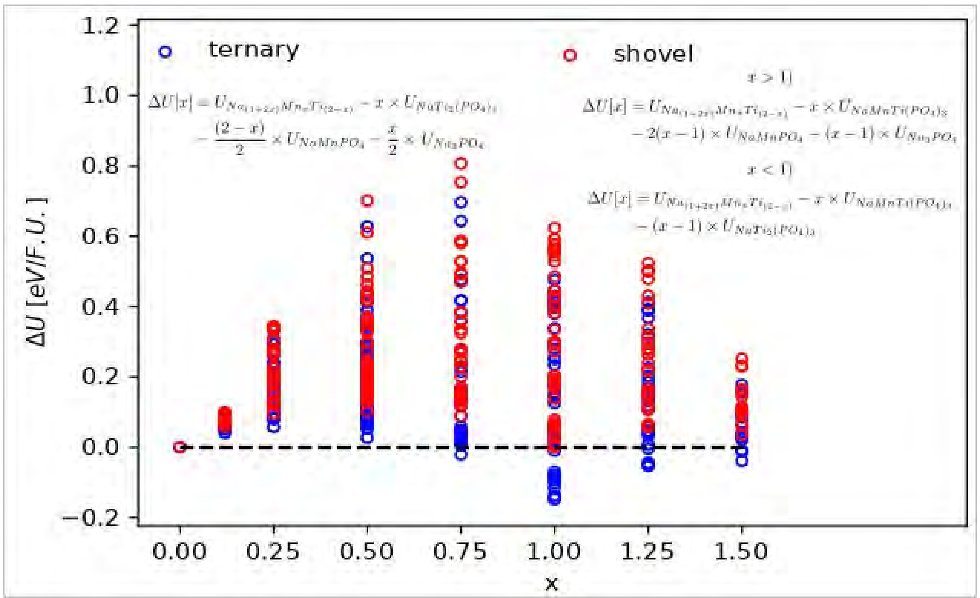

Fig. 1. Formation energy diagram. The case where x=1.0 is used as a reference point is marked in red.

semen_mahov@mail.ru

Modern li-ion batteries based on $LiCoO_2$/graphite and $LiFePO_4$/graphite electrochemical systems offer customers a choice of high energy density or safety at operation. In the present work, we considered the alternative of li-ion system based on $Li_4Ti_5O_{12}$ (LTO) / $Li_2Fe_xMn_{(1-x)}SiO_4$ (LFMS).

$Li_4Ti_5O_{12}$ was obtained by the solid-state synthetic rout with preliminary mechanical activation. At the first stage, the Li_2CO_3 and TiO_2 mixture was subjected to mechanical activation. Next step was an annealing at 750°C for 5 hours in an air atmosphere.

$Li_2Fe_xMn_{(1-x)}SiO_4$ ($x = 0.33$) was obtained by sol-gel method. At the first stage, the initial precursors ($LiOH \cdot H_2O$, $Fe_2C_2O_4 \cdot 2H_2O$, $Mn(CH_3COO)_2 \cdot 4H_2O$, ethylene glycol, tetraethoxysilane) were mixed until a sol was formed. Then the sol was evaporated to form a gel. This gel was subjected to heat treatment at a temperature of 650°C for 5 hours in an argon atmosphere.

The electrochemical properties of both anode and cathode materials were studied by galvanostatic charge-discharge cycling. We used three-electrode laboratory cells with lithium reference and auxiliary electrodes to support the work of the electrode under investigation. A 0.67 M solution of lithium chlorate(VII) $LiClO_4$ in a mixture of propylene carbonate and 1,2-dimethoxyethane with a volume ratio of 7:3 was used as an electrolyte. The galvanostatic charge-discharge cycling of the cells was carried out at the rate of 0.02C-0.1C in the potential range of 1.50–4.50 V (vs. Li) for LFMS, and at 0.2 C in the potential range of 1.00–2.50 V for LTO using a P20X8 multichannel potentiostat-galvanostat (Elins, Russia).

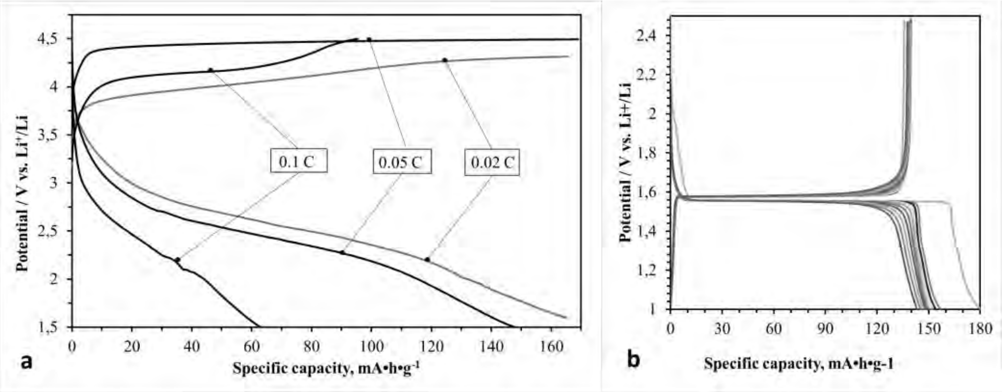

Figure 1. Galvanostatic charge and discharge curves of $Li_2Fe_xMn_{(1-x)}SiO_4$ ($x = 0.33$) electrode at the rate of 0.02 C – 0.1 C (a) and $Li_4Ti_5O_{12}$ electrode (b) at the rate of 0.2 C.

LFMS electrode showed increasing of specific capacity up to 164 $mAh \cdot g^{-1}$ (Figure 1) at 0.02 C rate comparing to usual specific capacity of Li_2FeSiO_4 electrode [1]. The shape of charge and discharge curves of $Li_2Fe_{0.33}Mn_{0.67}SiO_4$ electrode is smoother than Li_2FeSiO_4 electrode, and potential hysteresis between curves is lower.

LTO-based electrode material showed specific capacity of 140 $mAh \cdot g^{-1}$. The shape of the curves is identical for LTO obtained by other authors [2] and is characterized by a potentiostatic plateau at 1.55 V.

Acknowledgments. The reported study was funded by RFBR, project No 18-53-45004.

High-strength steels are widely used in many applications including oil and gas production, transportation and infrastructure, as a result of their optimised mechanical properties, relatively low price and high availability. However, most low-alloy steels are susceptible to corrosion. Corrosion of steels has significant negative consequences for the economy, the environment and human safety. The microstructure of the steel alloys is one of the factors influencing their corrosion resistance. It is desired to optimise the microstructure design of the alloy to control or enhance the corrosion resistance. For this, more insight into the interaction between microstructure and corrosion is needed. The influence of microstructural features on the corrosion and passivity of the steels is not well understood, with occasional contradictory tendencies. This is due the complexity of the microstructure where many different features (grain size, phase, crystallographic orientation, dislocation density) play a role in the overall corrosion and passivity behaviour. To separate the sole effect of microstructural features, it is crucial to design well-controlled model alloys by heat-treatments or thermomechanical processes to limit the combined effects of microstructural features on passivity and corrosion behavior.

In this work, a study is presented in which the individual effect of grain size and microstructural defects (e.g. dislocation density, grain boundaries) on the passivity and corrosion behaviour of model alloys is investigated. Three aspects are considered. (1) The role of grain size on the passive layer of pure iron is investigated with model alloys with grain sizes between 25 and 91 μm. It was observed that grain refinement leads to increase in the passivity current density in the potentiodynamic polarization curves and lower resistance in the electrochemical impedance spectroscopy (EIS) measurements. This effect in barrier properties of the passive film stems from the increase in donor density measured with Mott-Schottky analysis and decrease in fractions of protective γ-Fe_2O_3 in the passive film (composed of Fe_3O_4, γ-Fe_2O_3 and $FeO(OH)$) that it is measured with X-ray photoelectron spectroscopy (XPS). (2) The effect of dislocation density on the corrosion behaviour of interstitial free (IF) ferritic steels was investigated in 0.1M HCl solution. It is shown that the corrosion rate increases with increase in dislocation density. This is attributed to the increasing Volta-potential difference in between grains with increase dislocation density, measured by Scanning Kelvin Probe Force Microscopy (SKPFM). This leads to a higher driving force for galvanic coupling. (3) In the third case, the role of microstructural defects (dislocation density and grain boundary) on passive layer properties of IF steels is studied. It is revealed that the barrier properties of passive film deteriorate with increasing microstructural defect density due to an increase in donor density and a lower γ-Fe_2O_3 fraction in the passive film.

Electrochemical Analysis of Fentanyl and Fentanyl Analogs Towards a Rapid Screening Assay

The use of opioids is on the rise nationwide, and the potential danger of an unintentional exposure is increasing. One of the current deadliest synthetic opioids if fentanyl. There are also numerous fentanyl analogs that have been synthesized, often illicitly, that are hazardous: some of which are more potent than fentanyl itself. There are many laboratory-based methods used to detect fentanyl, but they lack the portability and rapid response necessary for early detection in the field. The focus of this project is to use electrochemistry as a fast detection method answering those needs and allowing for early detection of fentanyl and fentanyl analogs. In the body, fentanyl undergoes an oxidative N-dealkylation reaction, which generates metabolites. The electrochemical reaction of fentanyl appears to be mimicking this, with an irreversible oxidation, which then generates metabolites in solution. We use cyclic voltammetry to monitor oxidation of fentanyl and the oxidation and reduction of possible fentanyl metabolites. The irreversible oxidation peak appears around 0.80 V *vs.* Ag/AgCl for fentanyl, and this irreversible oxidation results in additional oxidation and reduction peaks observed in subsequent scans. The parameters to electrochemically characterize fentanyl are currently being optimized, such as the supporting electrolyte, concentration of the supporting electrolyte, working electrode, and scan rate. Square wave voltammetry (SWV) is also being considered to analyze the oxidation of fentanyl, because of the greater sensitivity of the method. The optimal parameters for the step, amplitude and frequency are being explored for SWV. The long term goal of this project is to develop a method common to fentanyl and fentanyl analogs to allow for a rapid detection of these drugs that will benefit in-field techniques.

Electrochemical Tape-and-paper-based Chlorate Sensors for Forensic Applications

Carolina Vega, Kiyomi Kukoyi, Meagan Olsen and Frédérique Deiss
Department of Chemistry and Chemical Biology, Integrated Nanosystems Development Institute, Indiana University – Purdue University Indianapolis
402 N Blackford Street, Indianapolis, IN, USA
cguimara@iu.edu ; Corresponding Author: fdeiss@iupui.edu

The use of chlorate salts as oxidizers in improvised explosives devices (IEDs) has recently increased. IEDs are a global threat due to easy access to raw materials, many manufacturing instructions available on the internet and their lethal potential. The standard methods to detect chlorate are mostly designed for laboratory testing and thus do not meet the requirements for in-field detection. Recent developments in electroanalytical assays integrated with flexible substrates have led to user-friendly analytical devices which are inexpensive, portable and disposable. We are developing an electrochemical tape-and-paper-based device for rapid in-field detection of traces of chlorate. The sensing element of our device is an electrodeposited molybdate layer. Indeed, chlorate was reported to have a catalytic effect on the reduction of molybdate. Our sensor detects chlorate by monitoring the change in redox activity of the electrodeposited molybdate using cyclic voltammetry and other electrochemical techniques. We have effectively demonstrated the detection of chlorate in solution and started evaluating the quantification capabilities of the device. We optimized the conditions for the electrodeposition of molybdate (supporting electrolyte, scan rate, pH, type of acid, concentration of molybdate, etc.) by cyclic voltammetry. In addition, we are evaluating square wave voltammetry and differential pulse voltammetry to achieve the most observable effect of chlorate on the molybdate sensing layer. Also, a quality control of the sensors has been developed through chemometric methods. In order to allow a convenient sample collection at crime scenes, an in-field presumptive test, and storage and transport for in-laboratory confirmatory tests we are optimizing the design of tape-encased prototypes. The sensing element of the tape-and-paper-based device is sandwiched in a wider layer of tape which will protect the electrodes from damage when collecting samples in-field. This research was made possible with the support of the National Institute of Justice (2017-DN-BX-0172).

Fabrication and Deposition of Metallic Nanoparticles By Plasma Electrochemistry In Ionic Liquids

Metal nanoparticles have found extensive attention due to their unique electronic properties, chemical reactivity and potential applications such as: catalysis, optical, magnetic and electronic devices.

Ionic liquids are well known in today's literature to be successfully employed for the synthesis and stabilization of metal nanoparticles without the addition of stabilizing agents. Moreover, ionic liquids have very low vapor pressures (typically 10^{-9} Pa at room temperature), which makes them suitable in either vacuum or atmospheric pressure experiments as fluid substrates or solvents.

Plasma electrolysis, is carried out to produce metallic, alloys or ceramic nanoparticles. Unlike conventional electrochemistry system, in plasma electrolysis system, the cathode or the anode is positioned just above the electrolyte surface, and the counter-electrode is immersed in the electrolyte. For the fabrication of metallic nanoparticles, plasma-induced cathodic discharge electrolysis technique is used. In principle, the cathode is positioned just above the electrolyte surface, and a plasma-induced stationary discharge is generated between the cathode and the electrolyte surface to allow for continuous electrolysis. The discharge is maintained by electron emission from the cathode, whereby atmospheric argon gas is partially dissociated to form condensed plasma in the gas phase. Therefore, when the metal ion source is dissolved in the ionic liquid, fine metal particles are formed on the surface of the ionic-liquid, which sizes are in the nano- up to micro-meter scale (depend on the experimental conditions). The plasma–electrolyte interface can provide a reactive region where active species are formed; further, due to the high-energy electrons in the plasma region, plasma chemistry and electrochemistry reactions occurs, which deviate from the conventional Faraday Law. Ionic liquids are well suitable electrolytes for the plasma electrochemical processes, because compared to water it is much easier to obtain stable and homogeneous plasma, due to their low vapor pressure.

In this work, we will demonstrate plasma electrochemistry capabilities to fabricate metallic copper nanoparticles using $CuSO_4$ salt which is dissolved in1-Ethyl-3-methylimidazolium ethyl sulfate ([EMIM][$EtSO_4$]). Glow plasma was formed in the cathode-electrolyte interface, under atmospheric pressure conditions using argon gas flow which was continuous supplied above the solution. We used a DC power source to apply 200V of potential difference, between the cathode (tungsten wire) and copper foil anode. Our visual pictures of the cell clearly show formation of particles that diffuse from the surface to the bulk electrolyte. Our current vs. time data, combined with in-situ optical emission spectroscopy, allow us to recognize a pattern of particle nucleation followed by growth of the nanoparticles in the ionic liquid bulk. Initial experiments were conducted to obtain Cu nanoparticles-coated carbon paper electrodes. We also extracted nanoparticles from the ionic liquid solution for further elemental analysis such as XRD and TEM. Since electrolysis using multi-discharge electrodes array can be achieved, it seems in the present research stage that plasma electrolysis method is suitable for the mass production of a variety of nanoparticles, whether discrete or incorporated in substrates.

Modification of carbonaceous nanostructured materials for application in Li-Ion batteries

Li-Ion batteries (LIB) have been exhaustively studied because of their potentialities for green transportation and renewable energy storage due to their high power, high energy density and long cycle life [1, 2]. Most commercialized LIB employ graphite as the principal material for the anode, however this material has a low theoretical capacity. Consequently, a wide range of materials has been considered to replace or modify it in order to increase the capacity of the anodes [3]. On the other hand, it was shown that the use of carbonaceous highly ordered two-dimensional porous material CMK-3 as anodes in LIB leads to a significant increase in the conduction of lithium-ion and electrons [4]. In this work, we present a new material based on CMK-3, functionalized by NiFe2O4 spinel, using different impregnation methods. The employment of this particular spinel is grounded on his promising features, for e.g. it has a high theoretical capacity, and both Ni and Fe are low-cost abundant elements (which is important for the possible applicability to the industry) [5].

The resulting materials were characterized by means of the following techniques: Low and high angle x-ray diffraction (DRX), scanning and transmission electron microscopy (SEM and TEM), elemental analysis (EDX), nitrogen adsorption isothermal analysis with BET model, ultraviolet-Visible diffuse reflectance spectroscopy (UV-vis), programmed temperature reduction (TPR), X-Ray emitted photoelectron spectroscopy (XPS).

The following graph shows the battery performance by means of galvanostatic cycling considering different variables: impregnation method (wet and dry), percentage of spinel (23% y 50%) and the binder type (PVDF y CMC).

In contrast to observed in conventional methods, like the steam methane reforming, H_2 molecule can be satisfactorily generated by electrochemical and photoelectrochemical (PEC) methods. The main advantages in methanol oxidation reaction (MOR) is the possibility to obtain H_2 by a greener method (without large CO_2 emissions in comparison to fossil fuel consumption) [1]. The use of TiO_2 in photo assisted MOR, especially as composites or heterojunctions, using materials of high charge mobility, like graphene, carbon nanotubes, and poly (heptazine imide) (PHI) can reach high yields. PHI structure is up to date one of the closest structures from a "truly graphitic" carbon nitride. Obtained from relative low-cost precursors [2], PHI shows a suitable band gap for utilization of visible radiation (around 2.7 eV), and also can be used to stabilize transition metals as single sites in its structure, proportioning the maximum utilization of the element, in comparison to nanoparticles or clusters [3]. In the present work, we report the synthesis and application in MOR of a photoanode based on TiO_2 loaded with PHI(Ni) (PHI structure containing nickel II atomically dispersed). For the synthesis, the TiO_2 paste was loaded with 2.5 % wt. of PHI and PHI(Ni), spin coated in clean FTO electrodes at 3000 rpm for 30 seconds, obtaining initially a thin film (95 nm thickness), that was thermal annealed at 400 ºC for 20 min in air. The photoelectrochemical experiments were conducted under UV light (365 nm, $100 mWcm^{-2}$) using acidic solution (0.5 mol L^{-1} H_2SO_4) and methanol 13.8 mol L^{-1}. The bare TiO_2 film produced achieved a photocurrent of 109 $\mu A\ cm^{-2}$ at 0.2 V vs. RHE. On the other hand, a significant increase in the activity was observed for the photoanodes containing carbon nitride (pure and containing Ni^{2+} single atoms), TiO_2-PHI and TiO_2-PHI(Ni) films reached 185 and 441 $\mu A\ cm^{-2}$ at the same potential, respectively. The better activity can be explained by two factors: (i) the formation of a TiO_2/PHI heterojunction that leads to better charge separation, and (ii) Synergism between the heterojunction along with the cocatalysis of MOR by $Ni^{2+}|Ni^{3+}$ species that facilitate the charge transfer process. As the TiO_2-PHI(Ni) film proved to be the most promising, it was studied the influence of the thickness of the film, repeating the deposition process. The 30-layers deposited TiO_2-PHI(Ni) film reached a photocurrent of 11 mA cm^{-2} in 0.2 V vs RHE, the best MOR photoelectrochemical activity of films with higher numbers of layers is directly related to the material's absorptivity. While the one-layer TiO_2-PHI(Ni) film was almost translucent and, the 30 layers on the other way had a high opacity. Also, the excellent stability of this film must to be emphasized, the initial photocurrent decays only a 5% at 120 min of measurement, Lastly, *in situ* FTIR measurements allows insights about the reaction mechanism, the three samples TiO_2, TiO_2-PHI and TiO_2-PHI(Ni) apparently follows the same pathway of oxidizing methanol to formaldehyde in dark, and in the UV irradiation higher oxidized products as formic acid and CO_2 are obtained.

A multivariate exploratory analysis applied to a simultaneous voltammetric determination of dopamine, ascorbic acid and uric acid

Thágor M. Klein, Vladimir Lavayen, Jacqueline Arguello
Universidade Federal de Rio Grande do Sul, Instituto de Química,
Porto Alegre, RS, Brasil, 91501-970
thagor.k@gmail.com

Electrochemical techniques offer the advantages of simplicity, low cost, and quickness for analytical determination of several biomolecules, including dopamine (DA), ascorbic acid (AA) and uric acid (UA). However, due to their very close oxidation potential, to perform a simultaneous determination of these analytes usually requires the use of non-conventional electrodes, capable of producing well-defined and separated oxidation peaks. In this case, the use of mathematical procedures for pattern recognition on multivariate data analysis offers a great perspective to solve the drawback of overlapping peaks [1,2]. This work shows an exploratory study of analysis by hierarchical clusters (HCA) and principal component analysis (PCA) in the simultaneous determination of DA, AA, and UA using differential pulse voltammetry. The voltammograms were registered from 0.0 to 0.5 V, at of 5 mV s^{-1}, in a Britton-Robinson buffer solution (pH = 7.0) using a potentiostat/galvanostat Autolab PGSTAT302N. The three-electrode system consisted of a carbon composite electrode (4 mm of diameter) as the working electrode, a Pt wire as the counter electrode, and SCE as the reference electrode. The samples were in the range of $1.5 \times 10^{-5} – 6.0 \times 10^{-3}$ mol L^{-1}, and identified as A1 to A7, from the most diluted to the most concentrated. The data was processed using the free software Chemostat for analysis by hierarchical clusters (HCA) and principal component analysis (PCA) [3]. The dendrogram obtained by the HCA in Figure 1, indicates four groups of concentrations: the first of the lowest concentration (A1), the second group corresponds to samples A3 and A4. The other groups are composed of the most concentrated samples, A5-A6, and finally A7. According to PCA, three main components explain the total variance, PC1 (97.1%), PC2 (2.8%), and PC3 (0.03%). The PC2 loading showed a small overlap attributed to a slight shift of the oxidation potential toward more positive values with increasing concentrations. PC3, on the other hand, shows a strong positive influence from the baseline that increases during the additions, which can be ascribed to the adsorption of the analytes between voltammetric analyzes, which can be corrected with an electrochemical cleaning step of the electrode.

Acknowledgments. The authors thank the financial support of the INCT of Bioanalytical (CNPq/INCT), CNPQ, and CAPES.

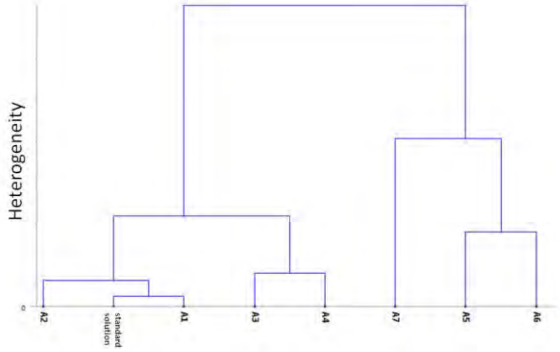

Figure 1. Dendrogram obtained by HCA. A1, A2, A3, A4, A5, A6 and A7 represent the seven successive additions of the analytes.

In this work, the electrochemical performance of aerosol-assisted chemical vapour deposited vanadium pentoxide cathodes at 600 °C, is presented. The as-grown oxides indicate specific discharge capacity of 300 mAh g^{-1} with capacity retention of 92 % after 10000 scans, coulombic efficiency of 100 %, noble structural stability and high reversibility. The present study shows the possibility to grow large-area magnesium cathode material with extended cycle stability via the utilization of an aqueous electrolyte under a corrosive environment. This enhanced performance may be a combination of electrode morphology and adherence compared to previous work employing electrode's growth temperature at 500 °C.

Screen-printed modified electrode based on gold nano/microstructures and MoS_2 exfoliated for determination of lead (II)

Thágor M. Klein[1], Nathalie Ribeiro Wingert[2], Vladimir Lavayen[1], Jacqueline Arguello[1]

In the last decades, global pollution has experienced a significant increment as a direct consequence of anthropogenic activities. Among heavy metal, lead (II) ions are one of the primary pollutants that have a cumulative effect and several deleterious implications in human health [1]. As a result, alternative analytical methods apart from the classic ones needs to be developed, looking for reliability, rapidity, and low cost. In this sense, many electrochemical sensors are currently being developed, with great emphasis on the preparation of modified electrodes using various types of nanostructured systems [2,3]. The present work presents a modified electrode consisting of electrodeposited gold, exfoliated MoS_2, and gold nanoparticles deposited on the surface of printed carbon electrodes (SPE), Figure 1(A) shows the steps followed for the modification. Differential pulse anodic stripping voltammetry (DP-ASV) was employed to determine lead (II) ions, where the preconcentration step involved a potential applied of -0.8 V for 180 s under a stirring condition. After 5 s of equilibration time, a differential pulse voltammogram was recorded, using a pulse width of 50 mV, a potential ramp of 5 mV, and a scan rate of 40 mV s^{-1}. The electrolyte solution consisted of a 0.1 mol L^{-1} solution of H_2SO_4. Figure 1(B) depicts the modified and unmodified electrodes' responses in the presence of 5 µg mL^{-1} of lead (II) ions, for comparative purposes. The proposed modified electrode, named as SPE/Au/MoS_2/AuNPs, significantly increased the intensity of the anodic peak; this can be attributed to the enlargement of the surface area caused by gold nano/microstructures, that also may promote an improvement in electron transfer.

Acknowledgments. The authors thank the financial support of the INCT of Bioanalytical (CNPq/INCT), CNPQ, and CAPES.

Microbial fuel cells can directly convert chemical energy in organic waste into electrical energy, which gives an excellent opportunity for renewable energy production, wastewater clean-up and elemental recovery. The rapid progress in the field has led to bringing this technology closer to application. One of the most promising approaches to boost MFCs implementation is the modular configuration of multiplied MFC units for usable electricity levels [1]. To achieve that, the anode and cathode location within the MFC bioreactor must be optimised to boost power performance by keeping the two electrodes in close proximity, i.e on the opposite sides of the Nafion membrane [2]. A cost-effective alternative to Nafion incudes porous ceramic materials as ion exchange membrane [3] where the permeability of the ceramic body allows for good ionic conductivity and sufficient cathode hydration.

This work presents the development of a novel, simplified design of a membrane-less MFC using a ceramic plate as a porous, permeable baffle between both electrodes that share the same electrolyte. A fully submerged anode and partially exposed to air cathode were attached to either side of the ceramic plate in order to keep the minimum distance, while maintaining electrical separation to maximise the output. Such a design was investigated in individual (large scale, 300 mm height) and stacked (medium scale, 100mm height) MFCs. Finally, miniaturised membrane-less reactors (30mm height) were compared with identical membrane-based MFCs where the ceramic functions as a membrane, fully separating the anolyte from the open to air cathode (Fig.1). This is to understand the role of the ceramic separator in a simplified and optimised construction for primarily power production in both membrane-based and membrane-less designs.

Results showed that a single large-scale MFC constructed from a terracotta floor tile produced up to 3.8 mW (1.9W/m^{3}) and successfully operated a small-scale dc motor while the cumulative power production from the medium-scale 6-unit stack reached up to 13 mW of power (6.5W/m^{3}) over 270 days of operation. A miniaturised membrane-less design showed similar or slightly increased raw (actual) power output up to 0.84mW (21W/m^{3}) in comparison to the membrane-based configuration that produced 0.75 (37.5 W/m^{3}) (Fig.1) which makes it a promising application for the membrane-less MFC stacks.

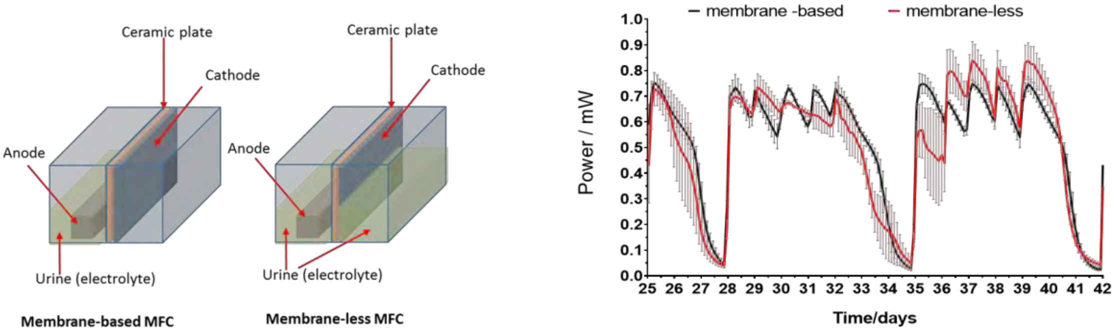

Figure 1. Miniaturised MFCs with ceramic plate functioning as a membrane in a membrane based design and as a permeable baffle in a membrane-less configuration. Power output comparison with error bars (n=3) between the two configurations.

Results showed increased performance with the scale-down of the reactor size and long-term stability, which is promising for future scale-up. The integration of ceramic baffles in membrane-less MFCs shows similar performance to membrane-based units. Scaling down MFC reactors in vertical height is of interest for the future development of multi-modular cascade systems maximising the number of modules that can be fitted within a single cascade therefore increasing the overall, usable power output of the stack.

The oxygen evolution reaction (OER) is a critical reaction for successful energy conversion. For instance, in water electrolyzers it predominately determines the energy demand for the production of green hydrogen. An optimization of this reaction is therefore very desirable. Electrocatalysts for the OER are typically measured as thin films (either made from powders or otherwise deposited), and for laboratory screening the rotating disc electrode (RDE) is the classical characterization technique.

The advantage of the RDE is supposed to be the controlled mass-transport towards the electrode. The OER is typically considered to be only little mass transport dependent, especially for the educts that are either water or OH^-, both available in excess. However, first reports indicate that there might be a limitation to this assumption, and also the transport of the produced O_2 can be a limiting factor.[1,2]

Here, we show the impact of mass transport in terms of rotation rate in the RDE and compare those results to complementary measurements in an electrochemical flow cell with various flow velocities. We will show that the use of a flow cell can improve the mass transport especially at higher current densities. Additionally, we address the importance of O_2-removal on thin layer electrodes with different hydrophobicity. These can for instance be achieved by the addition of different binders, i.e. ionomers that are used to stabilize the layer mechanically. However, besides affecting the hydrophobicity, we show that different binders can influence the electrochemical behavior by their own properties and current response. These results will illustrate how different experimental parameters can be interconnected and point out their influence on the measured activity of an electrocatalyst.

Nanocomposites based on conducting polymers (CPs) and mixed transition-metal oxides (MTMO) have been shown distinguish properties, e. g. high specific capacitance and stability values. MTMOs, present multiple cations valence, which increase the electrochemical activity and the conductivity. Among metal oxides, ruthenium oxide (RuO_2) has higher capacitive response, but it is expensive and toxic, reducing severely its application.[1] In this way, we combined ruthenium oxide with tungsten oxide (WO_3), a transition metal oxide with unique electrochemical properties, in order to decrease the amount of ruthenium in the mixed oxide obtaining the RuO_2-WO_3. Combining this structure with one of the most studied conducting polymers (polyaniline - PAni), is an efficient tool to improve the polymeric conjugation and enhance the electrochemical performance of this system. In this way, we present the synthesis, characterization, and the electrochemical performance of RuO_2-WO_3/PAni nanocomposite. The synthesis the nanocomposite was performed by the in-situ chemical polymerization of aniline monomers in the presence of the presence of the previously synthesized MTMO. All the synthesized materials were characterized by spectroscopy and morphologic techniques, in order to ensure the success of the synthesis. Comparing the electrochemical performance of the RuO_2-WO_3/PAni to the neat PAni, we noticed a considerable variation in the capacitance values of 930 mF cm^{-2} for the nanocomposite and 100 mF cm^{-2} to the polymer. Once the good electrochemical performance for the RuO_2-WO_3/PAni was attested, we prepared some symmetrical energy storage devices, using the nanocomposites as electrodes. Theses devices showed good specific capacitance values and also the good stability. Finally, these results allow us to say that by the synergism of all the materials we were able to develop a novel nanocomposite with good capacitive performance. Supercapacitors (SC) are playing a central role in the transition to a green economy based on renewable energy sources and electric vehicles. The exponentially growing market of supercapacitor requires to replace flammable, volatile and toxic chemicals such as acetonitrile by cheap and environmentally friendly components.

Therefore, valuable strategies are the use of aqueous electrolytes and bioderived components such as biochar-based carbon that enable the valorization of wastes in a circular economy approach. Here we report about a physicochemical study and electrochemical characterization of a supercapacitor based on Argan fruit shell derived carbon electrode and a non-toxic super-concentrated aqueous electrolyte, i.e. a Water In Salt (WIS) solution of ammonium acetate.

Indeed, the utilization of WIS enables high voltage which are the main limitation of aqueous based electrolyte. The reported SC featured up to 47 F/g of specific capacitance and 4 Wh/Kg of specific energy at a temperature room temperature

To prove the practical applicability of this kind of electrolyte, electrochemical measure at into a wide range of temperatures (from -10 °C to 80°C), have been performed. This preliminary work aims at paving the way towards the design of novel green SCs based on non-dangerous aqueous based electrolyte and sustainable carbon sources.

Air Stable Black Phosphorus-based Cathodes for Na-ion Batteries

Jéssica E. S. Fonsaca,[1] Sergio H. Domingues,[2] Elisa S. Orth,[1] Aldo J. G. Zarbin[1*]
[1]Department of Chemistry, Federal University of Paraná (UFPR) – Curitiba - PR; [2]Graphene and Nanomaterials Research Center – Mackgraphe – Mackenzie Presbyterian University – Sao Paulo – SP.

Notable progress in the field of electrochemical energy storage devices has been achieved due to the increasing exploitation of black phosphorus (BP) structure and properties. BP is highly unstable under O_2 exposure, which seriously limits its manipulation and consequent application. Thus, we have protected BP with polyaniline (PANI), leading to a stable and reliable material targeted for energy storage devices. For this purpose, BP-polymeric materials were synthesized through the liquid/liquid interfacial method, as previously described,[1,2] leading to thin, transparent and homogenous green films of BP/PANI nanocomposites. After Raman spectroscopy confirming the coexistence of both materials in the resulting film, both bare and capped materials were exposed to the same ambient conditions and evaluated through different techniques. Scanning electron microscopy (SEM) images and Raman spectra indicated the beginning of degradation of the uncapped material (without PANI) with only 3 days of exposure, while BP/PANI films have taken up to 60 days for the same process to begin, indicating a material 1500% more stable than the bare one. Electrochemical response and stability of BP/PANI nanocomposites were evaluated through cyclic voltammetry (CV) and charge-discharge (CD) studies (NaCl 0.5 mol L^{-1} pH 3), in order to evaluate energy storage properties.[3] Films of BP/PANI were evaluated and compared to pure PANI and BP, under air and inert atm ($N_{2(g)}$). CVs results have shown that all materials have the same behaviour after 200 cycles either with or without $N_{2(g)}$ purge. BP is degraded right after the first cycle, evidencing the expected low stability. BP/PANI, however, has evidenced the preservation of BP even after the 200 cycles under air, which was confirmed through post-characterizations. CD studies were performed from 0.5 A g^{-1} to 3 A g^{-1}, reaching capacities up to 200 mAh g^{-1} at 0.5 A g^{-1} rate with a coulombic efficiency of 100%, without compromising the integrity of BP in the films. To further explore the performance of the materials and understand the ion behaviour during the process, we analysed the electrodes through electrochemical impedance spectroscopy (EIS). In general, the obtained Nyquist plots evidenced a lowered resistance and improved diffusion properties of BP/PANI composite compared to neat polymer, corroborating with the best results verified in CD analysis. Aiming to investigate the competition between H^+ and Na^+ in BP intercalation during the electrochemical processes, we have also analysed the samples in pure 1 mol L^{-1} HCl (*i.e.* without Na). Unlike the previous case, similar profiles were found for BP/PANI and PANI, indicating equal performances towards H^+ insertion/expulsion regardless of BP presence. Thus, we can attest the interference and participation of Na^+ during BP/PANI processes in NaCl pH 3. **FIGURE 1** summarizes all described results. Overall, this work provides new possibilities heading for the development of oxygen friendly thin films to build new BP-based electrodes for sodium aqueous batteries.

There is a demand for reducing the environmental load of automobiles to solve the current environmental problems. Fuel cell electric vehicles (FCEVs) which use hydrogen as fuel emit no carbon dioxide, and have already been commercialized. platinum-based materials are widely used as oxygen reduction reaction (ORR) catalysts. However, their high cost and limited durability impedes large-scale implementation. Until now, non-platinum group metal (non-PGM) Fe and N doped carbon (Fe-N-C) catalysts have achieved promising ORR activity [1]. However, these Fe-N-C catalysts still suffer from poor durability, due to the formation of reactive peroxide radicals as a side reaction during the ORR. Meanwhile, the use of Co species avoids the production of such radicals, potentially preserving the electrocatalyst [2]. Therefore, in this study we investigate the dependence of ORR activity on a variety of different metal ions by synthesizing alternative Me-N-C carbon foam electrocatalysts (Me = Co, Ni, Sn).

Pt-free electrocatalysts were synthesized from nitrogen-doped carbon foams (N-C) and various metal salt and small molecule precursors. Porous nitrogen-doped carbon foams with large surface area were made in-house. These were adsorbed with metal acetate and then heated in inert atmosphere, followed by acid washing to remove metallic phases. Finally, heat treatment under ammonia was performed. The effect of heat treatment temperature and metal loading on the microstructure and porosity was evaluated. The resulting catalysts were evaluated for catalytic activity using rotating-ring disk electrode voltammetry (RRDE) in acid.

For Co-N-C electrocatalysts it was found that heat treatment of the nitrogen-doped carbon foam support has a significant effect on catalyst performance, largely due to changes in surface area and porosity. The metal loading also has a strong effect on the performance, with an optimum Co loading of 0.1 wt% resulting in an onset potential of 0.8 VRHE and a half-wave potential of around 0.65 VRHE. Different metal ions were also systematically investigated, and it was found that Sn is highly promising as an alternative to Fe in non-PGM electrocatalysts. These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated.

Abstract

Peroxicoagulation process combines electrochemical generation of ferrous ions (Fe^{2+}) and hydrogen peroxide (H_2O_2) for the production of hydroxyl radicals ($^\bullet OH$) in acidic medium by Fenton reaction (eq. 1-3), to oxidize organic pollutants in wastewater (Nidheesh, 2018; Brillas *et al.*, 1997). Nevertheless, not all the effluents present acidic conditions, requiring previous acidification before its treatment by peroxicoagulation process. This requirement could limit its application for the treatment of large amounts of water due to the increased demand for chemicals. Also, the current density could affect the pH of the medium, so it is important to know the influence of the pH and current density on the production of the different oxidizing species during the peroxicoagulation process.

$$Fe \rightarrow Fe^{+2} + 2e^- \tag{1}$$

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \tag{2}$$

$$Fe^{+2} + H_2O_2 \rightarrow Fe^{+3} + OH^- + {}^{\cdot}OH \tag{3}$$

In this research, H_2O_2 and $^\bullet OH$ production generated by peroxicoagulation were assessed. A two electrodes (3.1416 cm^2) electrochemical cell without division (50 mL of solution volume) was used, applying current densities of 3.2, 9.5, 15.9 and 22.3 mA cm^{-2} for 30 min of electrolysis, in a synthetic solution with initial pH of 3 to 9 and 0.05 M Na_2SO_4 as supporting electrolyte. For H_2O_2 generation assessment, a Ti/Pt anode and a graphite cloth-polytetrafluoroethylene (PTFE) gas diffusion electrode (GDE) as cathode were used. For $^\bullet OH$ generation assessment, an iron plate anode and a GDE as cathode were used. During all the experiments, the GDE was fed with pure oxygen at a flow rate of 1 L min^{-1}.

H_2O_2 was analyzed by UV/Vis spectroscopy using a HACH DR-6000 spectrophotometer via the Ti (IV) oxysulfate method (λ = 406 nm). For the $^\bullet OH$ detection, coumarin ($C_9H_6O_2$) was used as a probe compound, which reacts with $^\bullet OH$ resulting in the formation of the fluorescent adduct 7-hydroxycoumarin ($C_9H_6O_3$). The detection and quantification of 7-hydroxycoumarin were carried out using an AGILENT Cary Eclipse fluorescence spectrophotometer (λ_{ex} = 340 nm, λ_{em} = 456 nm and slit 5).

The results indicated that the increment of current density has a positive effect on the production of H_2O_2 at pH 3. However, increasing pH from 3 to 9 reduced almost 50% the H_2O_2 at 22.3 mA cm^{-2}.

Concerning $^\bullet OH$ radicals production, its concentration decreased with increasing pH, which is consistent with the decrement of H_2O_2 in the GDE cathode at higher pH. On the other hand, the increase in current density decreased the $^\bullet OH$ radicals generation. The highest production and stability of $^\bullet OH$ radicals during the 30 min of electrolysis was obtained with the lowest applied current density.

This study reflects the importance of the pH solution and the current density in the generation of H_2O_2 and $^\bullet OH$ radicals, making the application of peroxicoagulation process plausible for the treatment of wastewater.

Modification of the Carbon Fiber Microelectrodes with Carbon Black for Dopamine and Serotonin Simultaneous Detection

Wojciech Mazurkiewicz, Magdalena Kundys-Siedlecka, Martin Jönsson-Niedziółka, Emilia Witkowska Nery
Institute of Physical Chemistry of Polish Academy of Sciences
Warsaw, Kasprzaka 44/52
wmazurkiewicz15@gmail.com

Adequate concentration of neurotransmitters in the neural structures is crucial for the proper functioning of the whole body. Due to the small size of brain structures and rapid nature of the neurotransmitters' transport[1] microelectrodes has been proposed as a suitable device for their measurement.

Carbon black (CB) is known for its excellent properties toward neurotransmitter detection[3]. Deposition of CB on carbon fiber has until now mainly been done by chemical vapor deposition[2]. In this study the possibility of CB deposition on microelectrodes from sol-gel solution was investigated.

Carbon fiber microdisk electrodes (CFMEs) with a 7 μm tip have been prepared. Electroassisted deposition under negative potential and dip-coating deposition from CB suspension in a polymeric matrix were tested. Scanning electron microscopy was applied for the analysis of the tip structure (Fig. 1). Cyclic voltammetry and differential pulse voltammetry measurements of dopamine (DA), serotonin (5-HT), uric acid (UA) and ascorbic acid (AA) were performed. Phosphate buffer solution (PBS) and Dulbecco's Modified Eagle Medium (DMEM) were used as a background solution to mimic the cell culture conditions. The distinction of overlapping DA and 5-HT signals[4] was the primary objective along with the interference and stability study in DMEM as secondary objectives.

During the electroassisted deposition, a thin layer on the surface of the electrode was produced, while after dip-coating a shell with multiple cracks was observed (Fig.1). Test measurements indicate stable microelectrode behavior of the CFMEs even a few weeks after preparation. Complete separation of DA and 5-HT signals on CFMEs with deposited CB was not achieved, although a new peak overlapping with the DA/5-HT peak was observed. CV studies showed that DA can be measured simultaneously with UA and AA without interference. The DA signal was linear in the concentration range 0.1 - 10 μM in PBS (R^2=0.99) and DMEM (R^2=0.96) on bare CFMEs, however on modified CFMEs signal was linear only in the range 0.1 - 1 μM in PBS and random in DMEM. 5-HT measurements showed low reproducibility on bare and modified CFMEs.

Detection of DA and 5-HT on CFMEs with deposited CB particles was achieved, however, the appearance of an additional peak might indicate incomplete covering of the electrodes' surface. Further investigation of proper CB deposition is essential. Other catalysts should be taken into consideration.

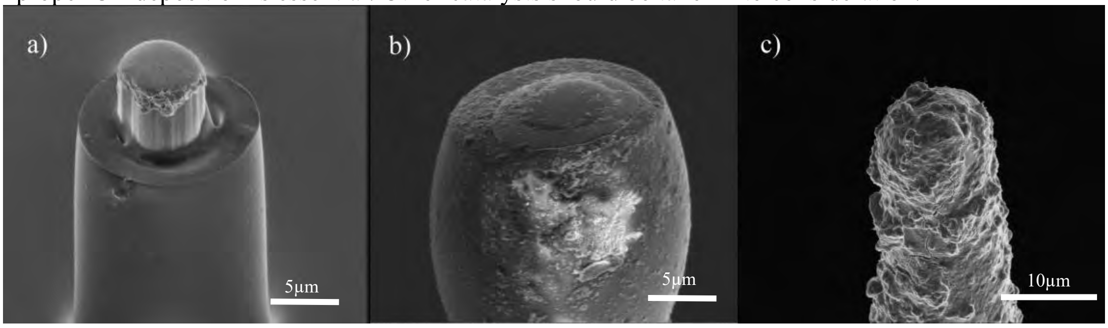

Figure 1. SEM images of the microdisk electrodes' tips: a) bare CFME during polishing b) CFME after electroassisted deposition of CB c) CFME after dip-coating deposition of CB

Characterizing and mitigating the degradation of oxidized cathodes during capacitive deionization cycling

Rana Uwayid†, Nicola Seraphim‡, Eric N Guyes†, David Eisenberg‡, Matthew E Suss*, †
†Faculty of Mechanical Engineering and ‡ Schulich Faculty of Chemistry, Technion – Israel Institute of Technology, Haifa, Israel
sranauw@campus.technion.ac.il

The surface chemistry of carbon electrodes plays an important role in capacitive deionization (CDI) cell performance. Applying appropriate surface chemical treatment to CDI electrodes results in an improvement of maximum salt adsorption capacity (mSAC) [1] and charge efficiency[2], yet the performance of the treated electrodes often decreases significantly during long-term cycling, and the surface group degradation mechanisms are not well understood. We here study the performance reduction of an oxidized cathode in order to investigate the degradation mechanism and enhance the stability of the treated cathode during long-term operation.

Single-pass CDI tests were conducted with flow-through electrodes, operated in constant voltage mode (1V). We investigate the degradation of a cathode treated with nitric acid (OC) and an as-received cathode (AC) for a feed water containing 20mM of NaCl salt for charged to equilibrium for 100 cycles. Further, direct acid-base titrations and surface chemistry analysis were performed before and after CDI cycle testing in order to diagnose degradation mechanisms. The cathode oxidation allows for an increase in the cell's initial mSAC from 8.2 mg/$g_{electrode}$ to 15.7 mg/$g_{electrode}$. However, mSAC decreases during cycling to 11.2 mg/$g_{electrode}$ by the 100th cycle (Figure 1a). As can be seen in Figure 2b, OC post-experiment titration curve is shifted to the right relative to the OC pre-experiment curve. This latter observation indicates functional group loss, due to a lower concentration of negatively charged functional groups in the micropore relative to the OC before CDI experiments.

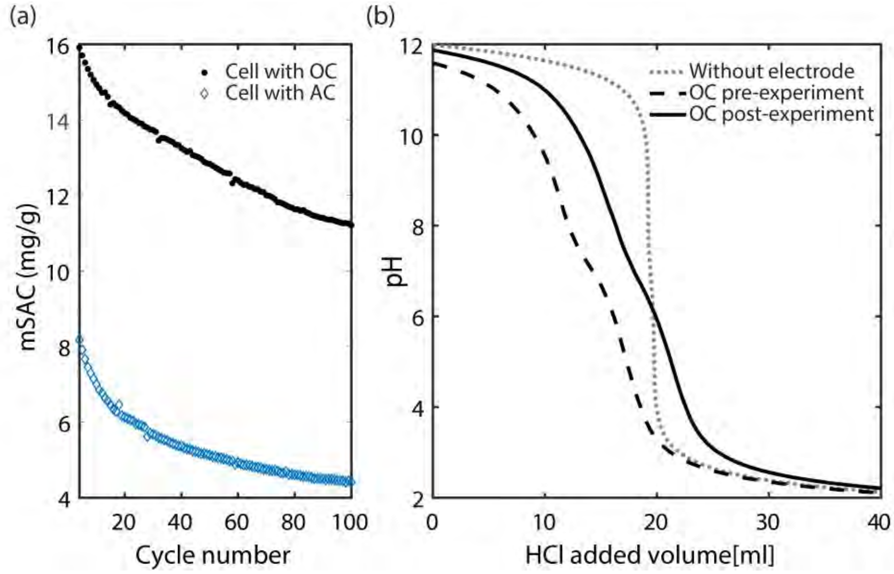

Figure 1- (a) Measured mSAC of cell with OC and cell with AC. The feed concentration is 20mM NaCl, the charging voltage 1 V, and discharge voltage 0 V. (b) Results of direct titration measurements for OC pre- and post-experiment. Also shown is the titration applied to a blank solution without electrode.

The oxygen evolution reaction (OER) is the anodic half reaction occurring within a water electrolyzer. Its oxidative condition could negatively affect the surfaces of materials consisting of an anodic compartment. Choice of the materials is strongly dependent upon their electrical conductivity and (electro)chemical stability. Carbon and titanium are the most practical examples. However, they could also be deteriorated by the prolonged operation of the OER due to accumulated stress. Considering the overpotential required for the OER, carbon could be corroded to give carbon oxides and titanium could be passivated to form an insulating oxide layer. These interfacial degradation phenomena would lead to the physical loss or electrical disconnection of the catalyst from the surfaces, thereby decreasing electrocatalytic performances. For the long-term functioning of the OER, the interfacial degradation must be comprehended to avoid it. In this study, we deploy *operando* techniques of surface-enhanced infrared absorption spectroscopy (SEIRA) and controlled polarization tests in order to simultaneously observe the interfacial degradation during the OER. In advance of it, we elaborate upon the fabrication procedure of structures idealized for the *operando* observations. We synthesize iridium-embedded carbon nanofibers and iridium oxide-electrodeposited titanium foils. We disclose that during the functioning of the OER, carbon surfaces are irreversibly impacted whereas the interfacial degradation on titanium surfaces could be circumvented. Our results highlight that the future research on materials for OER compartments should aim at the surface engineering of non-carbon surfaces by which sufficient conductivity and stability can be imparted. The material selection process can be facilitated by the methodologies suggested in this study.

Lithium Polysulfide-Based Electrolytes for Li Metal Anodes

Chen-Zi Zhao, Xin-Bing Cheng, Qiang Zhang*
Department of Chemical Engineering, Tsinghua University
Beijing 100084, China
zhang-qiang@mails.tsinghua.edu.cn, zcz15@mails.tsinghua.edu.cn

Li metal batteries such as lithium–sulfur (Li–S) and lithium-air batteries have been strongly considered as the promising candidates for the next-generation energy storage devices. Unfortunately, as the result of the notorious Li dendrite growth inherent in these batteries upon repeated charge/discharge cycling, the concomitant serious safety concerns and low Coulombic efficiency have retarded their practical applications.

Herein, we report a facile but effective strategy to in-situ construct a stable and compact solid electrolyte interphase (SEI) layer to protect Li deposits by the synergetic effect of Li_2S_5-based ternary-salt (LiTFSI–$LiNO_3$–Li_2S_5) electrolyte. LiTFSI affords a high Li conductivity of the electrolyte in a working battery. The reactions between $LiNO_3$ and Li_2S_5 induce Li_2SO_3 formation, which is favorable to build protective SEI layer. Compared with routine LiTFSI mono-salt electrolyte, the Li_2S_5-based ternary-salt electrolyte renders Li metal anode (1) dendrite-free morphology, (2) improved Coulombic efficiency (94% compared with 60% in routine electrolyte), (3) suppressed polarization, and (4) prolonged lifespan (80 h compared with 20 h). These superior characteristics are attributed to the enhanced stability of the SEI layer by deliberately introducing the Li_2S_5 polysulfide as a pre-existing precursor, which, however, is always considered as an undesirable intermediate in Li–S batteries. Further development of this electrolyte enables practical applications for rechargeable lithium metal batteries, especially Li–S batteries.

The development of low-cost and effective energy storage systems for renewable energy sources is an essential problem of the modern energy industry. At the moment, redox flow battery (RFB) is one of the most promising technology to energy storage in distributed energy grid. However, up to date, even the most studied vanadium RFBs have quite high cost due to the expensive vanadium electrolytes. In this work, a novel chemical power source - neutralization RFB with two hydrogen electrodes is developed. This RFB uses cheap and environmentally benign electrolytes - solutions of acid, alkali, and salt (fig. 1).

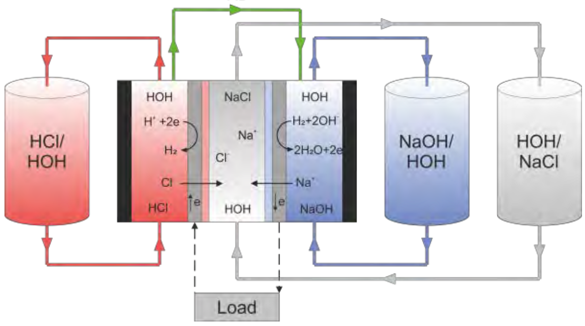

Figure 1 – Scheme of neutralization RFB with two hydrogen electrodes

In the course of the discharging process, acidic and alkaline solutions are neutralized due to hydrogen evolution/oxidation electrode reactions, while the salt solution at the middle compartment becomes more concentrated as a result of ionic fluxes of cations and anions. Thus, the overall reaction $H_3O^+ + OH^- = 2 H_2O$ gives 79.9 kJ per 1 mole of H_2O.

Several pH-dependent electrode reactions can be used as redox-component of neutralization RFB. We consider the hydrogen gas evolution/oxidation process for that purpose since the gaseous component (being the product of the cathode process and the reagent of the anodic one) can be easily transferred from cathodic to anodic compartments of the proposed cell. Anion and cation exchange membranes separating positive and negative electrodes from middle space are to prevent the leak hydroxonium and hydroxide ions and provide the ionic current of their counterions across the cell.

Energy can be obtained from neutralization of acid and alkaline solutions and saved employing the reverse process with a minimal loss if hydrogen evolution reaction and hydrogen oxidation reaction is carried out on reversible hydrogen electrodes in both acidic and alkaline medium.

The theoretical energy density of neutralization RFB using 4 M electrolyte solutions is 44 W·h/L [1]. Reported energy density and efficiency of existing neutralization batteries are modest compared to those of traditional RFBs [1, 2]. Advantages of proposed neutralization battery over analogs are the use of hydrogen as a self-supplied redox-component and two-membrane cell concept without bipolar membrane. The real energy output for discharge and round-trip energy efficiency of the cell has been determined for the laboratory-scale setup of 4 cm^2 membrane electrode assembly.

Platinum group metal-free electrocatalysts have shown promising features for catalyzing oxygen reduction reaction (ORR) at the cathode of different types of fuel cells [1-3]. However, high costs for synthesis, stability and activity issues under operating conditions, still limit their applicability. In our approach, Fe-N-C catalysts were synthesized from a nitrogen and iron wet impregnation of black pearls followed by pyrolysis steps. Three different nitrogen sources (dopamine, imidazole and benzimidazole), and two different pyrolysis atmospheres (Ar and NH_3) were used. The obtained materials were characterized in terms of structure, morphology, surface chemistry, thermal and electrochemical properties. Electrodes with a high porosity and accessible active sites were obtained tailoring the synthesis parameters, as indicated by Raman and X-ray photoelectron spectroscopies, cyclic (CV) and linear sweep voltammetry (LSV) with rotating ring disk electrode (RRDE). In particular, we found that the pyrolysis step under ammonia flow led to high double layer capacitance (CDL) electrodes (Figure 1a) and the use of imidazole as nitrogen-rich organic precursor improved ORR activity as compared to control Pt-based ones. In addition, the stability tests were carried out to evaluate the electrochemical active surface area (ECSA) changes after cycling 1000 times at a scan rate of 500 mVs^{-1}, with acquisition of CVs and LSV curves at 5 mVs^{-1} after every 200 cycles (Figure 1b) in alkaline pH, and the activity to ORR from RRDE experiments in the same measurements conditions with rotation speed of 1600 rpm (Figure 1c). The tests shown a stable activity after 1000 cycles of the electrocatalyst prepared using imidazole and pyrolyzed under ammonia atmosphere.

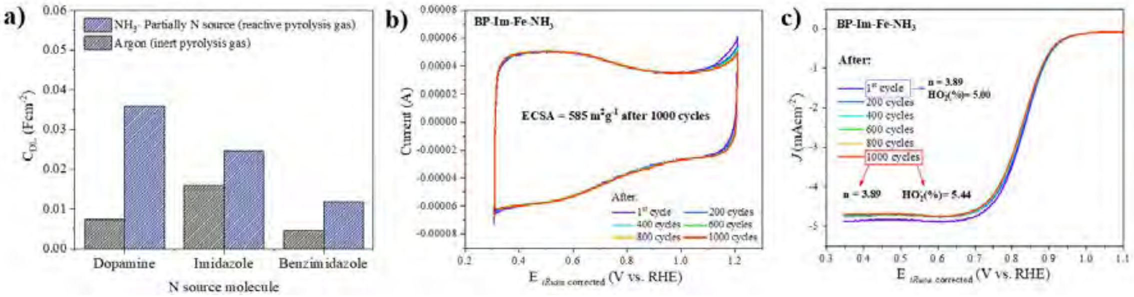

Figure 1. (a) C_{DL} of all synthesized catalysts, (b) cyclic voltammograms at a scan rate of 5 mVs^{-1} and (c) LSV curves at 5 mVs^{-1} and rotation speed of 1600 rpm in N_2 and O_2 saturated electrolyte (KOH 0.1 M) respectively, for the best performing material.

Rational Design of Stable Solid Electrolyte Interphase for Li Metal Batteries

Xin Shen, Rui Zhang, Xiang Chen, Xin-Bing Cheng, Xiaoyan Li, and Qiang Zhang*

Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology Department of Chemical Engineering Tsinghua University Beijing 100084, China
zhang-qiang@mails.tsinghua.edu.cn

Rechargeable batteries, powering portable electronic devices and electric vehicles, play a pivotal role in sustainable development. Currently, lithium ion batteries (LIBs) are almost approaching to its ceiling of theoretical energy densities, and then the research of post-LIBs with high energy densities becomes urgent. Li metal has been spotlighted as a promising anode for next-generation rechargeable batteries due to its ultra-high theoretical capacity and an extremely low redox potential. However, its practical application has been hindered by Li dendrite growth, which renders a low Coulombic efficiency and short lifespan. A stable solid electrolyte interphase (SEI) is crucial in suppressing the formation of Li dendrites (Figure 1) [1]. In this work, a quantitative electrochemical–mechanical model that couples stress, diffusion, electric fields, and electrochemical reactions was constructed, successfully tracking the dynamical failure process of SEI. Furthermore, the impacts of structural uniformity and mechanical strength on the stability of the SEI under different working conditions were investigated. This work affords an insight into the rational design of stable SEI layers and sheds light on a possible pathway toward practical applications of Li metal anodes.

Sensitive, specific and rapid detection of bacterial colonies is becoming the need of the hour. Food spoilage, prevention of pathogenic infections and antimicrobial resistance put such detection systems at highest priority in food and medicine industry. [1] Among these microbial communities, the bacterial strain of *Escherichia coli* (*E. coli*) is most commonly found, with pathogenic and non-pathogenic strains being biomarkers of bacterial contamination. [2] Here, we developed a novel electrochemical assay for *E.coli* utilizing DNA as electrical wires, mediating electron transfer between gold electrodes and a well-known DNA intercalator, Methylene Blue (MB).The binding of *E. coli* specific target DNA to the capture DNA-modified gold electrode surface triggers the intercalation of MB present in solution within the hybrid structure. The signal from MB is further electrocatalytically amplified in reaction with a commonly used redox indicator ferricyanide whose electrochemical reduction is otherwise very slow on the DNA-modified surfaces. The developed assay allows down to attomolar detection of both synthetic and isolated *E. coli* DNA and RNA. The high sensitivity of the assay allows direct application of it in point-of-care and industrial platforms for analysis of raw or minimally processed samples.

An amperometric cholesterol biosensor was designed using a glassy carbon (GC) electrode modified with a nanocomposite consisting of multi-walled carbon nanotubes (CNTs), ionic liquid (IL), Prussian blue (PB) and gold nanoparticles (GNPs).

Firstly, the GC electrode was modified with a bucky gel (BG) comprising CNTs and IL. Then, the PB and GNPs were co-electrodeposited on the surface of the BG/GC electrode. Afterwards, the Ni^{2+} ions were electrochemically incorporated into the PB structure in order to increase its stability in mild alkaline environment. Cholesterol oxidase was then immobilized on the modified electrode via a cross-linking method using glutaraldehyde.

Cholesterol was measured at −0.05 V vs. Ag/AgCl in 0.05 M phosphate buffer, pH 7.4. The cholesterol biosensor exhibited a high sensitivity of 173.56 $\mu A\ mM^{-1}\ cm^{-2}$ with a detection limit of 1.9×10^{-5} M and a linear range of $1.9\times10^{-7} - 2.8\times10^{-6}$ M. The proposed biosensor displayed a good storage stability of 1 month.

The development of new electrochemical power sources allows us to expand the capabilities of traditional energetics. One of the promising areas of modern electrochemical energetics is flow redox batteries, which generate electricity during the electrochemical reaction of energy-intensive liquid reagents. The use of bromates and chlorates as chemical oxidizing agents turned out to be promising, as this allows one to achieve high energy intensity and power density for a flow redox battery.

Nevertheless, until recently, the bromate anion was not considered as a promising reagent for electrochemical power sources due to its' non-electroactivity in the region of positive (vs SHE) potentials even on catalytically active electrodes. A few years ago in [1] the possibility of electroreduction of bromate anions in acidic media on carbon electrodes was shown due to the presence of trace bromine concentration.

In this case, the target gross process

$$LiBrO_3 + 3\,H_2 \rightarrow LiBr + 3\,H_2O$$

passes through a catalytic cycle consisting of a heterogeneous reaction on the electrode surface for a reversible bromine/bromide redox pair:

$$Br_2 + 2\,e^- \rightleftarrows 2\,Br^-$$

and irreversible (with high acidity of the solution) homogeneous reaction:

$$BrO_3- + 5\,Br- + 6\,H+ \rightarrow 3\,Br_2 + 3\,H_2O$$

This process demonstrates autocatalytic behavior and, by analogy with electrochemical redox-mediator catalysis (EC'), was called the mechanism of redox-mediator autocatalysis (EC″) [1].

The purpose of the work was experimental studies of the bromate reaction by basic electrochemical methods, an experimental verification of the mathematical model of the EC″ mechanism and the search of the main transport (diffusion coefficients) and kinetic (rate constants of a homogeneous chemical reaction) system characteristics.

During the study, series of experimental chronoamperograms and cyclic voltammograms of the electroreduction of sodium bromate in acidic media on electrodes of various nature were obtained. The voltammograms were used to evaluate the reversibility of the electrochemical stage of bromine electrooxidation. As a result of solving the inverse kinetic problem using the obtained experimental data, for the description of which an analytical model was applied, the values of the main process parameters were established.

jlolloqui@us.es

Human cytochrome c (hC*c*) stands out as a target for post-translational modifications, such as phosphorylation, which are related to the onset of diseases like ischemia. Previous works with mimetic phosphorylated hC*c*, in which tyrosine 48 or tyrosine 97 were replaced by *p*-carboxy-methyl-L-phenylalanine (hC*c*-Y48*p*CMF and hC*c*-Y97*p*CMF, respectively), have demonstrated that phosphorylation provokes significant structural changes that can be related to mitochondrial dysfunction of this protein [1, 2].

In this work, we have carried out a detailed characterization of the thermodynamics and kinetics of the interfacial electron transfer of wild type hC*c* and its phosphomimetic variants adsorbed onto gold electrodes modified with self-assembled monolayers of ω-mercaptocarboxylic acids, by analyzing their voltammetric response as a function of scan rate and temperature at pH 7.

The redox behavior of immobilized hC*c* was found to vary strongly with temperature. In particular, the temperature dependence of the redox potential and the electron transfer rate constant for the wild type variant were observed to be biphasic, with a transition point at approximately 30°C. This behavior has been ascribed to a reversible conformational transition between two states of the oxidized form leading to a more opened heme structure with a weakened Fe-Met80 bond. Moreover, it is shown that immobilized hC*c*-Y48*p*CMF and hC*c*-Y97*p*CMF display more negative redox potentials than the wild type, with a steeper temperature dependence. Both the enthalpic and entropic terms are shown to contribute to the observed shift of their redox potentials towards more negative values than those of the native protein. At the same time, the electron transfer rate constant of the phosphomimetic mutants are also lower than that of the native protein at temperatures below 40ºC, with remarkably larger values of both the electronic coupling between the redox center of the mutants and the electrode and the reorganization energy.

Overall, the present results point to a key role of phosphorylation into the modulation of the mitochondrial function of cytochromes that has been rationalized in terms of changes in the internal electric field of the protein around the heme caused by the extra negative charge brought about by the phosphorylation process. Bearing in mind that the electrostatic binding between the protein and the negatively charged surface precludes the alkaline transition of the protein, as lysine residues are involved in these electrostatic interactions, and based on the obtained thermodynamic and kinetic parameters for protein reduction, the structural change experienced upon phosphorylation is rather consistent with an increased lability of the Fe-Met80 bond of the native ferric state, and a larger protein solvation and flexibility.

The electrochemical behavior of new organic lipophilic PtIV complexes, namely, cis-[bis-nitroxyethyl isonicotinamide-N]tetrachloride platinum(IV) (**1**) and e-amine-d-(4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl)-a,f-bis(octanoato)-b,c-dichloroplatinum(IV) (**2**) were investigated in DMSO and MeCN solutions on Pt, Au and glassy carbon electrodes by cyclic (CVA) and square-wave voltammetry (SWVA). The results were compared with those for a model system, namely, wide-spread drug cisplatin.

The water-soluble hybrid materials of compounds **1** and **2** were prepared via solubilization of these PtIV complexes by copolymer nanoparticles of N-vinylpyrrolidone with (di)methacrylates [1-3]. They were characterized by dynamic light scattering (DLS), TEM, UV-Vis, and IR-spectroscopy. According to TEM and DLS, the hybrid materials consist of spherical particles with a hydrodynamic radius mainly ~(50–60) nm. The water-soluble hybrid forms of these Pt(IV) complexes were studied in aqueous phosphate buffer solutions (PBS) by electrochemical methods. The results were compared with those for their free and hybrid forms in DMSO and MeCN, and found to be quite different. CVA and SWVA curves of the water-soluble polymer particles loaded by compounds **1** and **2** and free Pt(IV) complexes in DMSO contain 3 to 5 irreversible cathodic peaks until E ~ -(1.5-2.5) V, resp. In contrast, only two overlapped peaks were observed for 1 within the potential region in PBS during a sufficiently long time. The free radical moiety of **2** exhibited one-electron irreversible cathodic and one-electron reversible anodic peaks in MeCN, and their potentials were substantially similar to those for long-lived 4-acetylamino-2,2,6,6-tetramethylpiperidine 1-oxyl radical (**3**). This free radical moiety kept its redox characteristics at the same level as **3**. Electrochemical and non-electrochemical data testified in favor of the inclusion of Pt(IV) complexes in polymer particles that were quite stable in the aqueous medium during a sufficiently long time but subjected to destruction in non-aqueous solvents under study.

These prepared hybrid materials with antitumor activity [1, 2, 4] can be promising as potential drugs with controlled properties including, e.g., water-solubility, bioavailability, prolonged action, duration of circulation in blood, accumulation in tumors, toxicity and foci of inflammation.

Electrochemical scanning tunneling microscopy studies on electrode/deep eutectic solvent interfaces

Zhuo Tan, Yu Peng, Jiawei Yan*, Bingwei Mao*
State Key Laboratory of Physical Chemistry of Solid Surfaces, and Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, Fujian 361005, P. R. China
jwyan@xmu.edu.cn, bwmao@xmu.edu.cn

A deep eutectic solvent (DES) is a mixture of a salt and an appropriate molecular hydrogen bond donor at certain quantity ratio. Like ionic liquids, DESs have the properties of low vapour pressure, non-flammable, wide electrochemical window, good conductivity and solubility. In addition, DESs are low cost and the preparation procedure is simple. As a novel class of eco-friendly solvent, DESs have already been proposed for applications in various fields, such as electrochemistry. [1-2]

High ionic strength and the existence of non-ionic hydrogen bond donor component make DESs involve multi-natured interactions including columbic interaction, Van de Waals molecular interaction and hydrogen bonding. The multi-natured interactions lead to the complexity of electrode/DESs interface. So far, fundamental investigations on the electrified interfaces in DESs remain limited.

In this work, potential-dependent electrode surface structures in different deep eutectic solvents were revealed by in situ scanning tunneling microscopic imaging, the preliminary results on surface reconstruction, etching and adsorption on single crystal electrode surface are reported.

bprice@lercorp.com

Cost effective hydrogen production is vital to many industries tied to the hydrogen economy. Perovskites, such as doped barium cerate and barium zirconate, have been investigated as proton conducting electrolytes for many industrial applications including fuel cells and steam electrolysers [1,2]. Barium cerate has a high protonic conductivity however, poor stability under CO_2 and H_2O containing atmospheres leads to rapid degradation. Oppositely, barium zirconate exhibits good stability under those environments however poor protonic conductivity makes it an impractical solution [3]. In this study, the conductivity and stability of $BaCe_{0.7}Zr_{0.1}Y_{0.16}Zn_{0.04}O_{3-\delta}$ (BCZYZ) has been investigated under both 5% H_2/Ar and 3% wet Ar atmospheres. The highest conductivity of $2.7\text{x}10^{-2}$ $S{\cdot}cm^{-1}$ is obtained at 711°C under 3% wet Ar. Area specific resistance (ASR) is similar in both atmospheres (4.0 $\Omega{\cdot}cm^2$ under 3% wet Ar and 4.1 $\Omega{\cdot}cm^2$ under 5% H_2/Ar) at 711°C. ASR increased at lower temperature, 511°C, and a new arc (with 4.45 $\Omega{\cdot}cm^2$ ASR and $2\text{x}10^{-8}$ F equivalent capacitance) is formed under 3% wet Ar, indicating a second phase formation. No second phase formation is observed under 5% H_2/Ar. ASRs of electrolyte are determined as 7.6 $\Omega{\cdot}cm^2$ and 8.2 $\Omega{\cdot}cm^2$ under 5% H_2/Ar and 3% wet Ar, respectively. The second phase formation/degradation of electrolyte is attributed to $Ba(OH)_2$ and/or $BaCO_3$ formations around 500°C under wet atmospheres. At elevated temperatures, ~700°C, $BaCe_{0.7}Zr_{0.1}Y_{0.16}Zn_{0.04}O_{3-\delta}$ exhibits both good protonic conductivity, and good stability for use in fuel cells and electrolysers.

shmunoz@ubu.es

EC-SOERS (*Electrochemical-Surface oxidation enhances Raman scattering*) is a new phenomenon discovered in 2018, which enhances the Raman signal during the electrochemical oxidation of a silver electrode under particular electrolytic conditions[1]. This phenomenon has proven to be really useful in quantification of different organic compounds such as citric acid, uric acid or nicotinic acid[1–3]. Aiming to expand the knowledge on this phenomenon it is important to quantify the effectiveness of the SOERS substrate. Nowadays, achieving effective and reproducible SERS substrate remains a challenge; however, SOERS substrates emerge as a good alternative to classical SERS substrates in terms of stability and reproducibility.

Assessment of the enhancement factors (EF) is one of the best ways to study the performance of a SOERS/SERS substrate. EFs are usually calculated taking into account the number of molecules adsorbed on the surface of the substrate. Nevertheless, in EC-SOERS, which is a dynamic phenomenon, the silver surface is being oxidized during the experiment and, therefore, it is challenging to estimate the number of molecules adsorbed on the surface. Considering this limitation, the analytical enhancement factors (AEF) could be used instead of EF, in which the concentration of the sample could substitute the number of molecules adsorbed on the electrode surface[4] (eq. 1).

$$AEF = \frac{I_{SOERS} \cdot C_{Raman}}{I_{Raman} \cdot C_{SOERS}} \qquad \text{(Eq.1)}$$

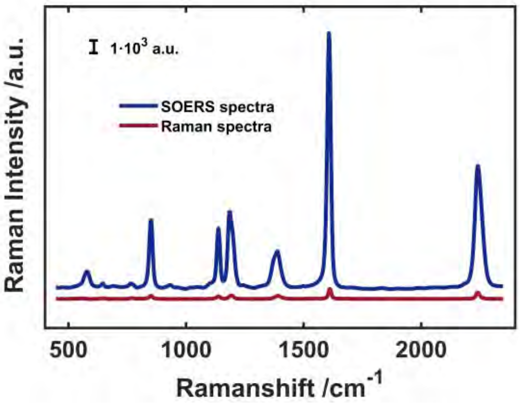

Figure 1. Ordinary Raman spectra of 0.9 M 4-CNBzA (garnet line), compared with EC-SOERS spectra of $2 \cdot 10^{-4}$ M 4-CN-BzA (blue line) registered at +0.40 V during a Raman-SEC experiment.

Since derivatives of benzoic acid are good candidates to evaluate the EC-SOERS effect, due to the presence of carboxylate group and delocalized charge around the benzenic ring, the assessment of AEF using such compounds have been carried out in this work. Figure 1 shows the comparison between the ordinary Raman spectra and the EC-SOERS spectra of 4-cyanobenzoic acid (4-CN-BzA). The intensity of these spectra is used in eq.1 to calculate the AEF of this molecule and a similar treatment is made with other isomers and derivatives of benzoic acid. A higher concentration of these molecules is necessary to have a measurable Raman spectrum whereas in EC-SOERS good spectra are obtained using lower concentrations.

Simultaneous Electrochemical Removal of Nitrate and Terbuthylazine Pesticide from Low-Conductivity Groundwater

Roger Oriol, Enric Brillas, Pere L. Cabot, Francesc Centellas, Ignasi Sirés
Laboratori d'Electroquímica dels Materials i del Medi Ambient, Departament de Química Física,
Facultat de Química, Universitat de Barcelona, Martí i Franquès 1-11, 08028 Barcelona, Spain
e-mail address: rogoriol@ub.edu; i.sires@ub.edu

The great intensification and centralization of agricultural and farming activities over the last decades to supply the increasing demand of food has entailed the accumulation of different types of organic and inorganic pollutants in soils and freshwater reservoirs as aquifers. Some of the former ones, mainly those with an anthropogenic origin such as pesticides or antibiotics are classified as contaminants of emerging concern (CEC) due to the uncertain associated ecological or human health impact. The pesticide terbuthylazine (TBA), a chloro-triazine, has become ubiquitous in the EU, being frequently detected in natural water bodies. TBA and its main by-product desethyl-terbuthylazine (DET) are toxic towards aquatic organisms and act as endocrine disruptors. Unfortunately, they are only partially removed by conventional water treatments [1]. On the other hand, the EU is the world's second biggest producer of pork after China and the biggest swine exporter. Pig farming involves the generation of large volumes of swine wastewater, with its associated intrinsic difficulties to get rid of it. Its disposal is getting currently under strict control in some of the most affected European countries such as Spain and Denmark, since it is a major source of nitrate in groundwater.

In recent years, several technologies have been developed for the removal of refractory organic pollutants. Electro-oxidation (EO) stands out among the eco-friendly electrochemical advanced oxidation processes (EAOPs) as the simplest method, with high ability to produce hydroxyl radicals ($^{\bullet}OH$) adsorbed on the anode surface. Coupling a highly efficient anode for EO with a suitable cathode that allows the simultaneous nitrate electroreduction in groundwater has been the aim of this work. This is not a straightforward task, since such water has low conductivity and contains Mg(II) and Ca(II) ions that can precipitate mainly as $CaCO_3$ and $Mg(OH)_2$ on the cathode surface, eventually causing its fouling. In practice, this is detrimental regarding the electrocatalytic properties of the cathodic surface and results in an excessive cell voltage increasing the energetic cost and making the treatment not economically viable.

This communication reports the performance of an electrochemical system developed on the basis of our previous studies [2,3]. The cell consisted of two mesh electrodes, i.e, Nb/BDD (mainly) or DSA$^{®}$-Cl_2 (for comparison purposes) anode coupled with a custom Fe mesh cathode, separated 3 mm to treat 500 mL of solutions containing 5 mg L^{-1} TBA and about 100 mg L^{-1} nitrate. The experiments were carried in two different water matrices: (i) simulated groundwater, mimicking the main characteristics of an actual groundwater in presence and absence of chloride anion, and (ii) the actual groundwater, which has been conveniently softened prior to the electrolyses. Large percentages of both, cathodic denitrification and EO of the pesticide, were attained at different current densities from 5 to 30 mA cm^{-2}, decreasing their concentrations below human consumption thresholds. The concentration of the main products and by-products were followed over time.

Direct electron transfer (DET) between an electrode and redox/catalytic center(s) in oxidoreductases is a core "elementary" process in enzyme bioelectrochemistry.[1,2] Favourable orientation and high enzyme loading on electrodes are paramount in DET-type bioelectrocatalysis to ascertain high catalytic activity and ET rate.[3] Fructose dehydrogenase (FDH) from *Gluconbacter japonicas* is a membrane-bound oxidoreductase with three subunits, subunits I (67 kDa), II (51 kDa) and III (20 kDa).[4] Subunit I holds a flavin adenine dinucleotide (FAD) cofactor as the active center of two-electron fructose oxidation to 5-keto-D-fructose. Subunit II carries three heme *c* moieties, serving as ET relays between electron acceptors and FAD. Subunit III has no redox center and possibly contributes to structural integrity of enzyme.

We present here systematic investigation of the effects of both self-assembled molecular monolayers (SAMs) and nanoporous (Au-)electrode structure on DET-type bioelectrocatalysis of FDH absorbed on SAM-modified Au(111) electrodes. Two different SAMs with varying functional terminal-groups and alkyl chain lengths were studied. FDH on a 2-mercaptoethanol (BME) SAM showed the best DET performance with a maximum current density ($\Delta j_{\mathrm{max,det}}$: 54.88 ± 3.03 μA cm^{-2}) and DET-capable fraction derived from $\Delta j_{\mathrm{max,det}}$ over mediated $\Delta j_{\mathrm{max,met}}$ (χ_{det}: 13.33 %) due to the most favourable FDH orientation on the electrode surface. FDH on Au(111) functionalized with 3-mercaptopropanoic acid (MPA) SAM exhibited the best mediated ET with Δj_{max} of 640.76 ± 7.65 μA cm^{-2} using ferrocenemethanol as the mediator. This can be explained by the negatively charged SAM surface efficiently adsorbing FDH. Non-linear fitting to the electrocatalytic profiles was performed. The FDH catalytic properties strongly depend on the alkyl chain length, showing significant decrease with increasing SAM carbon chain length. Nanoporous gold supported FDH was also prepared. Porous gold structures not only improved the catalytic performance by increased enzyme loading and χ_{det}, but also increased notably the operational stability.

Acknowledgments

Noise Measurements During Charging of Lithium Metal Anode Reveal Uneven Growth

Gözde Karaoğlu, Burak Ulgut
Bilkent University, Chemistry Department
06800, Ankara, Turkey
gozde.karaoglu@bilkent.edu.tr

Electrochemical noise measurements are well known in the corrosion literature where the noise that is to be measured is appreciable in amplitude.[1] From the measured noise of corroding systems it is possible to identify the mode of corrosion and distinguish between localized corrosion from the uniform. Our group has previously shown that non-rechargeable batteries with Li / MnO2 chemistry shows increase in voltage noises after being exposed to a short circuit.[2] In our further studies, batteries were opened in nitrogen environment to determine the source of the increase in the noise level of the battery and the chemistry of the battery was examined using the necessary characterization methods. As a result of this research, which was inspired by the corrosion literature, it was observed that the pure lithium metal on the anode surface of the batteries exposed to the short circuit reacted inhomogeneously. No noise increase was observed in the noise measurements made in the slowly-discharged batteries, but it was also observed that the pure lithium metal on the anode surface of the battery decreased homogeneously. In light of the findings obtained, it shows that the increased noise level with the short circuit is caused by the anode / lithium metal of the battery cell rather than the changes on other battery components such as the corrosion of existing collectors.[3] It is known that charging of a battery with a metallic lithium anode causes the lithium metal to settle unevenly on the anode surface, resulting in the formation of lithium dendrites and/or mossy structures. Growing lithium dendrites can disrupt the separator separating the anode from the cathode, exposing the battery to a short circuit or even causing the battery to burn or explode. For this reason, the pre-detection of any dendrite formation that may occur in the anode of the battery is both academically and industrially important. Some preliminary studies show that noise level increase drastically after it is charging and discharged. (Figure 1) Just like noise measurements on non-rechargeable batteries with lithium chemistry exposed to short circuits, it is worth studying noise measurements during charging and discharging cycles in lithium batteries that are prone to form dendrite. Some other preliminary noise measurements on Lithium anode indicated that noise levels increase after charge and discharge cycles. In this presentation, we will first explain the details regarding electrochemical noise measurements and continue to investigate the origin of increase in noise levels in Lithium anode. We will present optical and electron microscopy to correlate the noisy features in noise measurements with mossy and dendritic structures that forms during the charge and discharge processes.[4]

Methodological Considerations in Simulating Dynamic Electrochemical Interfaces and Reactions from Density Functional Theory

Rasmus Kronberg and Kari Laasonen
Research Group of Computational Chemistry, Department of Chemistry and Materials Science, Aalto University, P.O. Box. 16100, FI-00076 Aalto, Finland
rasmus.kronberg@aalto.fi

Atomistic density functional theory (DFT) based simulations of electrochemical interfaces and reactions have become irreplaceable as a complementary method in the rational development of sustainable approaches to energy conversion and storage. The field of computational electrochemistry is, however, still in its infancy and applied models require careful benchmarking for precise physicochemical predictions. Particularly, the importance of explicit solvent dynamics remains to be rigorously assessed. Considering the highly dynamic nature of electrochemical interfaces, a proper sampling of finite-temperature fluctuations by means of density functional molecular dynamics (DFTMD) may indeed be highly important.

We have explored the influence of interfacial dynamics on the potential energy surface of the Volmer–Heyrovský hydrogen evolution mechanism on a nitrogen doped carbon nanotube[1], as well as in simulating the potential-dependent hydrogen adsorption isotherm of single-crystal Pt(111)[2]. In both cases a thorough comparison with corresponding static approaches, namely the nudged elastic band (NEB) method and the computational hydrogen electrode (CHE) formalism, is performed. In the former we demonstrate decisive competing effects of solvent reorganization and entropy on activation and reaction free energies which are observed to *decrease* considerably compared to minimum energy paths obtained by static NEB calculations. Although the entropic contribution is intuitively expected to *increase* the energies, the relaxation of steric hindrance is found to dominate in the DFTMD simulations as compared to the problematic frozen solvent model conventionally employed in NEB transition path optimizations.

However, DFTMD simulations of dynamic water–adlayer structures on hydrogenated Pt(111) suggest that the determination of potential-dependent hydrogen adsorption isotherms is complicated by the challenging description of hydrogen and water co-adsorption on Pt(111) at intermediate hydrogen coverages. This balance appears particularly delicate, critically influencing electrostatic properties. Underestimation of water chemisorption by the employed RPBE-D3 functional is indeed found to overestimate sampled electrode potentials due to impeded charge transfer to the metal surface, thus demonstrating the necessity of an accurately converged interfacial structure. Conversely, the CHE scheme is found to reproduce the experimental isotherm with a surprising accuracy, thereby displaying the persisting value of carefully employed static, solventless approximations when considering the energetics of hydrogen chemisorption on single-crystal platinum. The influence of solvation and dynamics is nevertheless expected to remain significant in non-equilibrium reaction path simulations, as demonstrated in the previous direct simulation of the Volmer–Heyrovský mechanism.

Feluric Acid Electropolymerization for a Novel Glucose Biosensor

Gabriela Valdés-Ramírez, Leonardo R. Salgado Juárez, Laura Galicia Luis.
Universidad Autónoma Metropolitana Unidad Iztapalapa.
Av. San Rafael Atlixco 186, Leyes de Reforma 1ra Secc, 09340 Ciudad de México, CDMX
gabrivra@gmail.com

In this work, a polymeric membrane based on 3-methoxy-4-hydroxycinnamic acid (feluric acid) has been used for glucose oxidase immobilization onto carbon paste electrode by electrochemical polymerization. Feluric acid, is the most abundant hydroxycinnamic acid in the plant world, due to its autoinflammatory, anticancerogenic and antioxidant properties, it has been widely used in the pharmaceutical and food industries [1-3], due to its properties and redox behavior, we used feluric acid for the development of a polymeric film for a glucose biosensor.

The membrane has been synthesized by cyclic voltammetry at scan rate of 20 mV/s in acetates media 100 mM, pH 7.05 ± 0.5, in 2 mM of feluric acid, by utilizing this approach the enzyme has been entrapped into the polymeric membrane in a single step generating a glucose biosensor. The figure 1A, shows the typical cyclic voltammogram for the polymerization, it can be observed that after the first cycle the currents decreases as the usual behavior for the electropolymerization compounds with phenolic rings [4]. The biosensor has been evaluated for glucose response at constant potential of 800mV in phosphate buffer 100 mM, pH 7.34 at room temperature, the glucose biosensor shows a sensitivity of 36.1 nA/mM, linear response in the range from 0 to 30 mM covering the glucose dynamic range of clinical relevance. The 90% of the glucose response is achieved after 60 s for all the glucose dynamic range, the detection limit is 0.01mM. The figure 1B, shows the calibration curve for glucose biosensor with successive additions of glucose in 5mM increments. Figure 1C, shows the response stability for the calibration curve; all the measurements were measured vs $Hg/Hg_2SO_{4(sat)}$ electrode.

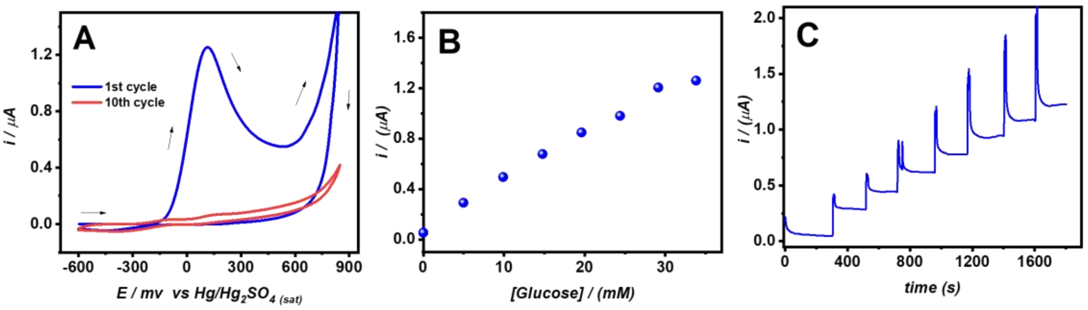

Figure 1. A) Cyclic voltammetry for feluric acid – glucose oxidase electropolymerization, 1st and 10th successive cycles at scan rate of 20mV/s. B) Calibration curve for glucose biosensor. C) Chronoamperometry for successive additions of glucose in 5 mM increments.

[2] *University of Canterbury, Christchurch, New-Zealand*

florent.struyven@univ-ubs.fr

The aim of the project is to certify the phenomena involved at the microfluidic scale in the production of electrogenerated bubbles, and to improve the efficiency of the electrolytic process by acting on the wettability and geometry of the electrodes. This study aims to validate the experimental results provided in the literature by using a multiphase model based on the VOF-HF (volume of fluid - heigh functions) method, which allows to model interfaces with variable surface tension and to limit the usual errors of multiphase models at micro-fluidic scales (parasitic currents, volume conservation).

Usually a force balance is done to predict bubble detachment. However, to be accurate this balance must include the Marangoni forces (FM) generated by the variation of the surface tension of the gas-electrolyte interface and due to the concentration and temperature gradients around the bubble [1].

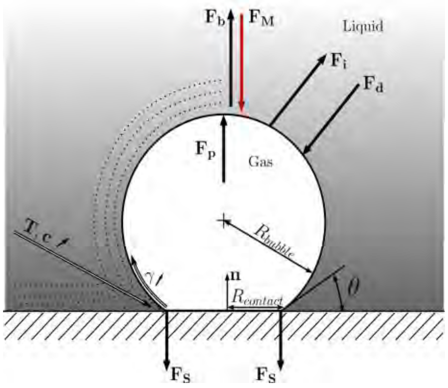

Figure 1 – Force balance made on a electrogenerated bubble on a micro-electrode

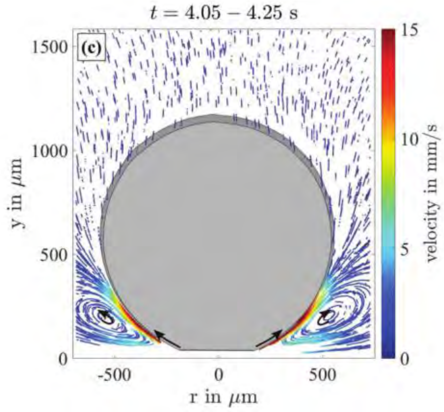

Figure 2 – Extract from [1], Marangoni effect around an electrogenerated bubble, captured using the Particle Tracking Velocimetry technique.

The Marangoni effect results in a micro-convection motion generated at the interface by the tangential stress due to the variation of the surface tension. To avoid numerical errors (parasitic currents, volume conservation problems) which are not negligible at the microfluidic scale, a robust numerical model must be used. An interface model based on "Heigh function" implemented in a "volume of fluid" (VOF) method was chosen, which allows to limit parasitic currents and to model the Marangoni effect. Numerical modelling is carried out using the ANSYS Fluent software (Pennsylvania, USA) which provides a basis for multiphysical modelling. The implementation of the interface model is based on user functions programmed in C language.

Dendritic Sensor for the Simultaneous Detection of Ethambutol and Isoniazid in TB Treatment

Ashiqa Fakier, Candice Franke
Sensorlab, University of the Western Cape
Robert Sobukwe Road Bellvile 7535, Western Cape, South Africa
3540637@myuwc.ac.za, cfranke@uwc.ac.za

Tuberculosis (TB) is an airborne disease that is one of the most infectious diseases in the world. It is specifically a problem in South Africa due to the high number of HIV cases present. The World Health Organisation has stated in a recent report that South Africa is on its way to meet the milestone of managing TB to some extent and that is an even greater reason to focus on the patients still battling with this disease [1]. TB affects the lungs, but can also affect other part of the body such as the abdomen, central nervous system and bones and joints. These different parts of the body require their own type of treatment regime of TB drugs and periods of treatment [2]. There are four first line drugs that are used in the treatment of TB that are isoniazid, pyrazinamide, rifampicin and ethambutol. If a patient is unable to take one (or a few) first line drug(s) due to the drug resistance of their TB, then a regime is made up with the other first line drugs with the incorporation of second line drugs [3]. Dosages for TB drugs are prescribed by the patient's weight and not by the type of metabolism the patient has; i.e. the more a patient weighs, the higher the dosages they are told to consume. If the patient metabolises the treatment regime too fast then it is clear that a more frequent dose of the drugs are required whereby for a slower metaboliser, a less frequent dose is needed to give the patient's body time to use up the drugs. The quantification of TB drugs is needed to check how much is present in after the patient has taken them. Determining the concentration of these drugs in the patient's body allows for information on the type of metabolic profile the patient has. Standard methods used for detection of compounds as well as for their quantification requires some sort of sample preparation or is quite bulky and not fit for crowded hospitals. These methods include chemiluminescence, mass spectrometry and electrophoresis [4]. This is why electrochemical detection methods are looking more promising, especially in the case of crowded hospitals because of its small size and point-of-care features. The monitoring of how fast or slow a patient is able to metabolise the respective TB drugs is relevant since the effectiveness of the drugs in the treatment regime can be observed this way. A step forward is presented in this study whereby a dendritic sensor is used to simultaneously monitor two of the first line drugs (isoniazid and ethambutol) in phosphate buffer since with TB treatment there are many drugs to be taken by the patient. The setup involved a three electrode electrochemical cell whereby the Au working electrode was drop coated with the dendrimer and used to monitor additions of various standards containing different concentrations of isoniazid and ethambutol. This approach is one of the ways to make TB treatment more effective for TB patients.

In the context of global warming and intermittent renewables energy integration, hydrogen production via alkaline water electrolysis is a promising CO_2-free energy storage. However, this process produces expensive hydrogen and suffer from high inertia. Therefore, this study is focused on the optimization of the process using CFD simulation to solve those problems. The price of the hydrogen is due to initial investment (IC), energy cost (EC) and the cell voltage U_{cell} Eq(1-3).

$$\mathrm{CAPEX} = 2\ F\ IC\ T^{-1}\ S^{-1}\ M_{H2}^{-1}\ j^{-1} \tag{1}$$

$$\mathrm{OPEX} = EC\ U_{cell}(j)\ F/3600 \tag{2}$$

$$U_{cell}(j) = E_{rev} + R\ j + \eta_{act}(j) + \eta_{conc}(j) \tag{3}$$

With T the life-time of the electrolyzer in s, F the Faraday's constant in C mol^{-1}, j the current density in A m^{-2}, M_{H2} the molar mass in kg mol^{-1}, E_{rev} in reversible tension in V, R the ohmic resistance in Ohm m^2, h_{act} and h_{conc} respectively the activation and concentration overpotential in V.

In industrial electrolyzer, an acceptable cell tension is 2V to 2.2V with a reversible tension between from 1.15 to 1.23V. The activation overpotential is the energy needed to overcome the activation energy of the reaction, it can be decreased using a performant electrocatalyst. Because the concentration overvoltage is negligible. The other way of improvement is to decrease ohmic resistance by finding the perfect design.Owing to find the minimum cell voltage, a two-fluid model has been developed and compared to experimental data from Boissonneau et al [1] and other models. This model takes into account the momentum conservation for all the phases, charge conservation. The flow is taken as isothermal and the species gradients are neglected. The standard model developed by Fluent does not reproduce the experimental flow. The current model reproducing the experimental data, it could consequently be used. The optimization has been performed using the Vaschy-Buckingham theorem and design of experiments. Special efforts have been made to find the optimum inter-electrode distance (Figure 1). Finally, a simple technical and economical approach has been used to find the optimum working conditions using a genetic algorithm.

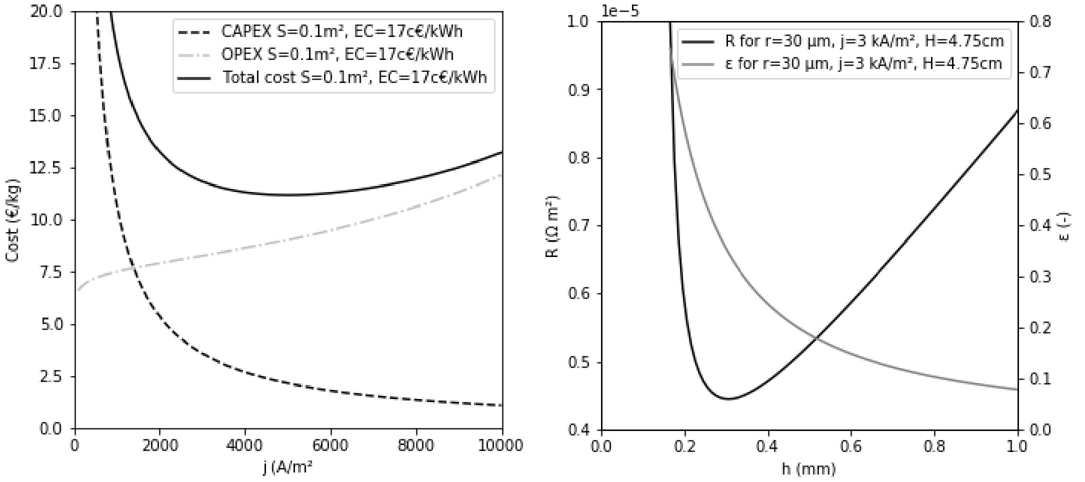

Figure 1-CAPEX, OPEX and total cost of hydrogen in € kg^{-1} (left) and ohmic electrolyte resistance and void fraction depending on the interelectrode spacing.

CYP phenotype biosensor for detection of TB drugs in spiked real samples

Candice Franke
Sensorlab, University of the Western Cape
Robert Sobukwe Road, Bellville, 7535
cfranke@uwc.ac.za

Tuberculosis is a respiratory disease that has plagued the globe for decades. Treatment for the disease has been available, however the disease remains one of the leading causes of death in the world, more prominently so in under-developed countries. One of the reasons for this is that patients suffer from adverse drug reactions (ADR's), which cause them to not complete the 6-month course of treatment [1]. Another reason is the unavailability of efficient treatment in rural areas. A mobile technology, which reduces ADR's is thus needed.

Portable electrochemical sensors for the detection of TB and the drugs used to treat it have been successful in the past [2] [3]. The development of biosensors are hindered by their efficiency in real life applications or complex matrices. Therefore, this study involves the development of a biosensor for detection of TB drugs in both synthetic urine and plasma. A simple sensor was developed using a metallodendritic electrocatalyst and a CYP3A4 enzyme immobilized onto the surface of a gold electrode. Smart nanomaterials such as this copper based first generation dendrimer allow for a higher surface area and conductivity of electrode surface for a highly sensitive sensor. The CYP3A4 enzyme was selected since it is a largely diverse enzyme in that it metabolizes up to 50% of all prescribed drugs and would mimic the bodily reaction sufficiently. The presence of a biological recognition element in an electrochemical sensor also allows for a much lower limit of detection (LOD) to be achieved.

The sensor was successful in detecting first line TB drugs in standard buffer as well as complex bodily fluids or matrices. In this case, the LOD ranged from 0.165 µM to 0.884 µM in both synthetic urine and plasma. Recovery studies when using real tablets in these complex matrices also yielded excellent results with an average recovery of 96%. The development of phenotype biosensors such as this is vital in tackling a disease that is so rampant in South Africa specifically. The possibility of determining metabolic profile of individual patients will aid in the fight against TB which is a part of the national development plan of South Africa [4]. Electrochemical sensor technology allows for a rapid testing which occurs at the point of care with minimal sample preparation. All of which are huge benefits when treating TB in rural areas i.e. townships or remote villages of Africa. Once a patients metabolic profile is determined, the dosage of treatment can be adjusted for fast, slow or intermediate metabolizers. Resulting in a more efficient treatment that avoids toxicity and adverse drug reactions and improves the quality of life for TB patients.

m.monteiro@lic.leidenuniv.nl

Probing pH gradients during electrochemical reactions is important to better understand reaction mechanisms and to separate the influence of pH and pH gradients from intrinsic electrolyte effects. Here, we develop a pH sensor to measure pH changes in the diffusion layer during electrochemical reactions. The probe was synthesized by functionalizing a gold ultramicroelectrode with a self-assembled monolayer of 4-nitrothiophenol (4-NTP) and further converting it to form a hydroxylaminothiophenol (4-HATP)/4-nitrosothiophenol (4-NSTP) redox couple. The pH sensing is realized by recording the tip cyclic voltammetry and monitoring the Nernstian shift of the mid-peak potential. We employ a capacitive approach technique in our home-built Scanning Electrochemical Microscope (SECM) setup in which an AC potential is applied to the sample and the capacitive current generated at the tip is recorded as a function of distance. This method allows for an approach of the tip to the electrode that is electrolyte-free and consequently also mediator-free. Hydrogen evolution on gold in a neutral electrolyte was first studied as a model system. The pH was measured with the probe at constant distance from the electrode (ca. 75 µm) while the electrode potential was varied in time. In the non-buffered electrolyte used (0.1 M Li_2SO_4), even at relatively low current densities, a pH difference of three units is measured between the location of the probe and the bulk electrolyte. The time scale of the diffusion layer transient is captured, due to the high time resolution that can be achieved with this probe. The sensor has high sensitivity, measuring differences of more than 8 pH units with a resolution better than 0.1 pH unit. The probe was also used to perform direct pH measurements in the diffusion layer during CO_2 reduction. pH measurements show how bicarbonate can buffer the interface and maintain the pH approximately 7 within a certain potential/current range, before extreme alkalinity starts to develop.

Several new research topics and technological developments in electrochemistry were born in the last decades together with the progress of nanoscience and nanotechnology. Bragg coherent diffraction imaging (BCDI) have been applied since late in the 1990s to obtain 3D images of nanomaterials, also giving information of lattice strain and defects. BCDI consists in imaging single nanocrystals using highly coherent and very intense x-ray beams, demanding the use of very powerful light sources. The use of phase retrieval algorithms allows to reconstruct three dimensional images of single particles from diffraction patterns.

Some examples of applications of BCDI to electrochemistry, and other fields relevant to the area, comprise very important contributions to the study of batteries[1] and the behavior of nanomaterials[2]. Figure 1 shows an outstanding result in the field of heterogenous catalysis[3]. Through the 3D image of a Pt NP and measuring the lattice displacement, the authors were able to follow the chemisorption of CH_4 and O_2 on the NP. It is worth noting that similar experiments are still missing in the field of electrocatalysis.

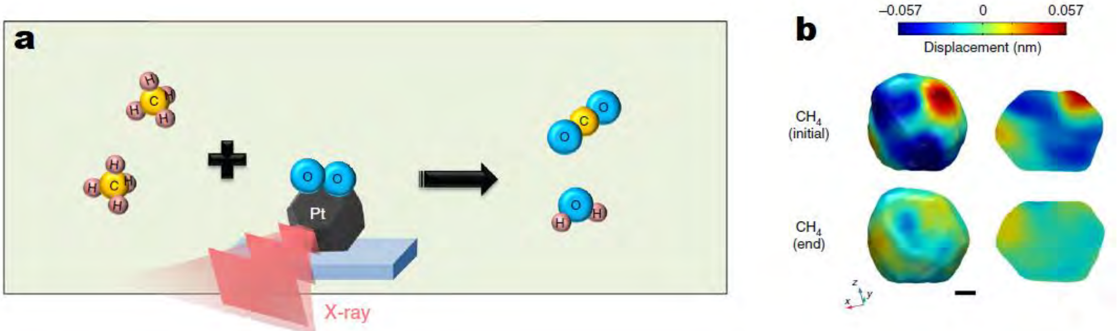

Figure 1. a) Scheme of *in situ* BCDI during methane catalytic oxidation. b) Displacement and 3D reconstructed of a 220 nm Pt nanocrystal during CH_4 oxidation. Red (positive sign) indicates the projected displacements along the [111] direction and blue (negative sign) implies the opposite direction. These 3D images show lattice contraction along the edges and corners owing to adsorption of oxygen atoms and methane. The cross-sections show that the distortion propagates deep into the interior of the Pt nanocrystal and is released after catalytic methane oxidation. The image was adapted from the literature[3].

In this work, we will summarize the most relevant advances of this technique applied to different electrochemical systems, including some interesting results recently reported at MAX IV[4], and we will also discuss about the future challenges that this technique must overcome to perform in situ/operando electrochemical experiments.

Iron-doped Calcium Titanate as co-catalyst for the Oxygen Reduction Reaction (ORR)

Lucia Mazzapioda[a], Riccardo Renga[a], Maria Assunta Navarra[a]
[a]*Department of Chemistry, Sapienza University of Rome,*
Piazzale Aldo Moro 5, 00185 Rome, Italy
lucia.mazzapioda@uniroma1.it

For sustainable economic growth and environment protection, energies generated from renewable sources result indispensable. In this field, polymer electrolyte membrane fuel cells (PEMFCs) are considered as a key element in the future clean energy becoming a promising solution. However, these devices present two major drawbacks, high cost and low durability that must to be solved for a their large scale application and commercialization. One main challenge concerns the development of highly stable reversible electrodes capable to catalyze efficiently the oxygen reduction reaction (ORR)[1,2]. Unfortunately, this reaction is kinetically sluggish toward electrons transfer because it is thermodynamically unfavorable, resulting in high overpotentials at the fuel cell cathode. Considerable efforts, in the last decade, were addressed to improve the electrochemical oxygen reduction reaction and to reduce Pt loading in order to achieve low-cost targets.

To this purpose, we here propose a study based on the use of a non-stoichiometric perovskite iron-doped calcium titanate ($CaTi_{0.8}Fe_{0.2}O_{3-\delta}$, CTFO) as co-catalyst for the oxygen reduction reaction (ORR).

Physical chemical investigations for the understanding of functional features of the proposed materials will be presented, such as the X-ray analysis of the perovskite reported in Figure 1.

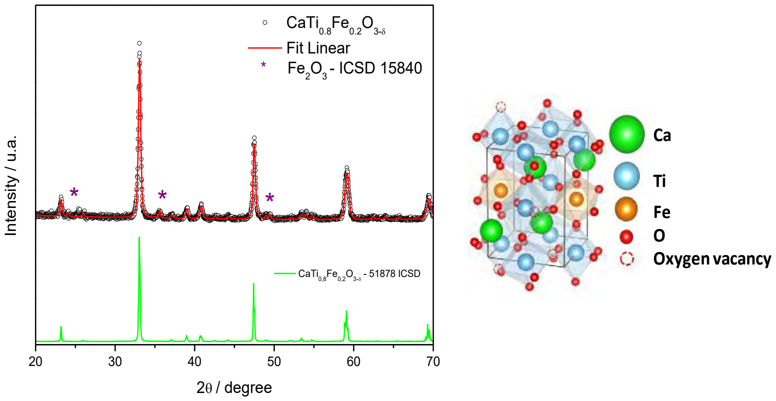

Figure 1: X-ray diffraction pattern of the synthesized $CaTi_{0,8}Fe_{0,2}O_{3-\delta}$ powder and its structure

Composite Pt/C electrodes, with different amounts of $CaTi_{0.8}Fe_{0.2}O_{3-\delta}$, were prepared and their catalytic performances were investigated by rotating-disk electrode (RDE) techniques. Two composite catalysts were prepared, Pt/C:CTFO 1:0,5 and Pt/C:CTFO 1:1 and compared with a commercial Pt/C catalyst used as reference. RDE measurements, have shown that the catalyst Pt/C:CTFO 1:1 posses the best activity toward the ORR presenting a 4 e-reduction pathway and exhibiting the most high limiting current density than the other samples. It is clear that the right amount of this perovskite can alter the ORR mechanism from 2e- pathway to a 4e- pathway, in fact a poor amount of additive seem to be not sufficient to improve the Pt/C catalytic activity.

By this preliminary study about the physical chemical and electrochemical properties of CTFO, we have demonstrated that this iron-doped perovskite is a promising electroactive material to be used as cathode catalyst support for low temperature fuel cells.

Advanced energy and sensor technologies require microelectromechanical systems with increased device performance, versatility, and efficiency. To enable this, 3D micro and nanoconductors have emerged as essential components for the miniaturization of next generation devices. Ubiquitous in the semiconductor industry, electroplating in wafer-scale lithography molds is a high-throughput fabrication method for micro and nanoconductive components. This work investigates methods to tailor the topology of electroplated 3D conductive components, such as electrodes, using CAD modeling in COMSOL Multiphysics. This enables meeting the design specifications of flat, convex, or concave substrate-distal electroactive surfaces. Flat conductor surfaces are ideal for microbump soldering and flip-chip fabrication methods and concave/convex designs increase the number of available electrode reaction sites for sensor applications. Coupled and uncoupled physics simulations were performed comprising laminar flow of a Newtonion fluid, the standard convection protocol for electrochemical baths, and electrochemistry modeling with the Nernst-Planck and Butler-Volmer formulations for mass transfer and reaction kinetics, respectively. Laminar flow or convection dominant electroplating conditions were found to create convex substrate-distal conductor topologies. Diffusion dominant electroplating conditions resulted in concave formations. Both effects can be coupled together to create a flat substrate-distal conductor topology. Simulation results are compared to directly corresponding experimental work, with positive correlation. By use of virtual mathematical modeling tools, such as COMSOL Multiphysics, crucial insights into the electroplating process can be gained. Herein, the phenomenon of substrate-distal electroactive surface topology is investigated with regards to the interplay between convection and diffusion dominant conditions. Our findings enable tailored and scalable surface topology processing options, which can be readily integrated into pre-existing research and industry standard operating procedures.

Increased levels of CO$_2$ in the earth's atmosphere, originating from excessive anthropogenic greenhouse gas emissions, are believed to be the main cause of global warming [1]. The electrochemical CO$_2$ reduction, however, provides a viable option for reducing anthropogenic CO$_2$ emissions, while at the same time closing the carbon cycle, by selectively converting CO$_2$ to for example formic acid. Formic acid is a valuable commodity chemical, not only because of its application in several chemical processes, such as textiles, pharmaceuticals and food chemicals, but also because of its potential as a hydrogen carrier [2].

Over the last decade, the electrochemical reduction of carbon dioxide towards formic acid has been studied extensively and several promising Cu/Sn electrocatalysts have already been reported [3]. Despite the reported high Faradaic efficiencies, the stability and activity of these state-of-the-art electrocatalysts and the contribution of the supporting material remains insufficiently studied.

In this work, we investigate the influence of the carbon support on the stability, current density (activity) and Faradaic efficiency, during the electrochemical reduction of CO$_2$ towards formic acid. This is done by comparing the performance of both unsupported- and carbon-supported Cu/SnO$_2$ core-shell electrocatalysts for the CO$_2$ reduction, through multiple chronoamperometric measurements, as this allows ranking the electrocatalysts with respect to their selectivity in function of applied potential. Furthermore, these catalysts were evaluated at industrially relevant conditions, in our in-house designed electrolyzer, revealing a good stability compared to literature. The supporting material is believed to play a key role in the enhancement of the stability and activity of our Cu/SnO$_2$ core-shell electrocatalysts.

Capacitive deionization (CDI) emerged as an energy-efficient desalination technology, in which ions are removed from the water and stored in the electrical double layer inside the pores of an activated carbon material. In this work, we demonstrated a comprehensive and systematic study of polyaniline activated carbon (PAC) electrodes prepared by blade-casting (DB) and free-standing (FS) techniques in order to enhance the salt adsorption capacity (SAC) and adsorption/desorption kinetics of the CDI process. The effects of interparticle porosity and electrode thickness on the textural and electrochemical properties of electrodes enabled a better understanding of how tuning the preparation technique of the CDI electrodes can improve the desalination performance. Although the different electrodes performed similarly in terms of gravimetric salt adsorption capacities, FS electrodes outperformed the DB electrodes in terms of volumetric salt adsorption capacities, because the carbon films were more compact and a large quantity of electroactive material was available for salt adsorption. In this case, a higher amount of salt can be removed using small CDI units equipped with FS electrodes. On the other hand, when the electrosorption and desorption kinetics are considered, the DB electrode presented superior performance due to its higher interparticle porosity that provides faster mass transfer in voids, thus increasing the ions transport to the PAC surface and the electrosorption rate. In this case, the DB electrode displayed the best performance for CDI applications involving aqueous diluted salt electrolytes. In summary, the presence of large interparticle porosity in thin thickness electrodes is important to obtain superior performance in the CDI process.

Copper hexacyanoferrate obtained from a nanocomposite between reduced graphene oxide and copper oxide nanoparticles for application in batteries

Maria Karolina Ramos, Aldo José Gorgatti Zarbin

mariakarolina05@gmail.com, aldozarbin@ufpr.br

Prussian blue (PB) is one of the most studied mixed-valence materials and has become a class of compounds useful for large-scale metal-ion batteries, and its structure allows modifications that lead to a series of compounds, the so-called Prussian blue analogs (PBAs).[1] Among all PBAs, copper hexacyanoferrate (CuHCF) has unique characteristics, which can present reversible redox reactions in various supporting electrolytes containing Li^+, Na^+, NH_4^+, K^+, among others. Obtaining nanocomposites between PBA and carbon nanostructures improves some PBA characteristics, increasing both the electronic conductivity and the electrochemical stability. Several studies have demonstrated the potential of these nanocomposites as active materials to be used in batteries and capacitors, in which the charge and discharge processes are fast and reversible, showing high charge densities.[2] In this work we present a new route to obtain nanocomposite thin films between copper oxide nanoparticles (Cu_xONPs) and reduced graphene oxide (rGO) through a liquid-liquid interfacial reaction developed in our research group.[3] Twenty different films between Cu_xONPs and reduced graphene oxide (rGO) was obtained varying the ratio between the components. The precursors of the rGO/Cu_xONPs nanocomposite were reduced simultaneously and formed a self-sufficient thin film at the interface of the biphasic system. These films were deposited on different substrates and characterized by different techniques. The morphology of the copper oxide nanoparticles obtained from these materials varied in each sample, in relation to shape and size: smaller spheres (57 nm), larger spheres (179 nm), cubes (120 nm) and ellipses (200 nm) . Through X-ray diffractometry, it was possible to verify that the smaller spheres are Cu_2O species and the other morphologies were attributed to CuO, where most of these films are formed by mixtures between these species. After characterization, some films were used as precursors for the formation of nanocomposites between rGO and CuHCF, through an electrochemical reaction with $K_3[Fe(CN)_6]$ solution. After a systematic study the optimal condition to the electrodeposition was fixed in pH 2, potential range from 0.0 to 1.0 V (vs Ag/AgCl) and scanning speed of 20 mV s^{-1}. The best rGO/CuHCF film obtained was studied as a potential material for cathodes of aqueous metal-ion batteries. This film was evaluated for three different electrolytes (NaCl, KCl and LiCl) in the charge and discharge curves and different current densities (0.05; 0.10; 0.25; 0.50; 0.75; 1.00 and 2.00 A g^{-1}), where the best results were for Na^+ and K^+ reaching a capacity of 25 mA h g^{-1} at a rate of 0.05 A g^{-1}. The summary of this work is represented in the figure below.[4]

Atomic Layer Deposition of IrO_2 and NiO thin films as anodes in Alkaline Water Electrolysis

DJ Donn Matienzo[1], Emanuele Instuli[1], Daniel Settipani[2] and Tanja Kallio[2]
[1]New Application Research, Research and Development Division, Industrie De Nora S.p.A., 20134 Milan, Italy;
[2]Department of Chemistry and Materials Science, School of Chemical Engineering, Aalto University, 02150 Espoo, Finland
djdonn.matienzo@denora.com

Recent studies show that the application of thin film materials to catalytic systems has begun to attract much attention, and the capacity to deposit these catalytic films in a highly controlled manner continues to gain importance. Atomic layer deposition (ALD) which is a special type of chemical vapor deposition (CVD) technique, is considered as one of the most attractive thin film deposition techniques where the conformality, uniformity, and thickness controllability of the films are crucial [1].

In this work [2], iridium dioxide (IrO_2) and nickel oxide (NiO) thin films (approximately 25 to 60 nm) were deposited on Ni expanded mesh suitable for industrial applications and on an Si (100) substrate, which served as a reference material. Subsequently, thin films deposited on Ni-expanded meshes were applied as anodes for alkaline water electrolysis. The choice of these two materials comes from the need to demonstrate the electrochemical activity of thin films for what are known to be particularly active noble and non-noble metal oxides for oxygen evolution reaction. Various ALD operating parameters (i.e., total number of deposition cycles, sublimation and deposition temperatures, and precursors pulse and purge lengths) were varied to determine their effects on the structure and the electrochemical performance of the thin film materials. With the requirement to run the electrolysis system at the lowest power consumption as possible for industrial applications and the next generation alkaline water electrolysis will operate at current loads around 1000 mA cm^{-2} (10 kA m^{-2}), the focus of this study is to compare the oxygen overpotential at such high current density. Results from the electrochemical tests (6 M KOH, 80 C, continuous agitation) showed the catalytic activity of the samples. Oxygen overpotential values were 20 to 60 mV lower than the uncoated Ni expanded mesh. In summary, the study has demonstrated the feasibility of using the ALD technique to deposit uniformed and electroactive thin films on industrial metallic substrates as anodes for alkaline water electrolysis.

Unconventional media like Room Temperature Ionic Liquids (RTILs) and Deep Eutectic Solvents (DES) are promising electrolytes for the electrochemical valorisation of biobased compounds. Indeed, their ability to solubilize lignocellulose and its by-products[1], their low vapour pressure and their large electrochemical window are particularly attractive. In addition, DES are inexpensive, easy to produce and environmentally friendly.

In this work, the ILs [BMPyrr][NTf_2] and [BMIm][NTf_2] and the DES Choline Chloride-Urea (ChCl-U) and Choline Chloride-Glycerol (ChCl-Gly) were used for the electroconversion of furfural (FF), a molecule extracted from hemicellulose. FF can be obtained in large quantities from agricultural waste like sugar cane bagasse, wheat straw or corn stover[1] and is a promising building block for the chemical industry[2].

NMR measurements after long-term electrolyses and in-situ FTIR coupled with electrochemical techniques were used to study the FF behaviour in these media.

In [BMPyrr][NTf_2], the reduction of FF leads to the formation of furfuryl alcohol, meso-hydrofuroin and d,l-hydrofuroin after electrolysis irrespective of the electrode material tested (Au, Pt, Cu, Ag, C). At carbon electrode, the electrochemical window is large enough to observe the oxidation of FF, tough electrolyses showed a blockage of the electrode resulting from adsorption processes.

In [BMIm][NTf_2], a single product, furoin, is observed after reduction at a gold electrode. The presence of carbene evidenced by NMR measurements supports an N-heterocyclic carbene catalysis mechanism for the formation of furoin.

In ChCl-U at 25°C, the degradation of FF by a condensation reaction between urea and FF was evidenced by NMR measurements and this medium was thus discarded. By contrast, FF showed to be stable in ChCl-Gly.

In ChCl-Gly, reduction of FF and formation of furfuryl alcohol were detected by the combination of in-situ FTIR and electrochemical techniques at gold and copper electrodes. The electrochemical stability of the DES itself was monitored by the same techniques. Degradation of the DES appears to be less significative on copper in comparison with gold. The electrochemical activity of synthesised Au/C and Cu/C nanoparticles for FF reduction was compared with the bulk materials.

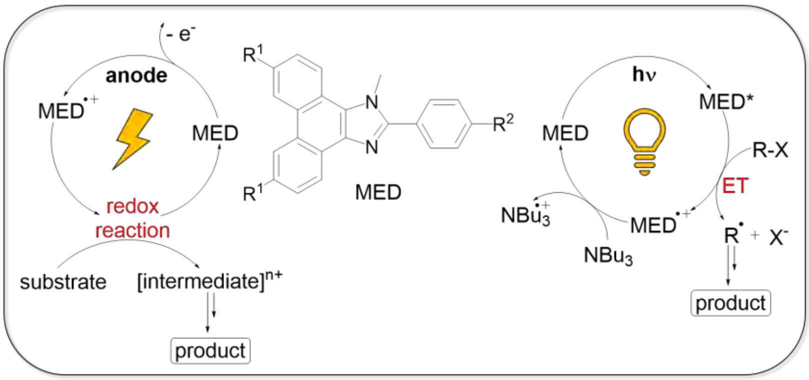
The phenanthro[9,10-*d*]imidazole framework as a new mediator platform for photo- and electrochemistry

Patrick Enders, Michal Májek, Robert Francke
University of Rostock
Albert-Einstein-Str. 3a, 18059 Rostock
patrick.enders@uni-rostock.de

Redox mediators are often used in electro- and photochemistry to enable reactions that are otherwise not feasible or very slow.[1] For a long time, researchers in both fields have independently developed their own systems based on the individual requirements. Herein we present a new organocatalyst platform based on the phenanthro[9,10-*d*]imidazole structure (MED, see figure below), which can be used both for electro- and photochemical applications.[2],[3] Moreover, the mediator properties can be flexibly tuned by variation of R^1 and R^2.



Anodic oxidation of MED leads to formation of a radical cation, which can act as a single electron acceptor toward a substrate in solution and thereby trigger synthetically useful reaction sequences.[2] On the other hand, photoexcitation by blue light leads to an excited state MED* that can act as a strong reductant. MED* is capable of performing reductive dehalogenations leading to radical intermediates that can be used for C-C bond forming reactions.[4]

The properties of MED were investigated using cyclic voltammetry, preparative scale electrolysis, UV-Vis spectroscopy, fluorescence quenching studies and photochemical test reactions. In the present contribution, the results of these studies will be presented, including a comparison between the photo- and electrochemical applications and the influence of the substitution pattern on key-properties such as redox potential, light absorption and reactivity.

Electrochemiluminescence is a luminescent emission induced by an electrochemical stimulus. In the last decades, ECL emerged as a powerful analytical technique in many fields, like clinical assay and bioanalysis, thanks to the unique signal-to-noise ratio and spatial control of the emission [1].

The ECL intrinsic spatial resolution is crucial in the combination with microscopy, an emerging approach for the visualization of micro and nano-metric objects and biological materials in close proximity to the electrode surface. ECL microscopy applications and features are being deeply studied for increase the sensitivity and the successful surface-confined mapping of analytes [2]. In the quest for reaching these goals, ECL microscopy can be coupled to nanotechnologies.

Nanomaterials, such as nanoparticles and carbon nanotubes (CNT), are being widely studied in combination with ECL for enhancing the analytical signal [3]. Herein, nanomaterials will be used for extending the spatial emission of ECL imaging, which is normally confined in close proximity to the electrode surface (distance < 3 μm). CNTs or graphene, thanks to their highly conductivity, were used to create a sort of conductive layer all around labelled objects [4]. Here we demonstrated that ECL emission active area is extended with a consequent enhance in the ECL signal. This novel approach has been applied to beads with different dimension (ranging from 1 to 4 μm) providing novel insights into the mechanisms underlying ECL generation.

Due to technological progress and population growth, a huge increase in demand for energy is expected in the next years. However, energy production and consumption are accompanied by significant heat losses which generate a direct nuisance on the environment and contribute to climate change. One of the promising routes to new energy resources is the use of this waste heat. In such a context, an interesting way for the direct conversion of low grade heat into electricity is the use of thermogalvanic cells (TGCs) containing ionic liquids (ILs) as electrolyte [1, 2].

Our choice of the system was focused on the solutions of europium in 1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)imide (EMIM.TFSI). The apparent standard potential of the redox couple Eu(III)/Eu(II) strongly depends on the temperature in various ILs based on the anion $TFSI^-$ [3], our objective was therefore to explain this phenomenon and to develop new TGCs. We studied the properties of the solutions of europium(III) and (II) as a function of temperature and in the presence of various ligands (water, dimethylsulfoxide, dimethylacetamide, bromides, etc.) by numerous spectral and electrochemical methods.

Cyclic voltammetry study has shown that electroreduction of europium(III) species is irreversible in an anhydrous medium on a glassy carbon electrode. However, the redox process becomes quasi-reversible after the addition of ligands or the temperature increase. In particular, we studied the competitive complexation of europium(III) ions by water and $TFSI^-$ or Br^- anions over a wide range of temperatures. The diffusion coefficients of the europium(III) species were of the order of 10^{-7} $cm^2.s^{-1}$ at 61.5 ° C. In our work, we have shown that the Seebeck coefficient can reach a record value of -5.5 $mV.K^{-1}$ due to the competitive complexation of europium ions in ionic liquid medium.

The new TGCs were tested under open and closed circuit conditions, and the obtained data were in perfect agreement with the results of cyclic voltammetry. The electrical power measurements were carried out and the optimization work is underway.

Nickel Catalyst Migration in Anion Exchange Membrane Fuel Cells

Lin Xie and Donald W. Kirk

Department of Chemical Engineering and Applied Chemistry, University of Toronto

200 college, Toronto, ON, Canada M5S3E5

Nickel materials have been widely studied as non-platinum group metal (non-PGM) cathode catalysts for anion exchange membrane fuel cells (AEMFC). Although the stabilities of many Ni catalysts have been tested by accelerated potential cycling, the studies do not fully simulate the operating Anion Exchange Membrane Fuel Cell (AEMFC) conditions. For back-up power systems, the standby AEMFCs are at a high steady state cell potential. For cathode catalysts, this is a more challenging condition than cycled potentials and the stability of Ni catalysts need to be re-examined.

Ni is stable in many alkaline electrochemical applications because of the formation of a NiO_x passivation film at the surface under water splitting potentials, which prevents further corrosion [1]. However, AEMFC operating conditions could disrupt the Ni passivation mechanism. According to the thermodynamic model by Beverskog et al., Ni formation of $Ni(OH)_3^-$ ([I]= 10^{-8} M) is possible when the pH > 11 and the potential is within 0.1V-1.0V vs. RHE potential, which covers the range of AEMFC operating conditions [2]. This suggests that, especially with high cathodic AEMFC potentials, Ni, including both Ni metal and Ni oxides, may potentially dissolve to form $Ni(OH)_3^-$. This could cause a significant challenge to the known Ni passivation mechanism as the surface NiO_x protection film may dissolve to form mobile ions leaving the underlying Ni susceptible to corrosion. Especially when the AEMFC is operating at a constant high voltage at standby, the steady state cathode potential could keep the Ni species dissolved and allow the mobile Ni species migrate to other AEMFC components, which could be detrimental to fuel cells,

This study was aimed at examining the stability of Ni at an AEMFC cathode, under steady state cell potentials. A basic Ni composite catalyst, Ni on Vulcan® XC72 carbon (Ni/C), was used as the catalyst to research cathodic Ni behavior under the study conditions in a simulated AEMFC with constant oxygen flow. A steady state potential of 0.9V was held across the cell for 1500 hours of testing. The resulting changes in Ni morphology due to dissolution and migration were significant and were examined at multiple cell locations, using scanning electron microscopy (SEM), scanning transmitted electron microscopy (STEM), and X-ray Photoelectron Spectroscopy (XPS) analysis. These analyses on Ni migration should provide a benchmark for the use of Ni catalysts in AEMFC.

Rechargeable aqueous zinc-ion batteries (ZIBs) are attracting more attention since the Zn anode possesses low redox potential (-0.76 V *vs.* standard hydrogen electrode (SHE)), high specific capacity (820 mAh g^{-1}), excellent stability in water and low cost.[1] The electrochemical performance of ZIBs mainly depends on the design of cathode materials. Recently, various active materials such as transition metal oxides or sulfides (based on vanadium[2] and manganese[3]), Prussian blue analogues[4] and organic compounds[5] were developed to serve as the cathode materials of aqueous ZIBs. Among them, organic materials are considered as a promising candidate because of their renewability, environmental friendliness, low cost and structural diversity.

The proton storage in rechargeable aqueous zinc-ion batteries (ZIBs) is attracting extensive attention due to the fast kinetics of H^+ insertion/extraction.[6] However, up to now, it is not achieved in organic materials-based ZIBs with a mild electrolyte. Herein, we developed aqueous ZIBs based on diquinoxalino [2,3-*a*:2',3'-*c*] phenazine (HATN) in a mild electrolyte. Electrochemical and structural analysis confirm for the first time that such Zn/HATN batteries experience a H^+ uptake/removal behavior with highly reversible structural evolution of HATN. The H^+ uptake/removal endows the Zn/HATN batteries with enhanced electrochemical performance. Proton insertion chemistry will broaden the horizons of aqueous Zn/organic batteries and open up new opportunities to construct high-performance ZIBs.

The hydrogen economy is one of the strategies to phasing out fossil fuel technology in the core sustainable development goal (SDG 7) where hydrogen (H_2) is generated from water and employed as fuel for clean and renewable energy. Alkaline water electrolysis has long histories and presently used in industries for H_2 production using platinum (Pt) catalysts.[1] However, the Pt is scarce and poor electrocatalytic activity in alkaline conditions compared to palladium (Pd) electrocatalysts.[2] This informed the interest to design a novel nanostructured Pd electrocatalyst on metal-organic framework (MOF)-derived carbon support. The MOF is used as a sacrificial template because of its interesting properties which are inherited in the derived carbon.[3] This work studies the cobalt-based MOF-derived carbons (MOFDC) as new carbon-based support for Pd catalyst for electrochemical water-splitting; i.e., hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in alkaline medium. The study shows a high increase in the HER activity, in terms of low onset overpotential (onset η = 35 mV *vs.* RHE), high exchange current density ($j_{o,s} \approx 0.22$ mA cm^{-2}), high mass activity ($j_{o,m} \approx 59$ mA mg^{-1}), high kinetic current ($j_K \approx 5 - 8$ mA cm^{-2}) and heterogeneous rate constant ($k^0 \approx 4 \times 10^{-4}$ cm s^{-1}) are attributed to the high porosity of the MOFDC and contribution from Co residue, while the large Tafel slope (b_c = 261 mV dec^{-1}) is ascribed to the high hydrogen adsorption onto the polycrystalline Pd as supplementary reaction step to the suggestive Volmer–Heyrovsky mechanism. These values obtained for the catalyst are comparable or better than many recent reports that adopted nano-carbon materials and /or use bi- or ternary Pd-based electrocatalysts for HER. The improved HER activity of the Pd/MOFDC is associated with the positive impact of MOFDC and Co residue on the Pd catalyst (i.e., low activation energy, $E_A \approx 12$ kJ mol^{-1}) which allows for easy desorption of the H_{ads} to generate hydrogen. Moreover, the Pd/MOFDC displays satisfactory OER activity than its analogue, with lower onset η (1.29 V *vs.* RHE) and b_a ($\approx$ 78 mV dec^{-1}), and higher current response (ca. 18 mA cm^{-2}). Indeed, this study provides a new strategy of designing and synthesizing MOFDC with physico-chemical features for Pd-based electrocatalysts that will allow for efficient electrochemical water-splitting processes.

Few-layer graphene structures (FLGS) doped with heteroatoms (N, P, S and B) and/or their nanocomposites with transition metals oxides demonstrate distinct catalytic activity towards the oxygen reduction reaction (ORR). Such materials are considered as promising candidates to replace platinum-based catalysts in the cathodes of fuel cells and metal-air batteries [1]. Recently, the usage of electrochemical methods for the synthesis of few-layer graphene structures (FLGS) has become increasingly popular. At current densities greater than 20 $A \cdot cm^{-2}$, high-voltage impulses applied to the graphite electrodes immersed into electrolyte solution lead to the formation of electrolytic plasma [2,3]. A certain advantage of plasma-assisted electrochemical exfoliation of graphite is the diversity of modes of carbon nanostructures synthesis.

In the present study, a bipolar electrochemistry approach was utilized to realize an electrochemical exfoliation of graphite in two separate electrochemical cells. A “closed” circuit was implemented in which a bipolar electrode (BPE) was located in the completely separated cathodic and anodic compartments and voltage pulses were applied to the driving electrodes with a significantly larger surface area compared to that of BPE. The process was carried out using the set-up designed in the laboratory of laser electrochemistry of IPCP RAS [3] in the mode of alternating anodic-cathodic plasma. Each cell contained a different electrolyte, namely 1 M Na_2SO_4 and 1 M Na_2SO_4 + 0.01 M $MnSO_4$ were used. As a result, FLGS were synthesized in the first cell and nanocomposite of FLGS with manganese oxides were produced in the second one. Materials obtained in this way were characterized in detail using elemental analysis, scanning electron microscopy and X-ray photoelectron spectroscopy. Besides, oxygen reduction reaction was studied by the rotating disk electrode method at individual electrocatalysts and their mixture as well. Based on the obtained data, it can be concluded, that the usage of solution containing manganese salts allows one to produce FLGS nanocomposites with Mn_3O_4 which demonstrate high electrocatalytic activity towards the oxygen reduction reaction.

Thus, these results indicate the possibility of production of active platinum-free ORR electrocatalysts based on the nanocomposites of carbon nanostructures with transition metal oxides in the course of electrochemical exfoliation of graphite in the mode of electrolytic plasma realized in a bipolar configuration.

This work was supported by the Russian Foundation for Basic Research, project No. 19-03-00310 and was carried out using the equipment of the Multi-User Analytical Center of IPCP RAS and the equipment of the Multi-User Center of Scientific Center in Chernogolovka RAS.

A Chemically Self-Charging Aqueous Zinc-Ion Battery

Yan Zhang
Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University
Tianjin, 300071, P. R. China
zhangynku@mail.nankai.edu.cn

Rechargeable batteries are widely used in many fields such as electric devices and grid-scale energy storage systems. In general, the commercial batteries are often charged by electrical grid. However, in the harsh environment or remote area, the electrical grid is unavailable, which limits the recharging and reuse of batteries. In order to solve this issue, various energy harvesting technologies, such as photovoltaic devices, piezoelectric nanogenerators, triboelectric nanogenerators and thermoelectrics, were integrated with batteries into self-charging power systems. However, the conventional integrated systems are highly dependent on the availability of the energy sources and generally possess complicated configuration. Herein, we develop chemically self-charging aqueous zinc-ion batteries with a simplified two-electrode configuration based on $CaV_6O_{16}{\cdot}3H_2O$ electrode. Such system possesses the capability of energy harvesting, conversion and storage simultaneously. It can be chemically self-recharged by the spontaneous redox reaction between the discharged cathode and oxygen from the ambient environment without any external power supply. Chemically self-recharged zinc-ion batteries display an initial open-circuit voltage of about 1.05 V and a considerable discharge capacity of about 239 mAh g^{-1}, indicating the excellent self-rechargeability. Impressively, such chemically self-charging zinc-ion batteries can also work well at chemical or/and galvanostatic charging hybrid modes. This work not only provides a route to design chemically self-charging energy storage, but also broadens the horizons of aqueous zinc-ion batteries.

Engineering Active Sites of Polyaniline for $AlCl_2^+$ Storage in Aluminum-ion Battery

Shuai Wang
Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University
Nankai Univeristy, No. 94 Weijin Road, Tianjin 300071, China
e-mail: swang@nankai.edu.cn

Rechargeable aluminum-ion batteries (AIBs) have poured tremendous attention as energy storage devices due to its impressive advantages such as low cost, high safety, and environmental benignity.[1] Furthermore, aluminum is the most abundant metal in the earth's crust and possesses three-electron redox reaction characteristics. As a result, Al metal achieves an excellent gravimetric capacity of 2980 mAh g^{-1}, and a high volumetric capacity of 8040 mAh cm^{-3}.[2] Additionally, aluminum metal electrode is stable in air under ambient condition, which is convenient for manufacturing as compared to other active alkali metals. Therefore, AIBs are considered as a promising candidate of energy storage devices.

The reversible capacity of $AlCl_4^-$ intercalation/de-intercalation in conventional cathodes of aluminum-ion batteries (AIBs) is often difficult to be improved due to the large size of $AlCl_4^-$ anions. Therefore, it is highly desired to realize the intercalation/de-intercalation of other Al-based ions with smaller size.[3,4] Here, we fabricated polyaniline/single-walled carbon nanotubes (PANI/SWCNTs) composite films and further protonated the PANI nanorods in them. The protonation endows PANI with more active sites and enhanced conductivity. More importantly, hyper self-protonated PANI (PANI(H^+)) exhibits the reversible $AlCl_2^+$ intercalation/de-intercalation during discharge/charge process. As a result, the Al/PANI(H^+) battery displays a twice higher discharge capacity in comparison with the initial composite films. Furthermore, PANI(H^+)@SWCNTs electrodes also display stable cycling life with only 0.003% capacity decay per cycle over 8000 cycles. In addition, owing to the excellent mechanical properties, PANI(H^+)@SWCNT composite films can act as the electrodes of flexible AIBs. As a proof of concept, the flexible cable-type AIBs were assembled based on them and remained stable electrochemical performance at bending states. This work will pave the way for the applications of conducting polymers in AIBs and broadens the horizons of AIBs in flexible energy storage devices.

Ru-doped perovskite as new electrode material for SOFCs

Martina Marasi,[a] Leonardo Duranti,[a] , Cadia D'Ottavi[a], Elisabetta Di Bartolomeo[a]
[a]Department of Chemical Science and Technologies, University of Rome "Tor Vergata", Via della Ricerca Scientifica 1, 00133 Rome, Italy.
e-mail: martina.marasi@uniroma2.it

Solid oxide fuel cells (SOFCs) have a great potential among the emerging energy conversion technologies because they can efficiently convert various types of fuels (hydrogen, methane, CO, biogas) into electrical energy in the temperature range 650-850 °C. The choice of electrodes remains a challenge because most of metal oxides suffer of low chemical stability and conductivity in reducing atmosphere and low electrocatalytic activity toward oxygen reduction reaction (ORR) in the intermediate temperature range [1]. In this view, perovskite oxides (ABO_3) have shown promising properties in terms of thermal stability, compatibility with other cell components, low production cost and, most importantly, great flexibility [1]. $La_{0.6}Sr_{0.4}FeO_{3-\delta}$, (LSF) perovskite oxide have been widely investigated for its high electrical conductivity and electrochemical properties [2]. However, the main drawback is the poor activity towards ORR in the intermediate temperature range (500-700 °C), as in the case of the most iron-based perovskites [3]. The B-site doping with metal catalysts can sensitively improve the properties and make the compounds suitable for electrodes application.

Ruthenium is a low-cost noble metal and a promising catalyst for hydrogen oxidation and methane reforming [4]. The addition of Ru into LSF structure can be an innovative approach to improve the electrocatalytic properties. Specifically, we synthesized B-site doped LSF powders with different mol % of Ru (2%, 5%, 10%) by using a solution combustion synthesis (SCS). The synthesized powders were calcined at quite low temperature (750 °C for 6h) to get as high as possible surface area (>15 m^2/g). All compounds show a single perovskite phase. As reported in Fig. 1 (a), the addition of Ru in the structure causes a progressive shift of the XRD peaks to lower 2θ angles indicating an expansion of the perovskite lattice due to the substitution of Fe^{3+} sites (0.645 Å) with larger Ru^{3+} ions (0.68 Å).

The compounds were investigated both in oxidizing and reducing conditions. Fig. 1(b) shows the Arrhenius plot of area specific resistance (ASR) values of LSFRu perovskite oxides in air. The ASR values were measured by electrochemical impedance spectroscopy (EIS) on LSFRu/$La_{0.8}Sr_{0.2}Ga_{0.8}Mg_{0.2}O_{3-\delta}$ (LSGM)/LSFRu symmetric cells in the temperature range 550-800 °C. By increasing Ru amount the activation energy is reduced, and, most importantly, the ASR values of LSFRu compounds are lower than that of LSF at T<700°C. These features suggest that Ru substitution positively affects the electrocatalytic and conductivity properties valuably for cathodic applications.

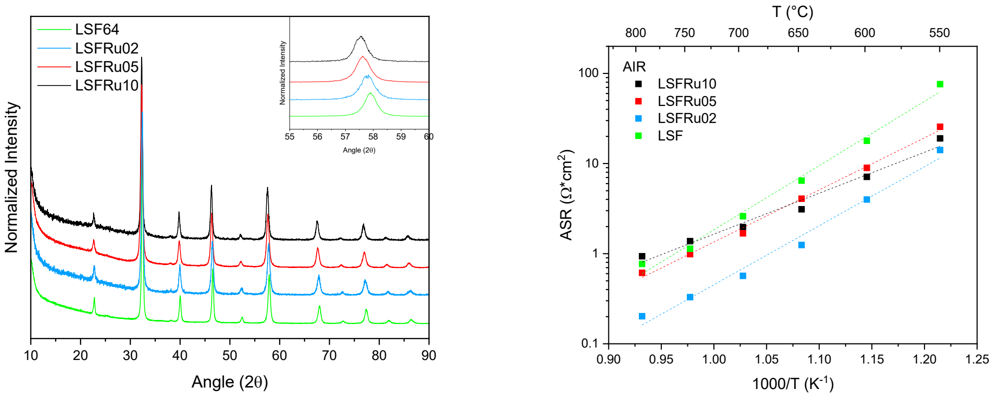

Figure 1. Structural and morphological characterization of LSFRu (a) XRD patterns (b) ASR values obtained in air flux (100 cm^3/min) from 800°C to 550°C

Insights into the Electrochemical Degradation of Real Effluents Using Modulated Current

Kaíque S. G. C. Oliveira, Alyne B. Veroli, Luís A. M. Ruotolo
Federal University of São Carlos, Department of Chemical Engineering
Rod. Washington Luiz km 235, 13565-905 São Carlos – SP, Brazil
pluis@ufscar.br

In this work, we demonstrated the feasibility of using the modulated current (MC) technique, in which the applied current is maintained at the limiting current for energy minimization in the electrochemical mineralization of effluents from coffee processing using boron-doped diamond electrode [1]. Although the wet coffee processing reduces the costs with drying and provides a superior product quality, this process generates effluents containing high concentrations of phenolic compounds, among them the caffeic acid (CA). Prior electrolysis, the wastewater was filtered and acidified with H_2SO_4, which worked as supporting electrolyte to increase the conductivity. Due to the effluent complexity, a new criterion to establish the operational conditions for electrooxidation is presented, based on the total organic carbon (TOC) and the CA diffusion coefficient (k_m) to determine the limiting current (I_{lim}). It was demonstrated that a combination of the modulated and galvanostatic (CC) current control is more effective to remove TOC and phenolic compounds after 12 h of electrolysis. Using the combined MC+CC approach, the energy consumption diminished ~79.5% compared with fully galvanostatic procedure. Importantly, attention must also be paid to avoid performing the MC control at currents below the water discharge since electrode passivation may occur. A 100% mineralization current efficiency (MCE) was observed throughout the electrolysis of the wastewater, indicating that the process operated under activated control. This result suggests that the criterion used to calculate I_{lim} and modulate the applied current was not satisfactory to optimize the reaction rate since the I_{lim} was underestimated. In this case, the chemical oxygen demand seems to be a more reliable parameter to estimate k_m and I_{lim}, and an apparent kinetic constant including the contributions of mass transfer and bulk oxidants may be considered since industrial effluents are complex mixtures of organics and ions. After the wastewater electrolysis, the MCE and energy consumption were 99.1% and 30.5 kWh kg^{-1} TOC, respectively, leading to a treatment cost of 1 m^3 of the coffee processing wastewater estimated in US$ 4.39. In summary, the MC+CC technique is a simple and effective tool that reduces the energy costs of the electrochemical treatment of effluents containing organic pollutants.

Characterisation and Application of Weakly Coordinating Solvents for the Electrodeposition of Semiconductors

Alexander W. Black, Philip N. Bartlett
University of Southampton
School of Chemistry, Highfield Campus, University of Southampton, Southampton, SO17 1BJ
Alexander.Black@soton.ac.uk

Compound semiconductors based upon p-block elements are receiving intensive research for their use in advanced electronic devices. The possible combination of elements is significant and contains ternary or quaternary alloys. This creates a broad range of properties and permits a diversity of applications.

Electrodeposition requires an electrolyte containing the metal precursors of interest. p-block complexes have particularly labile ligands. In a solvated metal complex the solvent molecules can compete for coordination to the metal cation. As such, a complex with labile ligands in a Lewis basic, coordinating solvent is vulnerable to displacement by the solvent molecule. Different metal cations will differ in their interaction with the solvent and therefore inconsistent speciation across metal precursors is possible. Metal speciation affects all aspects of an electron transfer reaction and so unpredictable speciation greatly complicates the process of codeposition. Hence, a plating bath composed of precursors sharing common ligands and a weakly coordinating solvent (WCS) is desirable.

We present results of a study into the feasibility of five organic solvents classified as weakly coordinating (the classification process being a part of the present investigation), shown in Fig. 1, for the electrodeposition of p-block elements. Additionally, dichloromethane is used as a control due to its previous demonstration as a suitable WCS for semiconductor electrodeposition.[1, 2] Firstly, the criteria of a suitable solvent, including the degree of coordination, are identified and quantified using Kamlet and Taft's solvent descriptors,[3] and it is established that solvents typically used in electrochemistry, such as water, acetonitrile or dimethylsulphoxide are not suitable (see Fig. 1). Several of the solvents have seen little use in electrochemistry and so their capability as electrochemical solvents is examined with measurements including conductivity, potential window and the electrochemistry of the model redox couples decamethylferrocene and cobaltocenium hexafluorophosphate. Subsequently, those solvents deemed suitable are applied to the electrodeposition of bismuth telluride and other novel systems.

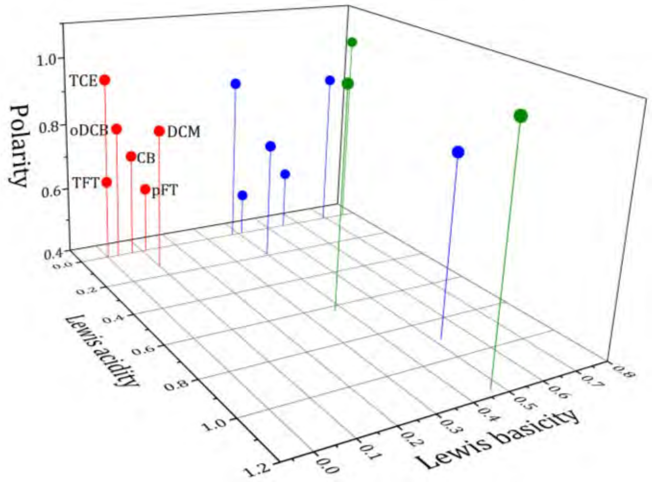

Figure 1: Kamlet and Taft parameters of red: candidate weakly coordinating solvents, blue: common electrochemical solvents, green: typical ionic liquids, from Ref. 4. DCM: dichloromethane, TFT: trifluorotoluene, oDCB: o-dichlorobenzene, pFT: p-fluorotoluene, CB: chlorobenzene, TCE: 1,1,2,2,-tetrachloroethane.

Advanced batteries will enable more widespread adoption of electric vehicles which, when charged with electricity generated from non-fossil fuel sources, can enable the achievement of global greenhouse gas emissions targets.

In LIB battery systems, the electrolyte has a crucial role in terms of allowing the transport of ionic charges and maintaining the physical isolation between anode and cathode. In commercial lithium ion batteries, dual-ion electrolytes such as $LiFP_6$ in organic solvent mixtures (EC/DEC or EC/DMC v/v=1:1) are commonly utilised. This type of electrolyte provides high ionic conductivity and has been widely in used commercial applications despite a couple of drawbacks.

Notwithstanding the high total ionic conductivity, common liquid Li-ion electrolytes have Li transference number lower than 0.5 [1]. The non-unity transference number of the active cation results in formation of a concentration gradient during charge/discharge. Accumulation of anions at the electrode-electrode interface and depletion of cations lead to increased interfacial impedance and reduced limiting currents. To overcome the drawbacks, polymer based electrolytes have been proposed, specifically, single ion conducting polymer and gel polymer electrolytes (SIPEs)[2], [3]. In SIPEs, the anion is fixed to polymer backbone to prevent its migration to the anode, which allows only Li^+ transport in the system. However, the low ionic conductivity of SIPEs has slowed their use in practical devices.

In this study, we report on the fabrication of crosslinked polymer gel electrolytes with varied nanostructures and containing both free salt and bound charge, via swelling of the network ionomers with liquid electrolyte solutions. We obtain a family of polymer gel electrolytes with varying lithium transference numbers (0.4 to 0.78) and total ionic conductivity ($2.71x10^{-4}$ S/cm to $1.93x10^{-3}$ S/cm). Interestingly, it is found that transference number and conductivity are not mutually exclusive and, for certain systems, an increase in the lithium transference number is not accompanied with a decrease in total ionic conductivity. It is also observed that the structure of the polymer has a great impact on transport properties. The effects of varying ion transport properties on Li-ion battery rate capability are investigated with the $Li/LiFePO_4$ configuration.

DFT Study on Nitrogen Reduction Electrocatalysts Regulated by Hydrogen and p-Block Elements

Guilan Fan, Wence Xu, Fangyi Cheng*
Key Laboratory of Advanced Energy Materials Chemistry, College of Chemistry, Nankai University, Tianjin 300071, China
E-mail: fycheng@nankai.edu.cn

Electrocatalytic nitrogen reduction reaction (NRR) represents an alternative eco-friendly strategy for sustainable N_2 fixation with renewable electric energy.[1] However, the NRR suffers from sluggish kinetics due to difficult N_2 adsorption and triple N≡N cleavage. Mechanistic understanding of the reaction helps to exploit strategies for performance enhancement of the NRR electrocatalysis. Density functional theory (DFT) calculation has been widely used to explore the electronic structure of catalysts, active sites and reaction pathways. Recently, we reported experimental and DFT computation on nanoporous palladium hydride as efficient electrocatalyst for electrochemical N_2 reduction under ambient conditions.[2] We showed superior catalyst activity of nanoporous hydrogenated palladium (exemplified composition of np-$PdH_{0.43}$) to nanoporous palladium (np-Pd). The projected density of states (PDOS) indicated that the d band center of np-$PdH_{0.43}$ is closer to the Fermi level compared to np-Pd (-1.61 vs. -1.68 eV) due to the hybridization between Pd and H atoms, resulting in the stronger interaction between catalysts and intermediates. The difference of Gibbs free energy (ΔG) for the energy-determined first proton-coupled electron transfer step was calculated at different Pd atoms on np-$PdH_{0.43}$ to predict the active sites. Charge density difference images further revealed stronger charge redistribution at np-$PdH_{0.43}$, which promoted the accumulation of internal electron concentration and enhanced the electrocatalytic activity. Then, the Gibbs free energy profiles of NRR confirmed that the enzymatic NRR pathway was favorable compared with distal and alternating pathways for both np-Pd and np-$PdH_{0.43}$, and the *NNH formation was the rate-limiting step. In addition to hydrogen, using p-block elements such as antimony (Sb) was also found to be a promotor to fix nitrogen. Results of PDOS indicated that d band center of transition metals (TMs) can be regulated by electrons from p orbitals of neighboring Sb atoms. Analysis of charge density difference again suggested activation of N_2 by TMs-Sb due to the redistribution of surface charges. In this scenario, the hydrogen injection and p-block element alloying would effectively modify the d-electron domination of TMs, thus stabilizing the intermediates and boosting the NRR.

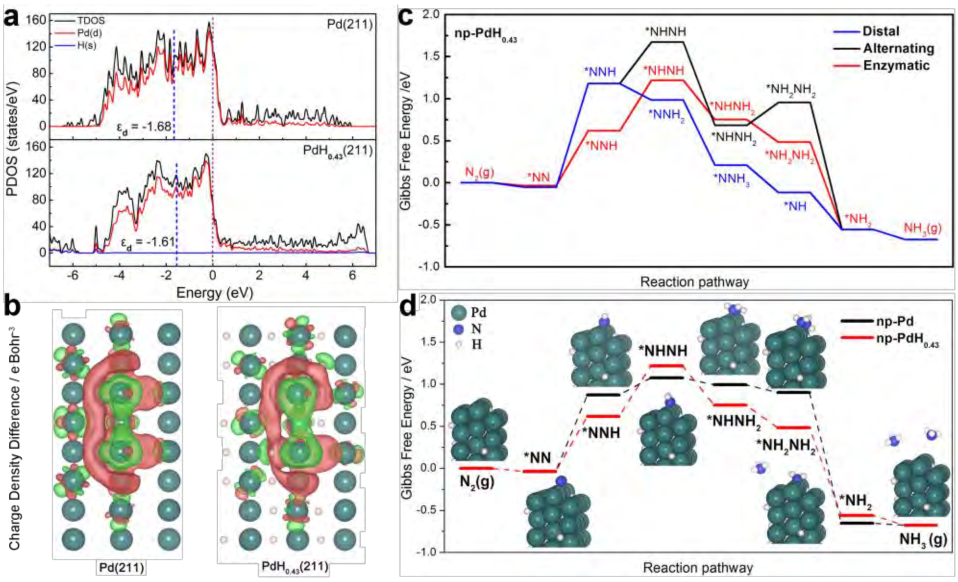

Figure1. (a) Projected density of states. (b) Charge density difference. (c, d) Gibbs free energy profiles of the NRR.

Coordination polymers (CPs) have attracted interest in recent years due to their properties such as gas adsorption, drug delivery, catalysis and ionic conductivity. CPs have advantages from its highly ordered and porous structure and a wide design latitude of compounds by choosing various metal ions and bridging ligands. In this communication, we will show a series of CPs ($\{[Fe(CA)(H_2O)_2]H_2O\}_n$ and $\{[Mn(CA)(H_2O)_2]H_2O\}_n$) [1] with one or two dimensionalities synthesized by environmentally friendly routes and low cost precursors. These CPs contain chloranilic acid, dihydroxybenzoquinone and pyrazine linkers combined with iron and manganese. These compounds were studied as electrode for lithium-ion batteries [2]. The lithium insertion potential changed depending on the metal used. This fact combined with the high voltages of reaction suggests the participation of both metal and organic linker on the redox processes (Fig. 1A). We also noticed that a thermal treatment on the CPs before the half-cell assembly was crucial to optimize the electrochemical performance of our compounds.

Furthermore since one of the Fe CPs showed two reversible redox stages at -0.5 and 0.5 V (Fig. 1B) it was studied as potential single electrolyte in redox flow batteries systems. Not all the CPs were suitable for the study, mainly due to the low stability of the suspension. However, by modifying the synthesis route, we manage to decrease the particle size and create slurries with high water-stability and study their electrochemical properties on a symmetrical cell.

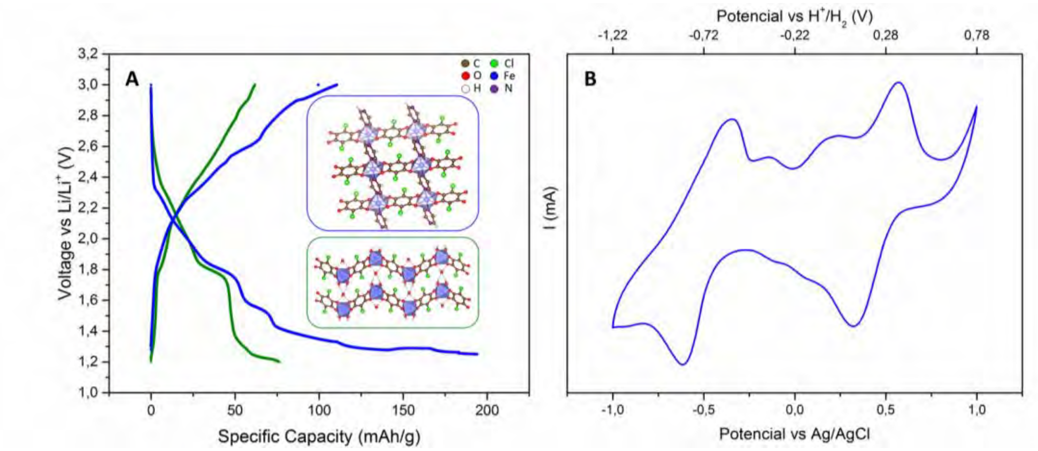

Figure 1. Galvanostatic charge-discharge cycling profile of two of the Fe CPs (A). Cyclic voltammetry of the Fe CP in an aqueous solution with 0.5 M NaCl at a current density of 20 mV/s (B).

The electrochemical water splitting (EWS) is composed of oxygen evolution reaction (OER) as an anode process and hydrogen evolution reaction (HER) as a cathode process. Pure hydrogen fuel produced by EWS could be a promising replacement for fossil fuels because of significantly lower pollution during its use and high energy transformation rate [1]. Alkaline water electrolysis (AWS) and its half reactions, OER and HER in alkaline media are presented by **Eq. 1, 2** and **3**, respectively.

AWS: $2H_2O \rightarrow 2H_2\,(g) + O_2(g)$ (1)
OER: $4OH^- \rightarrow O_2 + 2H_2O + 4e^-$ $E^0 = 0.404$ V vs. SHE (2)
HER: $4H_2O + 4e^- \rightarrow 2H_2 + 4OH^-$ $E^0 = -0.826$ V vs. SHE (3)

The overall energy efficiency of AWS is largely obstructed by the slow OER kinetics as a four-electron process with the high energy expended for oxygen-oxygen bonding [2] and high overpotential needed to break it [1,3]. Therefore, it is of utter importance to find appropriate low-cost OER electrocatalyst which could improve OER kinetics with more energy saving. Noble metals such as platinum (Pt) and their oxides such as ruthenium and iridium oxides (IrO_2 and RuO_2) are the most studied OER electrocatalysts [4]. High cost and scarcity of these electrocatalysts limit their application for OER in industrial electrolysers [4]. On the other hand, low-cost copper and cobalt co-doped Ni_3S_2 supported on nickel foam (CuCo-Ni_3S_2/NF) electrocatalysts were examined for OER in 1 M KOH showing high catalytic activity and low OER overpotential [5]. Different types of zeolites could be an excellent choice for low-cost OER catalyst support because of the unique structure and large surface area [6]. The basic type of zeolite consists of two types of anionic groups: tetrahedral $(AlO_4)^{5-}$ and $(SiO_4)^{4-}$ units charge-balanced with different positive ions such as sodium (Na^{1+}), silver (Ag^{1+}), nickel (Ni^{2+}), copper (Cu^{2+}) ions, etc. Different types of microzeolites (A and X) with Ni ions, studied in our previous work, showed OER catalytic activity and relatively good stability [6].

Herein, copper and nickel nanozeolites (CuX and NiX) were, for the first time, tested for OER in highly alkaline media by linear sweep voltammetry (LSW).

Polarization curves of CuX and NiX nanozeolites revealed that both of zeolite electrodes showed activity for ORR in alkaline media (1 M KOH). The current density of 1 mV s^{-1} was reached at overpotential of 530 and 670 mV for CuX and NiX zeolites, respectively. OER Tafel slopes at CuX and NiX electrodes were found to be 173 and 187 mV dec^{-1}, respectively. Significantly higher Tafel slope (463 mV dec^{-1}) was obtained for NiA zeolite in 1 M KOH [6]. A similar value of Tafel slope (144 mV dec^{-1}) was obtained at the Pt-modified Ni foam electrode in 1 M NaOH [3]. Co-Ni_3S_2/NF (150.9 mV dec^{-1}) and Cu-Ni_3S_2/NF (176 mV dec_{-1}) electrodes showed similar Tafel slope as herein tested electrodes [5]. CuX and NiX gave a current density of 8.5 and 1.20 mA cm^{-2} at 2 V vs RHE, respectively. CuX electrocatalysts gave lower overpotential, lower Tafel slope and higher OER current density than NiX which indicating its better catalytic activity during OER. Thus, low-cost CuX nanozeolite could be an excellent replacement for the expensive OER electrocatalysts based on scarce Pt-group metals or their oxides.

Fluoride-ion batteries (FIBs) are expected to be one of the candidates for next-generation rechargeable batteries due to their high theoretical energy density. FIBs contain monovalent fluoride ion as ion carrier, which can realize the multi-electron reactions of counter cations utilizing fluorination/defluorination in active materials such as metal fluoride compounds or metals. This feature enables the high theoretical energy density of FIBs for approximately 5000 Wh L^{-1}[1]. It was demonstrated that all-solid-state FIBs using MFn (M = Bi, Cu, Sn, KBi) cathode and Ce anode with $La_{1-x}Ba_xF_{3-x}$ solid electrolyte performed charge/discharge cycles at 150°C in 2011[2]. The charge/discharge of liquid-type FIBs using Bi/BiF_3 cathode and Pb/PbF_2 anode with ionic liquid electrolyte at room temperature has been also reported in 2017[3]. Although all-solid-state batteries are expected to be used widely owing to their high energy densities, long life cycles, and safety, FIBs using solid electrolytes is far from practical use due to lack of solid electrolytes which have high ionic conductivity and wide electrochemical potential window like lithium-ion solid electrolytes.

The reported solid electrolytes such as $PbSnF_4$ [4] and $La_{0.9}Ba_{0.1}F_{2.9}$ [5] are well known fluoride ion conductors. $PbSnF_4$ exhibits the highest ionic conductivity of 2 mS cm^{-1}, whereas the electrochemical potential window is 0-2 V vs. SnF_2/Sn, which is disadvantage for the high voltage battery operation. To obtain solid electrolytes which have both high ionic conductivity and wide electrochemical potential window, it is necessary to use rather rare-earth metals than cations with their poor chemical stability in the low voltage such as Pb and Sn. $La_{0.9}Ba_{0.1}F_{2.9}$ also exhibits high ionic conductivity of 10^{-1} mS cm^{-1} having wide electrochemical potential window. Room temperature operation using the La-Ba-F electrolytes requires higher ionic conductivity than the present conductivity. Mixed-anion compounds have recently attracted attention, and unique structures with multiple anions have been reported [6]. Compared with existing materials such as oxides and fluorides, mixed-anion compounds have the possibilities to exhibit innovative functions due to their specific crystal and coordination structure.

In this study, we synthesized La-Sr-F-S compounds containing fluoride and sulfides ions as anions by solid-state reaction under vacuum. The crystal structure of the synthesized compound was characterized by X-ray diffraction. In order to measure the conductivity and the fluoride-ion transport number of the synthesized compounds, electrochemical impedance spectroscopy and the DC conductivity measurement were performed, respectively. Moreover, cyclic voltammetry was performed to evaluate electrochemical potential window. In the synthesis, F^-- deficient and F^--excess type of La-Sr-F-S compounds were successfully synthesized by controlling the weight ratio of starting materials. We discuss the mechanism to realize fast fluoride ion conduction comparing them.

Visualization and Quantification of Electrochemical H_2 Bubble Nucleation at Pt, Au, and MoS_2 Substrates

Qianjin Chen, Yulong Liu, Cheng Jin
College of Chemistry, Chemical Engineering and Biotechnology, Donghua University
Shanghai, 201620, China
qianjinchen@dhu.edu.cn

Electrolytic gas evolution is a significant phenomenon in many electrochemical technologies from water splitting, chloralkali process to fuel cells. Although it is known that gas evolution may substantially affect the ohmic resistance and mass transfer, studies focusing on the electrochemistry of individual bubbles are critical but also challenging. Here, we report an approach using scanning electrochemical cell microscopy (SECCM) with a single channel pipet to quantitatively study individual gas bubble nucleation on different electrode substrates, including conventional polycrystalline Pt and Au films, as well as the most interesting two-dimensional semiconductor MoS_2. Due to the confinement effect of the pipet, well-defined peak-shaped voltammetric features associated with single bubble nucleation and growth are consistently observed. From stochastic bubble nucleation measurement and finite element simulation, the surface H2 concentration corresponding to bubble nucleation is estimated to be ~218, 137, and 157 mM, with critical nuclei contact angles of ~156°, ~161°, and ~160° at polycrystalline Pt, Au, and MoS_2 substrates, respectively. We further demonstrated the surface faceting at polycrystalline Pt is not specifically correlated with the bubble nucleation behavior.

Polypyrrole (pPy) polymer materials attract much attention of researchers due to their original properties. Proposed methods for deposition of pPy coatings as well as for the synthesis of various pPy-containing composite materials has opened prospects for their use in a wide range of practical applications, such as molecular electronics, electrochemical sensors, supercapacitors, etc. [1-3]. One of the main methods of polypyrrole synthesis is the electrochemical method, the essence of which consists of electro-oxidation of the dissolved monomer on the electrode surface with the formation of a polymer film.

The overwhelming majority of papers on electrodeposited polypyrrole conclude that the resulting conjugated polymer possesses an electrochemical activity potential region of about 1 volt. Beyond the negative limit, this material turns to a neutral/insulating state. In contrast, at more positive potentials, the "overoxidation" process occurs, leading to irreversible degradation. Such a narrow electroactivity range is a disadvantage of this material, limiting its applicability, for example, as an active element of supercapacitors or as a matrix for electrodeposition of most metals in the synthesis of composite metal-polymer catalysts/sensors. However, it was mentioned [4] that low deposition potentials and low monomer concentrations allows to obtain the polypyrrole films exhibiting electroactivity in the broader range of potentials. This change is irreversible and can occur either immediately after synthesis (electropolymerization) or during repeated cycling of the film in an extended potential limits.

The goal of this work is to study and to optimize the method of electrodeposition of polypyrrole under non-conventional conditions (ensuring a low rate of polymer formation on the electrode surface), as well as to investigate the structure and properties of the obtained promising materials. For that propose, we have studied several factors (concentration of pyrrole during electrodeposition within a sub-mmol range, oxidation potential, the thickness of the polymer coating, multi-scan parameters of the obtained polymer film, and the composition of electrolyte solution) affecting the electroactivity range of polypyrrole. Thus, the conditions for subsequent purposeful enhancement of this effect have been figured out.

Acknowledgments

Conducting organic materials and coatings based on poly 3,4-ethylene dioxythiophene (PEDOT) are currently a principal component of electrochromic coatings, displays, capacitors, photoelectric converters, and several other devices. The range of PEDOT applications is expanding due to intensive scientific research in this area. In most applications, PEDOT is used as part of a composition with polystyrenesulfonate anion (PSS) [1, 2]. Usually, the precursor for its preparation is an aqueous dispersion of PEDOT-PSS (fig. 1) representing a commercially available product. Its synthesis based on the chemical oxidation of a mixture of peroxodisulfate precursors anion, followed by ion-exchange purification from the products of the oxidant reduction and auxiliary substances [3]. The studies in this work are aimed at developing the fundamental principles and practical implementation of the electrochemical method for preparing a dispersion of PEDOT-PSS, consisting in the generation of EDOT radical cations on the surface of a porous anode with continuous intensive pumping through it of a polymerization medium containing a PSS polyanion without using an oxidizing agent.

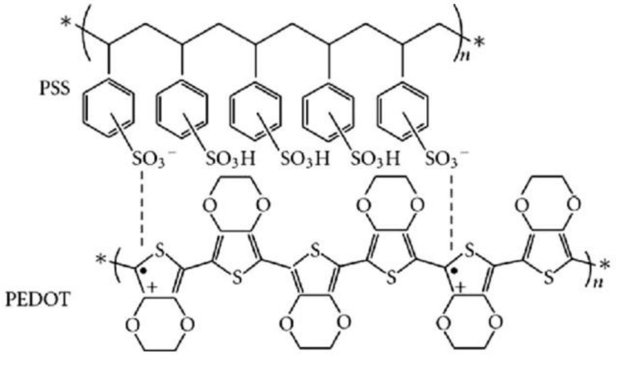

Fig. 1. Chemical structure of PEDOT:PSS

Electrooxidation of EDOT was carried out in a solution of polystyrenesulfonic acid (HPSS) at the working electrode with simultaneous pumping of the polymerization medium through the pores of the electrode at a given speed. PEDOT-PSS dispersion was synthesized in a special electrochemical cell with separated electrode spaces, through the anode of which an intensive pumping of the polymerization medium containing the monomer and polyanion is carried out. In addition to the direct oxidation of EDOT in the presence of HPSS, a redox mediator oxidation of EDOT in the presence of HPSS and a redox mediator was performed. The resulting suspensions were characterized by a complex of electrochemical, microscopic, and spectral methods.

Enhanced Performance of Spinel $LiMn_{1.5}Ni_{0.5}O_4$ Controlled by Oxygen Vacancy

Aderemi B. Haruna, Kenneth I. Ozoemena

School of Chemistry, University of the Witwatersrand, Wits P O, Johannesburg 2050, South Africa
e-mail: 1739079@students.wits.ac.za

The spinel $LiMn_{1.5}Ni_{0.5}O_4$ (LMNO) is a promising cathode material for lithium-ion battery because of its high working voltage: 4.7 V, considerable cost, high capacity and energy [1-3]. However, its structural relationship with the electrochemical properties is still a challenge [5, 6]. The electrochemical properties of the spinel are related to the degree of disorder, doping, impurities, Mn^{3+} content, morphology and oxygen vacancy, among others. Oxygen vacancy is identified as a key structural factor because of its correlation with the degree of disorder and Mn^{3+} content [5]. In this research works, we examined the relationship among the structural parameters (oxygen vacancy, disordered phase, Mn^{3+} and impurity contents); and their electrochemical effects. This work revealed for the first time the use of oxygen vacancy: β-MnO_{2-x} as precursors to synthesised spinel LMNO cathode materials and tune the oxygen vacancy, disordered phase, Mn^{3+} content and impurity contents without doping, higher synthetic temperatures (› 700 °C), use of organic compound, post-annealing or modification of the cooling profile. We showed that varying synthetic conditions of β-MnO_{2-x} can tune these structural factors in LMNO for improved electrochemical performance. The results of the studies showed that the oxygen vacancy changes concurrently with the degree of disorder and Mn^{3+} content, but not with the impurities. Our study has opened opportunities to explore the use of β-MnO_{2-x} to tune these structural factors in spinel LMNO for an improved lithium-ion battery.

Abstract

Fuel cells are electrochemical devices that convert chemical energy in fuels into electrical energy directly with promising power generation, high efficiency and low environmental impact. Fuel cell production techniques avoids the intermediate steps of producing heat and mechanical work common with most conventional power generation and are not limited by thermodynamic limitations of heat engines such as the Carnot efficiency and produce power with minimal pollutant since combustion is not involve in the production and operation techniques. This paper examines fuel cell production techniques as a clean sources of renewable energy, types of fuel cell, advantages and disadvantages of various fuel cells were also investigated. It also compares the cost effectiveness of small scale fuel cell power plants with that of large scale vis a vis other renewable source. The paper concluded that fuel cell is an essential component of sustainable energy mix for self reliance of power sector in Nigeria.

Key words: Carnot efficiency, electrolyzers, unit cells, phase interface and fuel cell stacking.

Room-Temperature Conversion of the Photoelectrochemical Oxidation of Methane into Electricity at Nanostructured TiO_2

Yanir Kadosh, Eli Korin and Armand Bettelheim

Be'er Sheva
Israel
yanirka@post.bgu.ac.il

The energy potential of methane is restrained by the energy input required to break its C-H bond. Therefore, most of the energy conversion processes of methane use thermochemical activation which is highly endothermic. The present work demonstrates the effective photoelectrochemical (PEC) activity of a TiO_2 nanotube arrays photoanode towards methane oxidation in acidic electrolyte and ambient conditions. PEC processes can dramatically reduce the activation barrier by the interaction with light. The use of a semiconductor photoanode in a PEC system can produce highly reactive holes upon irradiation, aiming for the activation of methane's C-H bond at moderate temperatures. The examined photoanode exhibits high photocurrent density response in the presence of methane as compared to that obtained in its absence (0.54 vs. 0.27 mA cm^{-2}, respectively). Products characterization reveals a relatively high faradaic efficiency towards the formation of CO_2 and formic acid (72 and 16% at 0.3 V vs. RHE, respectively). These results are correlated to the role of the special surface architecture of the nanotube arrays in dictating the reaction pathways. The first time room-temperature operation of a solar driven fuel cell (photo-fuel cell), in which methane oxidation is converted to electricity, is also demonstrated. The photo-fuel cell performance is characterized by a relatively high power density (69 µW cm^{-2}), when compared to such cells with liquid fuels, as well by long-term stability.

Lithium-Ion High-Performance Anodes using Silicon Nanowires/Graphite Composites

Lithium-ion batteries (LIBs) have enabled significant technological progress in recent years and are considered the state-of-the-art technology for electrochemical energy storage [1]. Yet, these LIBs still require substantial improvements in their power and energy density, particularly for applications in electric vehicles [2]. Most commercial LIBs use graphite, an intercalation-type material with excellent cycling stability, as negative electrode. However, its rather low theoretical capacity of 372 mAh g^{-1} and slow Li-ion intercalation kinetics result in an overall low volumetric energy density and poor rate performance.

The use of silicon nanowires/graphite composites is of particular interest, because it is anticipated to allow for combining the advantages of the two components – i.e., the excellent cycling stability of the carbon-type material and the much greater specific capacity (3579 mAh g^{-1}) and good rate capability of silicon. Indeed, the much greater specific capacity potentially allows for an increased volumetric and gravimetric energy density when combined with a suitable cathode in LIBs [3]. Furthermore, silicon is non-toxic and abundant in the earth's crust, rendering it a good candidate for high-performance and sustainable negative electrodes. The 1D silicon nanowire morphology compared to bulk silicon materials offers short Li^+ transport pathways [4] and provides better contact with the graphite particles within the composite.

Herein, we report on the evaluation of silicon nanowires/graphite composites (engineered wires composites) as lithium-ion anode active material. The structural and morphological investigations were carried out using amongst others x-ray diffraction, transmission electron microscopy, and scanning electron microscopy. Furthermore, we present our comprehensive electrochemical investigation of this material with galvanostatic dis-/charge tests in lithium-ion half-cells and full-cells using Ni-rich NMC as the cathode. The results reveal very good cycling stability and rate performance – even for high areal capacities in coin cells and in pouch cells.

N-doped Mesoporous Carbon Spheres from m-Aminophenol and Pluronic® F127 Template as Support for ORR Catalysts

Jithin Antony, Sakthivel Mariappan, Jean-Francois Drillet
DECHEMA-Forschungsinstitut, Theodor-Heuss-Allee 25, 60486 Frankfurt am Main
sakthivel@dechema.de

Despite the large and growing interest of polymer electrolyte membrane fuel cell (PEMFC) as an energy converter, high cost, relatively insufficient activity and long-term stability of the catalyst materials remain major obstacles for commercialization. Platinum is still considered as the state-of-art for catalyst material in PEMFC. However, it exhibits a slow kinetics for oxygen reduction reaction (ORR) that is mostly due to the strong bond of the oxygen molecules. The long-term efficiency of the electrodes is strongly influenced by the nature of the catalyst support that should allow optimal distribution and stabilization of the catalyst nanoparticles [1]. Most common mesoporous carbon syntheses rely on hard-template, time-consuming routes that are not suitable for industrial scale-up. Therefore soft-template methods appear to be more adapted.

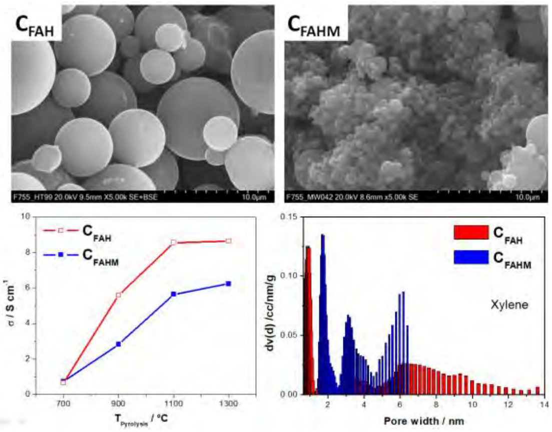

Fig.1: SEM image, conductivity and pore size distribution profile of as-prepared carbon

In this work, synthesis of carbon powder samples was prepared by autoclave hydrothermal (C_{FAH}) and microwave-assisted hydrothermal (C_{FAHM}) route by using *m*-Aminophenol as carbon source and triblock-copolymers Pluronic F127 as soft-template. Characterization of the as-prepared carbons was performed by means of XRD, Raman, TGA, BET and SEM. All synthesis led to formation of spherical carbon particles (Fig. 1) with diameter between 5.0 µm (C_{FAH}) and 0.7 µm (C_{FAHM}). By varying heating time, power of heat source, reaction temperature, reaction time of microwave reactor during polymer synthesis as well as optimizing pyrolysis temperature (T_{py}), the size of carbon particle was successfully reduced from 3.0 down to 0.7 µm. Reaction time for polymer synthesis was substantially reduced from 12 h for common hydrothermal route down to 5 min for microwave-assisted one. The pore size of carbon particles was successfully tuned from micro- to mesoporous (5 – 15 nm) range by using xylene, toluene or ammonium bicarbonate as a pore forming agent. The electronic conductivity of carbon particles was enhanced from 0.6 to 5.6 Scm^{-1} at 100 Ncm^{-2} by increasing pyrolysis temperature from 700 to 1100°C (Fig.1). The N content of carbon was found within 8 – 10 wt% at 900°C (T_{py}). Then, carbon particles were decorated with 40 wt% Pt by chemical impregnation/reduction of hexachloro-platinic acid in formaldehyde at 80°C for 1 h. Electrochemical activity of Pt/C catalysts for ORR was studied under RRDE and GDE conditions. The highest performance regarding ECSA retention during accelerated degradation tests (0.4-1.4 V, dE/dt = 1 V s^{-1}, 10,000 cycles) was achieved by Pt/C_{FAH} with 77% followed by Pt/C_{FAHM} with 75%, compared to only 8% for Pt/C_{Vulcan}. Best performance in terms of synthesis duration, particle size, conductivity, pore size distribution, Pt activity for ORR and ECSA retention was achieved by carbon powder from microwave-assisted hydrothermal synthesis route.

Last decades, scientific interest has been attracted for electrochromic coatings, since these are essential in a variety of novel technological applications such as switches, batteries and smart windows. Tungsten trioxide is one of the most common electrochromic film for smart window applications that can be used in order to reduce the energy consumption on buildings. To date many methods, such as sol-gel, hydrothermal synthesis, chemical vapour deposition (CVD) and magnetron sputtering, have been used for the deposition of WO3 layers. As has been shown, one very important parameter for the response of the layers is their morphology.

In this work, amorphous WO3 coatings were grown on indium tin dioxide glass substrates using magnetron sputtering with tungsten target and various amount of vacuum in the deposition chamber. The coatings were characterized by X-ray diffraction, XPS, UV-Vis-IR spectroscopy, scanning electron microscopy and cyclic voltammetry in order to investigate the importance of their porosity in the improvement of their electrochromic performance, including durability, time response, charge density and coloration efficiency.

fdanilov@optima.com.ua

Electrochemical deposition of nickel and nickel-based coatings is considered as the most significant and widespread metal finishing in up-to-date industry. Ni and Ni-based coatings can be deposited from "common" aqueous electrolytes, however these have a lot of drawbacks. Recently, some attempts were made to use a new type of electrolytes based on the so-called deep eutectic solvents (DESs) [1, 2]. DESs are ionic liquid analogues, which consist of eutectic mixtures of some inorganic and/or organic compounds. DESs show a number of excellent and useful properties, such as wide electrochemical potential window, high conductivity, negligible vapor pressure, easy accessibility, environmental safety and biodegradability [1]. Therefore, DESs attract close attention in electrochemistry, especially in electroplating [1, 2].

We investigated the electrodeposition of nanocrystalline nickel and composite Ni/TiO_2 coatings using a plating bath based on a deep eutectic solvent which is commercially known as ethaline (a eutectic mixture of ethylene glycol and choline chloride) [3–7]. Titania nanopowder (Degussa P 25, 25–30 nm) was used to prepare colloid electrolytes for electrodeposition of composite coatings.

It was established that the addition of some water to the nickel plating bath provides a decrease in viscosity and an increase in conductivity [3, 4]. An irreversible electrochemical reaction of metal deposition is decelerated when water is added to the ethaline + $NiCl_2$ solutions.

The electrodeposited nickel coatings exhibit an average crystallite size of about 3–9 nm. According to electrochemical impedance spectroscopy measurements, the coatings with enhanced corrosion resistance can be obtained from Ni electroplating bath containing some water additive.

Due to relatively high viscosity and density, DESs ensure excellent dispersion stability as compared with "common" aqueous solutions. The content of TiO_2 in deposits reaches 10 wt.%. The composite Ni/TiO_2 coatings show nano-sized type of structure.

The formation of composite coatings based on the nickel matrix provides an appreciable improvement in functional properties of deposits. Thus, their microhardness is higher and the corrosion resistance in a corrosive medium is better than in the case of pure Ni coatings. The incorporation of TiO_2 particles imparts the photocatalytic activity towards the photochemical degradation of organic dyes and the electrocatalytic activity in the hydrogen and oxygen evolution reactions to the synthesized composite coatings.

ABSTRACT

Polymer/semiconductor oxide composite fibers prepared by electrospinning is a multifunctional material. The components can be joined by covalent bonds, electrostatic attraction or other weak interaction forces, possessing combined properties of inorganic component and high molecular polymer. The addition of polymer can stabilize transition metal oxide and avoid agglomeration of nanoparticles during the photocatalytic process. At the same time, transition metal oxide can increase the surface area and porosity of fiber, giving full play to the adsorption and photocatalytic performance.

In this project, electrospinning method has been used to synthesize semiconductor metal oxide nanocomposites. Polyacrylonitrile (PAN) is the polymer matrixes to hold titanium dioxide (TiO_2) nanoparticles. Polyvinyl Pyrrolidone (PVP) is added as a pore-forming agent. Porous and flexible nanofiber membrane with high TiO_2 content was prepared by selectively dissolving PVP. SEM, BET, CA, XRD, FTIR, TGA and DSC were used to characterize the surface morphology, microstructure, composition and thermal stability of the fiber membrane. The effects of different pore-forming agents on the coupling adsorption and photocatalytic reaction of fiber membranes were investigated.

The detection of genetic diseases at early stage in clinical diagnosis requires the development of reliable, highly sensitive and selective genosensors capable of detecting single-nucleotide polymorphisms (SNPs)[1]. In contrast to traditional methods such as colorimetric, plasmonic, electrochemical sensors have advantages such as simplicity, low cost, ease of miniaturization, rapid response times and high sensitivity, required for this application.

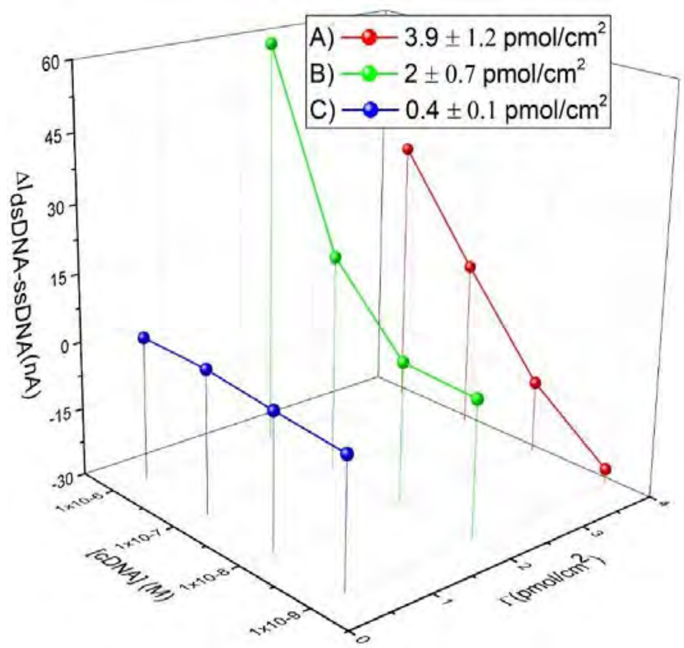

Figure.1 Influence of the probe surface coverage and concentration of cDNA on the signal increase upon hybridization. Results obtained via DPV in PBS at pH 7.4

The majority of electrochemical methods of detection of DNA are based on hybridization processes. These approaches offer high selectivity for the target DNA and low limits of detection, (LOD) approaching zeptomolar levels, that can enable the detection of disease at early stages. Nevertheless, the detection of SNP genosensors are still not available and such sensors would fill a significant need[2]. The detection of the TP53 cancer biomarker has been investigated electrochemically by monitoring changes in DNA structures before and after hybridization p with a maximum signal gain upon hybridization of 59.6 nA at a surface coverage of 2.0 pmol/cm^2 (Figure.1). The selectivity of the DNA biosensor was investigated using three types of tDNA sequences: complementary DNA, single base mismatch and triple base mismatch. The biosensor is capable of discriminating between a normal healthy sequence and a triple base mismatch with a discrimination factor of 8. The electrochemical signal gain upon hybridization with single base mismatched sequence is similar to that observed with cDNA, indicating that the biosensor is not capable of discriminating between normal and and single base mismatches.

For charge-discharge test in laboratory experiments of lithium-ion batteries, half-cell configuration with lithium as the anode is often used. In contrast, for practical lithium-ion batteries, lithium metal is not used for the anode, but full-cell configuration is used, in which the capacity of the anode is almost similar to the capacity of the cathode. While the half-cell configuration has lithium as a source of excess carrier ions in the anode, in the full-cell configuration, only the limited lithium-ions supplied from the cathode are used as carrier ions, limiting the actual charge-discharge capacity of the full-cell. Previous studies have reported differences in the degradation behavior between full-cell and half-cell [1,2]. It is important to understand the unique problems that occur with full-cell in order to maximize the performance of lithium-ion batteries in practice. In this research, we investigated the irreversibility in full-cell with lithium iron phosphate ($LiFePO_4$) cathode and lithium titanate ($Li_4Ti_5O_{12}$) anode as a strange case, where both active materials show two-phase reaction in almost all composition. In addition to the electrochemical measurements used three-electrode cell, the X-ray absorption fine structure (XAFS), which allows to observe the valence change, was used to determine the charge-discharge state in the full-cell.

In a constant-current charge-discharge measurement at 0.1 C in a half-cell, the charge-discharge reaction proceeded reversibly with a capacity of 155 mA h g^{-1} in the $LiFePO_4$ cathode and 150 mA h g^{-1} in the $Li_4Ti_5O_{12}$ anode. However, in our experiments, we observed an irreversible reaction in the $LiFePO_4$ - $Li_4Ti_5O_{12}$ full-cell configuration, with a capacity decrease with each cycle. The initial charge and discharge capacity were 162 and 126 mAh g^{-1}, respectively and this irreversibility was continuously observed in the subsequent cycle (Fig. 1). By using the three-electrode cell, we analyzed the potential changes of the cathode and anode. The potential of the anode increased and reached the cut-off voltage during the discharge before the change of the cathode. The valence states of the cathode and anode expected to be similar composition during charging and discharging (Li_xFePO_4 x = 1.00, 0.30 0.07) were examined by XAFS. Fe K-edge XAFS shown similar edge energy for the charged and discharged $Li_{0.3}FePO_4$ cathode. However, Ti K-edge XAFS of charged $Li_{5.8}Ti_5O_{12}$ anode shown the different edge energy from that of the discharged anode, which agrees with the results from the three-electrode test. Therefore, the irreversible capacity was caused by the shifting of state of charge in anode due to some side reactions on the $Li_4Ti_5O_{12}$ anode side during charge reaction.

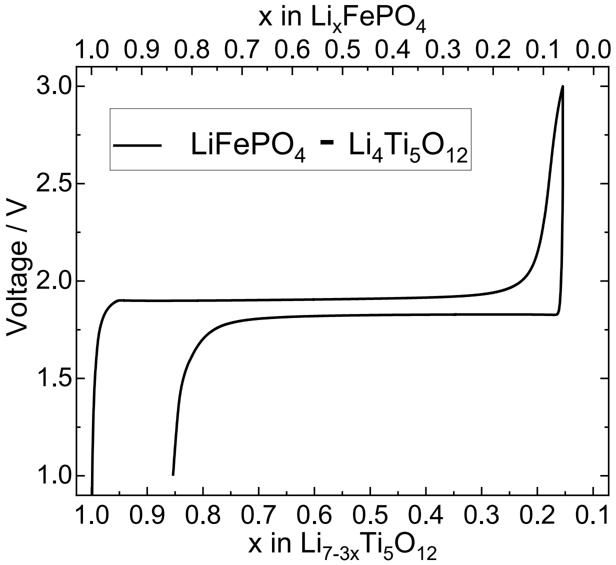

Fig.1 $LiFePO_4$ - $Li_4Ti_5O_{12}$ full-cell charge-discharge profile at 0.1 C.

Abstract

The relationship between surface properties of indium tin oxide (ITO) and its effect on surface modification and response to several biomolecules was investigated. ITO substrates were selected to compare the effect of its electrochemical surface properties on the voltammetric measurement. It was found that a small difference in surface properties affect the rest potential of ITO electrode in the electrolyte. In addition, surface properties can effectively change the monolayer modification properties and it was revealed that optimization of surface properties is important to get selective response for biosensor development.

$AuCeO_2/C$ as electrocatalysts towards ethylene glycol oxidation and oxygen reduction reactions

Different fuels such as methanol, ethanol, ethylene glycol or others recently have been used in direct alcohols fuel cells (DAFC). However, because of low methanol electro-oxidation kinetics and complication of getting the clean catalytic process using ethanol, ethylene glycol seems more reasonable as a fuel for DAFC due to its low toxicity, uncomplicated storage, easy transportation and production from biomass.

It is especially important to create and develop effective catalysts not only for fuel oxidation, but also for oxygen reduction. In this case Au was considered as one of the best catalysts for the fuel cell reactions in alkaline medium, due to its surface resistance of poisoning for the intermediates, which allows to achieve high electrocatalytic activity towards alcohols oxidation and oxygen reduction reactions. It is known that addition of metal oxides, such as CeO_2, Co_3O_4, SnO_x, MnO_2 or RuO_2 enhanced the electrocatalytic activity towards oxidation of ethylene glycol and reduction of oxygen. Cerium oxide is attractive because of its low price, synergistic effect between CeO_2 and gold and tolerance to the CO poisoning.

In this paper was investigated the electrocatalytic activity of $AuCeO_2/C$ and Au/C catalysts prepared by the adsorption of AuNPs on the CeO_2/C and C substrates from an Au colloidal solution. The composition, morphology and structure of the prepared catalysts have been characterized using Inductively Coupled Plasma Optical Emission Spectroscopy, Field Emission Scanning Electron Microscopy, X-ray photoelectron spectroscopy and X-ray Diffraction. Electrocatalytic properties of the prepared $AuCeO_2/C$ and Au/C catalysts have been investigated towards the oxidation of ethylene glycol in an alkaline medium using cyclic voltammetry, whereas the reduction of oxygen has been investigated by means of the linear sweep voltammetry using the rotating disk electrode method.

It has been found that the $AuCeO_2/C$ catalyst showed ca. 3 times higher electrocatalytic activity towards the oxidation of ethylene glycol compared to that of Au/C. Moreover, $AuCeO_2/C$ showed more positive onset potential, as well as higher current density in the mixed-kinetic-diffusion region towards ORR in an alkaline medium compared to that at the bare Au/C catalyst.

Selective Electrochemical Xanthine Biosensor based on PEDOT: PSS and Functionalized Gold Nanoparticles Nanocomposite Platform

Md. Zaved H Khan, M. Shamim Hossain, M. Daizy, M. Romzan Ali

Dept. of Chemical Engineering, Jashore University of Science and technology, Jashore 7408, Bangladesh

Abstract

An innovative biosensor assembly relying on glassy carbon electrode modified with nanocomposites consisting of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) as a host matrix with functionalized gold nanoparticles (GCE/PEDOT:PSS-AuNPs) is presented for the selective and sensitive detection of xanthine (XA). The developed sensor was successfully applied for the quantification of XA in the presence of significant interferences like hypoxanthine (HXA) and uric acid (UA). Different spectroscopy and electron microscopy analyses were done to characterize the as-prepared nanocomposite. Calibration responses for the quantification of XA was linear from 5.0×10^{-8} to 1.0×10^{-5} M ($R^2 = 0.994$), with detection limit as low as 3.0×10^{-8} (S/N = 3). Finally, the proposed sensor was applied for the analyses of XA content in commercial fish and meat samples and satisfactory recovery percentage was obtained.

Keywords: Electrochemical biosensor; PEDOT:PSS, gold nanoparticle; nanocomposite; xanthine.

Atomistic insights into the structural, transport and electrochemical properties of biredox ionic liquids from molecular dynamics

Biredox ionic liquids are a new class of functionalized electrolytes that are receiving increasing consideration for use in capacitive energy storage devices. They differ from conventional electrolytes in that both cations and anions are functionalized with redox-active moieties, [1] which may actively participate in the storage mechanism via electrochemical reactions at the electrode interface. In this work, TEMPO and anthraquinone are used as the redox active species. Given that these types of biredox systems are relatively new, much remains to be understood about the relationship between the size/volume of the IL cation/anion moiety, the solvent structure and dynamics, and the electrochemical properties of each system.

Here, we employ first-principles molecular dynamics to study biredox ionic liquids dissolved in acetonitrile. We investigate several combinations of anions and cations, differing in the hydrodynamic radius and we compare them with the bare redox molecules. We show that in all cases, it is necessary to introduce a two-Gaussian-state model to calculate the reaction free energies accurately, which are found to be slightly affected by the presence of the IL group on the molecule. MD simulations also provide the atomistic details used to characterize the structure of the solvation shell around the redox active part of the molecules. Our investigations suggests that for TEMPO-based molecules in particular, a strong effect of solvent reorientation influences the electron transfer process.[2] This study represents a first step in the understanding of electron transfer processes in these complex systems and will hopefully contribute to the design of new ionic liquids with better performances for use in energy storage devices.

Chitosan (CS), a natural non-toxic polysaccharide, shows intrinsic antimicrobial activity against a wide range of pathogens. CS and CS-based biomaterials can be effective additives in food and medicine-related industries to inhibit growth of pathogens. The application of inorganic nanophases, such as metal and metal oxide nanoparticles, has received attention due to their broad and pronounced antimicrobial activity. Upon combination with CS, which can act as stabilizer, with active inorganic nanophases, robust synergistic nanoantimicrobial (NAM) systems can be produced. These hybrid NAMs offer an alternative strategy to fight antimicrobial resistance and overcome limitations of conventional antibiotics. Bioactive ZnO, Cu and Ag nanophases produced by green electrochemical approach [1] can be combined with antimicrobial CS to develop synergistic antimicrobial nanohybrids with amplified biological action. CS-based NAMs were preliminary characterized by electron microscopies and spectroscopic techniques. Hybrid NAMs may find application in the control and inhibition of biofilm growth.

Because of the limited availability of fossil fuels and global environmental issues, hydrogen production by electrochemical water splitting using renewable energy sources becomes of increasing importance for future hydrogen economy. Currently, hydrogen is mostly produced from oil, coal and natural gas, and the processes generate also greenhouse gases as byproducts. Although fuel cells using hydrogen as a fuel are commercially available, this technology is still using fossil fuels to produce hydrogen. Thus, clean hydrogen production technology using renewable energies, such as solar, wind, water-based and biomass-based ones needs to be developed.

The main issue to utilize electrochemical water splitting for clean hydrogen production is sluggish kinetics of oxygen evolution reaction (OER). The oxides of Ru and Ir are known to show high activity and durability for OER, but their limited natural resources and high cost hinder their wide application to energy conversion and storage. Currently, extensive efforts are directed towards the development of noble-metal-free electrocatalysts for OER. In the present study, simple anodizing of NiFe alloys is used to develop a highly active electrode for OER.

The NiFe alloys with a range of Fe contents up to 21 at% were prepared by electrodeposition on Ni substrate. Then, the NiFe alloy deposits were anodized at 10 V in ethylene glycol electrolyte containing 0.2 mol dm^{-3} NH_4F and 0.1 mol dm^{-3} H_2O to form nanoporous anodic films. The OER activities were examined in 1.0 mol dm^{-3} NH_4F by cyclic voltammetry at a potential sweep rate of 10 mV s^{-1}.

The Fe content in the NiFe deposits increased almost linearly with the Fe^{2+} concentration in the deposition bath. The porous anodic films of ~400 nm thickness were formed by anodizing of the NiFe deposits in the ethylene glycol electrolyte containing NH_4F and H_2O. The STEM/EDS analysis of the anodic film indicated that Ni, Fe, O and F were distributed uniformly in the anodic film. The anodic film contained a crystalline phase of NiF_2 and the EDS analysis discloses the high concentration of fluoride in the anodic film. The Fe to Ni ratio in the anodic film was similar to that in the alloy deposit.

The OER activity of the anodized NiFe increased largely with CV cycling in KOH electrolyte. Thus, in situ activation occurred during potential cycling and the activation was much more significant in the anodized NiFe compared with the anodized Ni. The OER activity was largely composition dependent; the highest activity was obtained for the Ni-11.8 at% Fe, which showed the onset potential of OER as low as 1.49 V vs RHE. During in situ activation, ECSA increased by 3-5 times, but the OER current increased more markedly. More active sites for OER appeared to be developed during the potential cycling in KOH electrolyte.

Bidimensional spectroelectrochemistry. A new approach to compare the electrochemical behavior of modified electrode surfaces.

Aranzazu Heras, Pablo López, Fabiola Olmo, Jesús Garoz-Ruiz, Alvaro Colina

maheras@ubu.es

Bidimensional spectroelectrochemistry (Bidim-SEC)[1,2] is an analytical technique that allows recording in a single experiment information related to the electron transfer process occurring at the working electrode (WE) surface from three very different points of view. The first one comes from the electrochemical signal that includes all the aspects directly related to the oxidation or reduction process provoked by the potential or current applied to the electrochemical system. The other two arise from simultaneously recording the spectral changes taking place during the electron transfer process. Specifically, the electromagnetic radiation samples the solution adjacent to the WE in a normal (perpendicular) and parallel direction respect to it, deconvolving the information related to the processes mainly occurring at the WE surface and those taking place exclusively on the diffusion layer.

In this work, a new cell (Fig. 1) is developed that allows two Bidim-SEC experiments to be performed at the same time. In this way, it is possible to compare in the same experiment, for example, the consequences or effects that the modification of the electrode surface has with respect to the process of oxidation or reduction of a certain molecule. The new Bidim-SEC cell is tested modifying partially a HOPG surface with a thin film of SWCNTs and comparing the electrochemical and spectroscopic response of different molecules such as ferrocenomethanol (takes as test molecule), dopamine or 3,4-ethylenedioxythiophene.

In recent decades, direct borohydride fuel cell (DBFC) has attracted great attention because of its high theoretical power density (9 kWh kg^{-1}), high theoretical open circuit potential (1.64 V) with environmental benign reaction products [1–3]. Borohydride oxidation reaction (BOR) occurs at the anode side (**Eq. 1**) while oxygen reduction reaction (ORR) occurs at the cathodic side (**Eq. 2**) in a DBFC. Thus, the overall reaction of DBFC is given by **Eq. 3.**

Oxidation: $BH_4^- + 8OH^- \rightarrow BO_2^- + 6H_2O + 8e^-$ ($E^0 = -1.24$ V vs. SHE) (1)
Reduction: $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$ ($E^0 = 0.40$ V vs. SHE) (2)
Overall reaction: $NaBH_4 + 2O_2 \rightarrow NaBO_2 + 2H_2O$ ($E^0_{cell} = 1.64$ V) (3)

The electrochemical oxidation of BH_4^- ion at the anode side is a very complex process where anode catalyst plays the main role. The borohydride hydrolysis reaction (BHR) has a competitive role with BOR leading to the generation of hydrogen bubbles and at the same time to decrease of the performance of DBFC [1]. The direct borohydride reaction could be presented by **Eq. 4** where n is the actual number of exchanged electrons. Literature reports suggested that only gold (Au) and silver (Ag) could exchange $8e^-$ during electrochemical oxidation of each BH_4^- ion [1,4].

$BH_4^- + nOH^- \rightarrow BO_2^- + (n-2)H_2O + (4-0.5n)H_2 + ne^-$ (4)

B. Molina Cocha and M. Chatenet [5] showed that the BOR mechanism on Ag catalyst depends on electrolyte solution pH where increasing pH value leads to an increase in the number of exchanged electrons. In our previous work [4] was shown that Ag incorporated into three different types of zeolites offered low onset potential and high BOR current densities.

Herein, we tested three silver nanoparticles (AgNPs)-polyaniline(PANI)-polyvinylpyrrolidone(PVP) with different amount, morphology and size of AgNPs electrocatalysts for BOR at pH 14 by cyclic voltammetry (CV). Ag-PANI-PVP electrocatalysts with 3.4, 43.8 and 18.9 wt% of Ag were noted as Ag-PANI-PVP-1, Ag-PANI-PVP-2 and Ag-PANI-PVP-3 respectively

All three Ag-PANI-PVP electrocatalysts showed good BOR activity in the potential range from -0.6 to 0.3 V vs SCE with appearance of several oxidation peaks. In this potential range, AgOH layer and Ag oxides are formed on the surface of Ag-PANI-PVP electrocatalysts in 2 M NaOH [6] which indicated that this Ag forms catalysed BOR. CVs of Ag-PANI-PVP-2 and Ag-PANI-PVP-3 electrocatalysts showed well defined and high intensity oxidation peak a_1 while CV of Ag-PANI-PVP-1 showed a broad peak of significantly lower intensity. Namely, a_1 peak current densities of 1.29, 1.27 and 0.14 mA cm^{-2} were recorded at Ag-PANI-PVP-2, Ag-PANI-PVP-3 and Ag-PANI-PVP-1 respectively. a_2 oxidation peak was observed only in case of Ag-PANI-PVP-1 electrocatalyst. BOR mechanism continues to be a subject of discussion, but peaks a_1 and a_2 could appear~~ed~~ due to the oxidation of hydroxyborohydride ion (BH_3OH^-) produced by the hydrolysis of $NaBH_4$ and BOR, respectively [4]. Ag/C and bimetallic Cu-Ag/C electrocatalyst showed anodic peaks during BOR at the same position [7].These electrocatalysts offer a great opportunity for improvement of performances of DBFC, because of their low-cost, easy synthesis and good electrochemical behaviour during BOR.

Recently, there is more and more research on the biohybrid photoelectrochemical systems being conducted. While the photoactive proteins usually maintain charge separation quantum yields close to 100 % the further steps of electron and hole transfer are often limiting the overall system efficiency. Therefore, we propose to study the process of electron transfer between *Rhodobacter sphaeroides* reaction centers (RCs) and Os-complex redox polymers (Os-P) using transient absorption spectroscopy. RCs and Os-P were mixed in buffered solution in different ratios with addition of electron acceptor – water soluble quinone. Results show that the electron transfer between RCs and Os-P is 3-exponential under studied conditions and the fastest lifetime is of the order of a few microseconds. It also shown that the electron transfer rate increases with higher concentration of Os-P and decreases with higher concentration of RCs. These results suggest that there are a few types of complexes between RCs and Os-P being created. Their nature is discussed.

In situ Spectroelectrochemical Investigation of a Biophotoelectrode Based on Photoreaction Centers Embedded in a Redox Hydrogel

The field of biophotoelectrochemistry and its application in biophotovoltaics and biosensors has gained more and more attention in recent years. Knowledge of the redox potentials of the catalytically active protein cofactors in biophotovoltaic devices is crucial for accurate modelling and in discerning the mechanisms of their operation. Here, for the first time, we used spectroelectrochemical methods to investigate thermodynamic parameters of a biophotoelectrode in situ. We determined redox potentials of two elements of the system: the primary electron donor in photosynthetic reaction centers (RCs) of the bacterium *Rhodobacter sphaeroides* and osmium-complex based redox mediators that are bound to a hydrogel matrix. We observe that the midpoint potential of the primary donor is shifted towards more positive potentials in comparison to literature data for RCs solubilized in buffered water solution, likely due to interaction with the polymer matrix. We also demonstrate that the osmium-complex modified redox polymer efficiently wires the RCs to the electrode, maintaining a high Internal Quantum Efficiency with approximately one electron per two photons generated (IQE = 50±12%). Overall, this bio-photoelectrode may be attractive for controlling the redox state of the protein when performing other types of experiments, e.g. time resolved absorption or fluorescence measurements, in order to gain insights into kinetic limitations and thereby help in the rational design of bioelectronic devices. Ordered Mesoporous Carbons as Supports for Bimetallic Pt(Cu) Catalysts in PEMFCs

One of the main drawbacks when using Pt catalyst in the anode of polymer electrolyte membrane fuel cells (PEMFCs) is that it is easily poisoned by CO, even at low concentrations as 1 ppm. The use of PtRu catalysts or other strategies, like air-bleeding, have shown an increase of the CO tolerance in PEMFCs [1], but limited to few ppm of CO. Another strategy has been addressed the synthesis of nanoparticles with a core-shell structure or bimetallic systems, thus reducing the amount of Pt used in the electrode and increasing its tolerance towards CO [2]. A further step would be to modify the carbon support. In this sense, carbon blacks are the most typical used, but they do not have good textural properties and thermochemical stability [3], which ultimately can be detrimental for catalyst performance. On the other hand, other carbonaceous materials, such as carbon nanotubes (CNTs) and carbon nanofibers (CNFs) have been tested as support for Pt(Cu) nanoparticles [4]. Furthermore, in this work, Pt(Cu) nanoparticles have been synthesized on ordered mesoporous carbons (OMC), CMK-3 and CMK-8, as they also present improved textural and electrochemical properties as compared to carbon blacks, showing promising results, as can be seen in Figure 1, where the catalyst studied depict improved activity towards CO electro-oxidation.

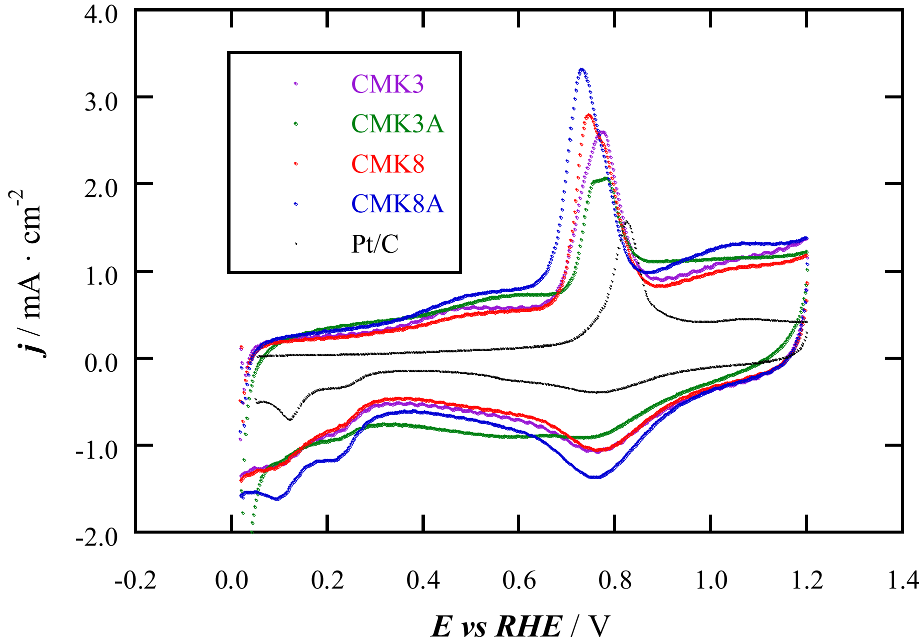

Figure 1. CO stripping curves of prepared and commercial catalysts in deaerated 0.50 M H_2SO_4 solution at scan rate of 20 mV·s^{-1}.

mpestebanez@ubu.es

Surface Enhanced Raman Scattering (SERS) is a phenomenon related to the amplification of the Raman signal of an analyte interacting with a plasmonic nanostructure. This phenomenon, discovered in 1974, had a significant impact among the spectroscopy community, since it helped to overcome the main disadvantage of Raman spectroscopy: the lack of sensitivity. Recently, our group discovered a new phenomenon called Electrochemical Surface Oxidation Enhanced Raman Scattering (EC-SOERS) [1], which allows to enhance the Raman signal of an analyte during the oxidation of a silver substrate.

Although many aspects of the origin of EC-SOERS remains still unclear, this phenomenon has shown considerable potential for quantitative analysis, being used for the determination of uric acid, citric acid or acetylsalicylic acid. In one of our last works, combination of EC-SERS and EC-SOERS was used to achieve a double quantification of nicotinic acid and nicotinamide [2], a couple of analytes with great similarity between Raman spectra.

In this communication, we expose the possibility of using EC-SERS and EC-SOERS to obtain a double characterization of an analyte in a single experiment, as exposed in Figure 1. Interestingly, several shiftings and changes in the relative intensity of the bands are observed. An analysis of the spectral differences will be carried out in order to further understand the interaction between the analyte and the substrate involved in each phenomenon.

This work shows the potential to provide a highly specific double characterization of analytes in a single experiment, giving enough information to avoid interferences.

5-Substituted uracil derivatives have been studied using EC-SERS and EC-SOERS. This family of compounds have been used for many decades in chemotherapy as antimetabolite drugs and also as radiosensitizers of DNA [3,4].

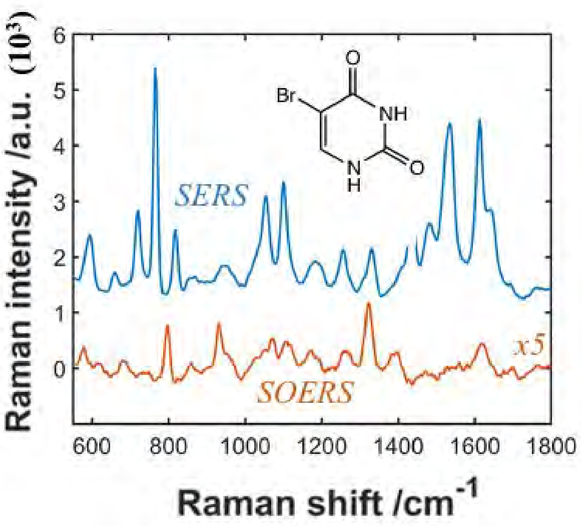

Figure 1. EC-SERS and EC-SOERS spectra of 5-Bromouracil 1mM during a time-resolved Raman spectroelectrochemical experiment.

The dynamic nature of CO adlayers on Pt(111) electrodes

J. Wei,[1,2] R. Amirbeigiarab,[2] Y.X. Chen,[1*] S. Sakong,[3] A. Gross,[3] O.M. Magnussen[2*]

[1] Hefei National Laboratory for Physical Sciences at Microscale, University of Science and Technology of China, Hefei 230026, China, [2]Institute of Experimental and Applied Physics, Kiel University, Kiel 24098, Germany, [3] Institute of Theoretical Chemistry, Ulm University, Albert-Einstein-Allee 11, 89081 Ulm, Germany

The adlayers of CO on the Pt(111) surface are a fascinating electrochemical model system of great relevance in electrocatalysis. The potential-dependent structure and dynamics of these adlayers are complex and still controversial. While at the negative limit of the double layer potential range the presence of a close-packed (2 × 2)-3CO adlayer is well established, a coherent picture in the pre-oxidation range is still lacking.

To resolve this mystery, we here employ in situ high-speed scanning tunneling microscopy for studying the surface phase behavior in CO-saturated 0.1 M H_2SO_4 on the millisecond time scale. At potentials near the onset of CO pre-oxidation local fluctuations in the (2 × 2)-CO adlayer are observed, which increase towards more positive potentials. Above 0.20 V (vs. Ag/AgCl), this leads to an adlayer where CO_{ad} apparently reside on every top site, but still exhibit a (2 × 2) superstructure modulation. We interpret this observation as a dynamic effect, caused by a small number of highly mobile point defects in the (2 × 2)-CO adlayer. Our data indicate the coexistence of a rather static primitive (2 × 2) CO sublattice with highly dynamic CO on the residual atop sites. Density functional theory calculations support this interpretation. They show that the CO lattice near such defects relaxes into a local (1 × 1) arrangement, which can rapidly propagate across the surface. This behavior resembles the “door-opening” mechanism, which enables a high CO_{ad} surface mobility during CO pre-oxidation, even in the presence of ordered adlayers of high packing density and thus ensures effective mixing of CO_{ad} and OH_{ad} on the electrode surface.

In addition, as the potential shifts further positively, or the partial pressure of CO in the solution decreases, the above-mentioned apparent (1 x 1)-CO adlayer will be transformed into the classic (√19 × √19) R23.4°-13CO structure. The potential for transformation depends closely on the density of point defect on the surface and CO partial pressure in the solution, and there is a sort of coexistence of (1 x 1) and (√19 x √19) motives in the middle of the transition.

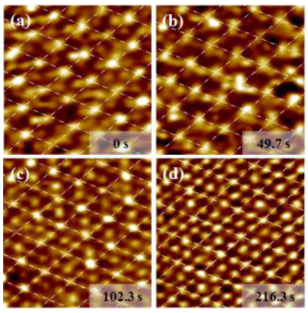

Figure 1. Potential-dependent structure of the CO adlayer on Pt(111) in CO-saturated 0.1 M H_2SO_4 solution. Video-STM images (3 nm × 3 nm) were recorded at (a) -0.10 V, (b) 0.12 V, (c) 0.20 V, and (d) 0.30 V and shoe gradual deviations from the (2 × 2) symmetry with increasing potential, resulting in a modulated (1 × 1) structure at the most positive potentials.

Does the Salt Really Matter?
Impact of the Counterion Upon ECL Signal

Kelly Brown, Christina Gillies, Pamela Allan, Lynn Dennany
WestChem. Department of Pure and Applied Chemistry, University of Strathclyde
Technology and Innovation Centre, University of Strathclyde, 99 George Street, Glasgow G1 1RD
kelly.brown.100@strath.ac.uk

Typical reporting of electrochemiluminescence (ECL) mechanisms details the reactions which occur between the luminophore complex and the core electroactive structure of the target molecule. Structural similarities between ECL co-reactants have long been utilized to determine the mechanistic pathways, predict the potential regions where emission will occur and ultimately the likelihood of a species being a suitable co-reactant.[1, 2]

But what influence do the counterions have?

Counterions are vital within a range of substances but in particular within the pharmaceutical industry. Here they are utilized to improve the physiochemistry of an active pharmaceutical ingredient, ensuring the required bioavailability is obtained, by providing control over properties such as solubility, drug stability and dissolution rate. However, consideration has to date not been given to the potential impact of a target molecules counterion upon its ECL response. Traditionally considered as a bystander, counterions were not believed to bare influence upon the recorded ECL emission.

However, within this contribution we report, for the first time, how the simple change of a counterion from HBr to a HCl salt form can significantly impact upon the recorded ECL response; how this can in turn influence the reported concentrations and the significance this will have upon the wider analytical community.

Scopolamine, a pharmaceutical product and recreational drug was utilized within this proof-of-concept study. Previous work has demonstrated the suitability of scopolamine to behave as an ECL co-reactant, with the drug species successfully detected within a range of biological matrices via a basic $[Ru(bpy)_3]^{2+}$ based sensor down to clinically relevant concentrations.[3]

With both salt forms containing the identical core tropane alkaloid structure (to which their electroactivity is attributed), indistinguishable pKa values and hence comparable influence of pH toward their ECL intensity, the distinct difference observed within their obtained ECL profiles is of great interest. Direct comparison between the HBr salt and HCl salt relived differences in respect of their emission potentials and intensity. The impact of the salt form upon the ECL response has been investigated in respect of the calculated concentrations based upon the construction of calibrations curves which each salt form. Results demonstrated vastly different concentrations were obtained dependent upon the salt form within the sample and that used to produce the calibration curve. As such this bares the question of whether this phenomenon is intrinsic across all co-reactants, solely to the amine functional group or specific to scopolamine. The impact of this outcome would be of interest to the wider analytical community, and in particular forensic practitioners where electrochemical and ECL based sensors are of increasing interest. Ultimately the application of a sensor within an analytical environment relies upon its accuracy and hence a thorough understanding of such a phenomenon would only stand to widen ECL acceptance within the wider analytical community and increase its potential applications.

Electrodeposited MnO$_2$ Nanostructures as Efficient Photocatalyst for Removal of TCs Antibiotics Pollutant

Roberto Cestaro, Albert Serrà, Laetitia Philippe
Empa Swiss Federal Laboratories for Materials Science and Technology, Laboratory for Mechanics of Materials and Nanostructures
Feuerwerkerstrasse 39, CH-3602 Thun, Switzerland
roberto.cestaro@empa.ch

Nowadays antibiotics are widely used not only for human and animals medicine but also as additives in feedstuff industries. Tetracycline antibiotics (TCs) are the most common antibiotics all over the world, accounting for about half of the global antibiotical production. However, TC is poorly adsorbed by animal metabolism and it is released into the environment in an active form. One of the biggest problems related to its long-term presence in water and soil is the development of antimicrobial resistance in animals which has the potentially threatens in ecosystem and human health[1]. Therefore, the global antibiotic resistance problem has reached an urgent point. Electrodeposited Manganese dioxide (MnO$_2$) has been considered as a promising photocatalyst for oxidative degradation of organic contaminants in wastewater due to its ease of synthesis, non-toxic properties, strong adsorption, strong oxidation ability, acid resistance and low-cost. However, only a few studies are available about the photocatalytic response of electrodeposited MnO$_2$ nanostructures. Besides, to the best of our knowledge, none of those studies considers the photocatalytic removal of TC pollutant. Herein, we report the synthesis of MnO$_2$ nanostructures by electrodeposition from a simple and green electrolyte bath under ambient conditions. The photocatalytic activity of MnO$_2$ was tested for the removal of TC antibiotic from water using LED visible illumination. LED lights are up to 80% more efficient and draw much less power than traditional lighting. The photocatalytic performances of the MnO$_2$ nanostructures result in an excellent photodegradation as well as an elevated percentage of mineralization of the TCs antibiotic. Besides, the photocatalyst showed good recyclability properties after performing several successive cycles, revealing its high photostability. We believe that the facile synthesis process can open up a new approach for the possible large-scale utilization of electrodeposited MnO$_2$ nanostructures as an effective visible light photocatalyst.

Figure 1: Scheme of the electrodeposited MnO$_2$ photocatalytical process for the TC removal.

Electrochemical Dissolution of PtRu Nanoparticles: Electrocatalyst Stability During Operation and Recycling of Spent Catalysts

Raghunandan Sharma[1,#], Sašo Gyergyek[2], Per Morgen[1] and Shuang Ma Andersen[1,*]
[1]Department of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, DK-5230 Odense M, Denmark

PtRu alloy nanoparticles supported on high surface area carbon (PtRu/C) are common electrocatalysts used for the hydrogen oxidation reaction at polymer electrolyte membrane fuel cell (PEMFC) anodes. Recycling of these precious metals at the end of the lifetime of fuel cells is important for their further applications in a sustainable energy technology scenario. In this study,[1] we explore the electrochemical dissolution of Pt and Ru from the PEMFC anode catalyst layer, i.e., a PtRu alloy supported on carbon catalyst (PtRu/C). Effects of different dissolution routes on the relative rates of dissolution for Pt and Ru have been explored with different electrolytes, namely 0.1 M HCl and 1 M H_2SO_4. Apart from studying the effect of the presence of chloride on their stability, this study explores the electrochemical dissolution-based recovery of Pt and Ru from PtRu/C electrocatalysts. During potential cycling in presence of chloride (0.1 M HCl), the stability of Pt is observed to be lower than that of Ru. On the other hand, in absence of chloride, due to redeposition of the instable dissolved species, Pt shows stability higher than Ru. For example, the % dissolutions of Pt and Ru are observed to be ~72% and ~33% during potential cycling between 0.2 and 1.6 V for 50 cycles at a scan rate of 100 mV/s, in 0.1 M HCl. On the other hand, for similar initial Pt and Ru loadings, the corresponding dissolution values for Pt and Ru after potential cycling between 0.2 and 1.6 V for 10k cycles at a scan rate of 1 V/s in 1 M H_2SO_4 are observed to be ~27% and ~61%, respectively (Figure 1). This difference of behaviors is attributed to the formation and stability of soluble Pt and Ru species during potential cycling. The fast dissolution of Pt and higher stability of Ru found during potential cycling in dilute HCl may be explored towards separation of Pt and Ru and for separable recoveries from spent alloy catalysts.

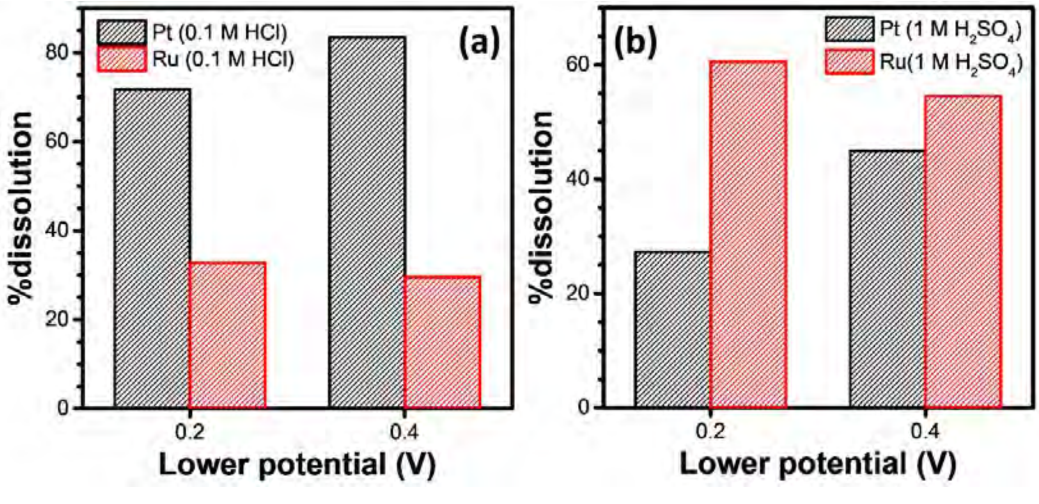

Figure 1: Variations of dissolution rate values for Pt and Ru for (a) 50 cycles between E_l and 1.6 V at a scan rate of 100 mV/s in 0.1 M HCl and (b)10000 cycles between E_l and 1.6 V at a scan rate of 1 V/s in 1 M H_2SO_4), for two different E_l values of 0.2 and 0.4 V.

Due to the high stability of sp^3 carbon towards active intermediates, boron doped diamond (BDD) is utilized as an electrode material in electrochemical devices for wastewater purification from toxic and not easily biodegradable organic ecopollutants. However, a drawback of BDD is a relatively low rate of electron transfer (ET) which limits the productivity of such systems. In the present study, the effect of plasma electrochemical treatment of BDD surface on the ET rate of outer and inner sphere electrode reactions was studied by the example of model redox systems.

A typical electrode used in the study was a 10–20 μm thick boron doped diamond film on a silicon substrate. ET rate constants were assessed on the basis of the data of cyclic voltammetry carried out in 5 mM $K_3[Fe(CN)_6]$ + 1 M Na_2SO_4, 5 mM $[Ru(NH_3)_6]Cl_3$ + 1 M Na_2SO_4 and 5 mM $FeSO_4$ + 0.25 M H_2SO_4 solutions on the initial and treated BDD electrodes. The electrode surface was treated in 1 M Na_2SO_4 solution as a result of ca. 20 impulses of anodic plasma generated at 300 V [1]. The rate constant of outer sphere electron transfer in the case of $Ru^{3+/2+}$ was determined not to depend on the state of BDD surface and equals ca. 10^{-2} $cm^2 \cdot s^{-1}$. For inner sphere electron transfer ($[Fe(CN)_6]^{3-/4-}$ and $Fe^{3+/2+}$), in contrast, the ET rate is sensitive to plasma electrochemical treatment. Namely, after electrode treatment with the anodic plasma impulses, the rate constant decreases from 10^{-3} $cm^2 \cdot s^{-1}$ to 10^{-4} $cm^2 \cdot s^{-1}$ for $[Fe(CN)_6]^{3-/4-}$ and increases from $5 \cdot 10^{-7}$ $cm^2 \cdot s^{-1}$ to ca. $3 \cdot 10^{-6}$ $cm^2 \cdot s^{-1}$ for $Fe^{3+/2+}$ which is considered to be the most sensitive to the surface state. The data of X-ray photoelectron spectroscopy demonstrate the increase in concentration of oxygen-containing functional groups on the surface of BDD after its plasma electrochemical treatment. Thus, such an effect of BDD electrode treatment on the electron transfer kinetics should be explained by the functionalization of boron doped diamond surface with oxygen-containing groups, which affect the rate of considered model redox reactions in a different way.

The study was carried out in the framework of the State Assignment no. AAAA-A19-119061890019-5 of 18.06.2019 using the equipment of the Multi-User Analytical Center of IPCP RAS and the equipment of the Multi-User Center of Scientific Center in Chernogolovka RAS.

Abstract

Microbial fuel cells (MFCs) are a versatile platform that aims at harvesting electricity by using the electrons coming from organic waste degradation catalysed by microorganism metabolism. However, challenges, such as high cost and low durability of electrode materials, lead to the use of platinum at the cathode side, limiting the applicability of MFCs [1]. To overcome this issue, low cost catalysts based on non-noble metals were developed demonstrating promising catalytic activity toward oxygen reduction reaction (ORR) [2]. Platinum-group-metal-free (PGM-free) are mostly based on transition metals supported on nitrogen-containing carbon matrix [2,3]. In this context, we propose novel catalysts based on FeN4 macrocycles supported on nanostructured carbon spheres (Fe-N-C), for direct oxygen reduction to water in neutral environment. A facile three-step-method of synthesis was developed to obtain Fe-N-C catalysts, were Iron (II) phthalocyanine (FePc) and urea (CH_4N_2O) were used as iron and nitrogen source, respectively, and carbon black pearls (BP) as carbon support. Figure 1 shows a flowchart of the synthesis strategy, together with a schematic of ORR mechanism and performance at a surface of a typical Fe-N-C catalyst. Structural, morphological and electrochemical properties of catalysts were investigated, and the set of results indicated that Fe-N-C catalysts have a good catalytic activity towards ORR in neutral pH, thanks to their high surface area and density of active sites which make them suitable for MFC applications.

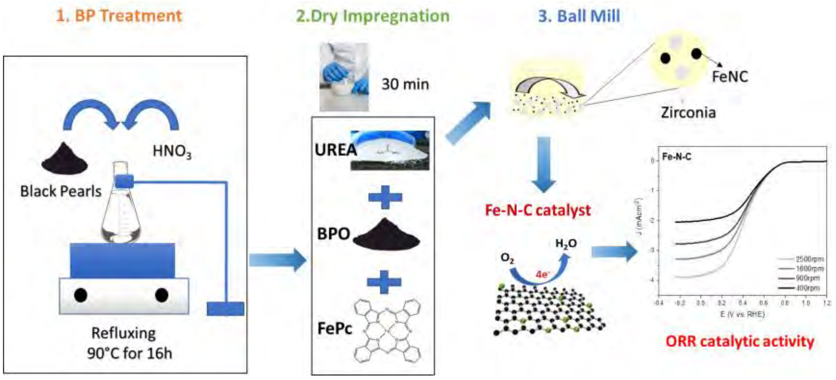

Figure 1. Schematic illustration of Fe-N-C catalyst production and its electrochemical performances via hydrodynamic linear sweep voltammogram.

Ion–Solvent Chemistry in Alkali Metal Batteries

Xiang Chen, Qiang Zhang
Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology
Department of Chemical Engineering, Tsinghua University, Beijing 100084, China
chenxiang16@mails.tsinghua.edu.cn, zhang-qiang@mails.tsinghua.edu.cn

Alkali metal batteries are considered as promising next-generation energy storage devices due to their ultrahigh energy densities. However, the high reactivity of alkali metal toward organic solvents and salts renders inevitable side reactions, which further leads to undesirable electrolyte depletion, cell failure, and evolution of flammable gas. Ion–solvent chemistry was proposed to prove the intrinsic instability of normal organic electrolytes towards alkali metal anodes through multiscale calculations (density functional theory (DFT) calculations, ab initio molecular dynamics (AIMD) simulations, and in situ microscopic observations. Once complexed with cations in electrolytes, solvent molecules exhibit a significantly reduced the lowest unoccupied molecular orbital (LUMO) energy level, facilitating the electrolyte decomposition and gas evolution. The origin of such phenomenon can be explained by two mechanisms in ether and ester electrolytes, respectively. The LUMO energy levels of ion–ester complexes exhibit a linear relationship with the binding energy, regulated by the ratio of carbon atomic orbital in the LUMO, while LUMOs of ion–ether complexes are composed by the metal atomic orbitals. AIMD simulations further prove the electrolyte decomposition kinetics on alkali metal anodes. The broken of C–O bond in electrolyte solvents is always accompanied by the formation of Li/Na–O bond, validating the role of coordinated cations in promoting electrolyte decomposition. In situ optical microscopic observations validated the theoretical predictions that electrolyte gassing on Li/Na metal surface is obviously promoted after introducing cations into electrolytes.

Based on the proved ion–solvent chemistry, several strategies were proposed to build stable electrolytes for alkali metal anodes, including additive design and regulating anions in electrolyte solvation shell. Both electrolyte additives and anions from salts can participate electrolyte solvation of cations and regulate the composition and structure of solid electrolyte interphase (SEI). More importantly, a fancy strategy of cation additive was proposed as different cations have a different impact on solvent molecules. Three principles, including the LUMO energy level decrease of solvents after coordinating with cations, the electrode potential of introduced cations in electrolytes, the binding energy between cations and solvents, were proposed to select proper cation additives for sodium metal batteries. Besides, the role of electrolyte solvation in regulating ion–solvent interactions was also systematically investigated. The cation additive strategy affords emerging chances for rational electrolyte design for stable and safe Na metal batteries and also affords a fresh research paradigm for other batteries.

[2]Tula State University, pr. Lenina 92, Tula, 300012, Russia
[1]davydov@elchem.ac.ru

При электросаждении металлов и сплавов достаточно широко используются растворы, содержащие комплексы ионов металла с отрицательно заряженными лигандами [1]. Процессы массопереноса в растворах с комплексами включают гомогенные химические реакции и потоки лигандов, возникающие при восстановлении комплексов, что позволяет существенно повысить эффективность электрохимических процессов за счет реализации электро- и автокатализа, эффекта экзальтации. Известно, что электромиграция может значительно увеличить значение предельной плотности тока в случае электровосстановления катионов из растворов, содержащих комплексы, а при определенных условиях предельный ток может вообще отсутствовать [2]. При теоретическом анализе массопереноса в условиях комплексообразования обычно используются упрощенные математические модели (приближение диффузионного слоя Нернста, условие равновесия реакции комплексообразования, равенство коэффициентов диффузии всех компонентов), что в ряде случаев позволяет получить приближенные аналитические решения [3]. Очень часто приближения, принятые в упрощенных математических моделях, не выполняются: ионы имеют существенно отличающиеся значения коэффициентов диффузии, наряду с электродиффузионным осуществляется и конвективный перенос компонентов, реакция комплексообразования является неравновесной, что может оказывать существенное влияние на закономерности массопереноса в условиях комплексообразования. В связи с этим представляет интерес исследование влияния гидродинамических условий, транспортных свойств и скорости гомогенной химической реакции на процессы переноса в условиях комплексообразования, которое можно выполнить только с использованием численных методов [4].

In this work the effect of complex formation on the mass transfer during the metal electrodeposition on a rotating disk electrode from the solution containing three types of ions (metal cation, cationic complex and non-electroactive anion) is studied theoretically. The dimensionless Nernst-Planck equations in the approximation of solution electroneutrality, which take into account the electro-diffusion and convective transfer of all types of ions and the homogeneous reaction of complex formation, are used as the mathematical model. The Butler-Volmer equations are used to take into account the kinetics of electrochemical reactions. In contrast to the known works, the approximations of the Nernst layer, equality of the diffusion coefficients of all types of ions, and the equilibrium of complex formation reaction were not used. As a result of numerical solution, the distributions of concentration, potential, and the rate of complex formation reaction are obtained at various parameters of the system under consideration. It is shown that the constants of the equilibrium and rate of complex formation reaction, as well as the ratio between the diffusion coefficients of complex cation and anion have the strongest effect on the mass transfer.

The work was performed with support of Ministry of Science and Higher Education of Russian Federation. The study was partially funded by Russian Foundation for Basic Research and Tula region, project no. 19-48-710008.

Abstract

Catalyst support is extremely important for future fuel cell devices. In this work, we developed double-shelled C/TiO_2 (DSCT) hollow spheres as an excellent catalyst support via a template-directed method. The combination of hollow structure, TiO_2 shell and carbon layer results in excellent electron conductivity, electrocatalytic activity, and chemical stability. These uniformed DSCT hollow spheres are used as catalyst support to synthesize Pt/DSCT hollow spheres electrocatalyst. The resulting Pt/DSCT hollow spheres exhibited high catalytic performance with a current density of 462 mA mg^{-1} for methanol oxidation reaction, which is 2.52 times higher than that of the commercial Pt/C. Furthermore, the increased tolerance to carbonaceous poisoning with a higher I_f/I_b ratio and a better long-term stability in acid media suggests that the DSCT hollow sphere is a promising C/TiO_2-based catalyst support for direct methanol fuel cells applications.

[1]davydov@elchem.ac.ru

Local electrodeposition (LED) is one of effective methods for formation of 3D micro- and nanostructures. It exhibits several important advantages: the absence of mechanical and heat impacts on the workpiece, no tool wear, wide possibilities for controlling the shape of microstructures by varying machining modes, low cost of electrochemical processes, and good reproducibility of results [1]. Electrodeposition is particularly unique in its ability to create deposit at sub-nanometer vertical resolutions [2]. Various schemes of maskless local electrodeposition are used: jet LED, scanning probe based LED and micro/nanopipette based LED (electrochemical micro/nanoprinting). At present, the schemes of LED using unipolar or bipolar electrodes [3, 4], are widely used, whereas the electrodeless LED remains almost unstudied.

This work is devoted to the theoretical analysis of electrodeless electrochemical nanoprinting using a nanopipette filled with the electrolyte solution more concentrated than the bulk solution. The external potential is not imposed onto the conductive substrate, and there are no other electrodes. As a result of different solution concentrations near the substrate, cathodic and anodic zones form on it. Local metal deposition from the solution occurs on the cathodic zone near the nanopipette, and anodic dissolution of substrate metal occurs on the large anodic zone on the periphery of electrochemical cell. The ionic transport equations, which take into account diffusion, migration, and convection, and the condition of electroneutrality, are used as the mathematical model. The boundary conditions on the substrate are set using the Butler-Volmer equation. The numerical solution of the problem is carried out by the finite element method on the deformable grid that takes into account the change of the substrate surface shape due to the local deposition and dissolution of metal.

As a result of simulation, the distributions of ion concentrations and potential over the solution, and the distributions of current density, overpotential, and concentration of electroactive ions over the substrate surface are obtained for various time instants and under various conditions.

The work was performed with support of Ministry of Science and Higher Education of Russian Federation. The study was partially funded by Russian Foundation for Basic Research and Tula region, project no. 19-48-710008.

Moscow, 119071, Russia
[1]volgin@tsu.tula.ru

Voltammetry is widely used in the study of electrode reaction mechanisms that involve homogeneous chemical processes coupled to electron transfer [1]. Теория cyclic voltammetry of homogeneous redox catalysis of electrochemical reactions достаточно хорошо разработана и позволяет выразить (описать) the cyclic voltammetric responses as functions of two dimensionless parameters: a kinetic parameter, and an excess factor [2]. Одним из частных, но весьма важным, случаем электрокатализа является гомогенный автокатализ (так называемый CE’’ механизм [3]) при котором количество катализатора увеличивается в ходе процесса. Упрощенно механизм гомогенного автокатализа может быть представлен следующей схемой (k>1):

$$A \pm e^- \leftrightarrow M$$

$$M + S \rightarrow kA + \text{products}$$

Этот механизм реализуется при электрохимическом восстановлении иода (который присутствует в растворе в весьма малой концентрации) с образованием iodide, и последующим the reduction of iodate by iodide (known as the Dushman reaction) [4]. В работе [5] показано, что the catalytic reduction of iodate at a rotating platinum disk electrode has been employed to study the kinetics of the reaction between iodate and iodide и при использовании ряда упрощений получено a closed form solution for the catalytic current.

Настоящая работа посвящена теоретическому исследованию процессов переноса при of homogeneous autocatalytic reduction of iodate on rotating disk electrode (RDE). В качестве математической модели использованы нестационарные уравнения ионного переноса, учитывающие диффузию, миграцию, конвекцию и гомогенные химические реакции, а также условие электронейтральности. Кинетика электрохимической реакции учитывалась с помощью уравнения Батлера-Фольмера. Численное решение осуществлялось методом конечных элементов на нерегулярной сетке, что обеспечивало высокую эффективность и требуемую точность численного решения.

В результате численного моделирования получены зависимости формы и параметров voltammograms от концентрации раствора, скорости развертки потенциала и скорости вращения RDE. Установлено, что при достаточно больших скоростях развертки потенциала пиковое значение тока окисления существенно больше пикового значения тока восстановления. Это объясняется тем, что при больших скоростях развертки потенциала за время изменения потенциала от наибольшего до наименьшего значений (точно не знаю, как сказать – прямой ход, изменение потенциала в катодную область и т.д.) не успевает образоваться достаточно большого количества iodide.

The work was performed with support of Ministry of Science and Higher Education of Russian Federation. The study was partially funded by Russian Foundation for Basic Research and Tula region, project no. 19-48-710008.

Comparison between microporous layered and non-layered GDLs; Experimentally validated in terms of gas transport and performance in membrane fuel cells

Mainak Mukherjee, Caroline Bonnet and François Lapicque
Laboratoire Réactions et Génie des Procédés (LRGP, Université de Lorraine)
1 Rue Grandville, 54000 Nancy. France
Mainak.mukherjee@univ-lorraine.fr

Gas diffusion layers (GDLs) used in membrane fuel cells are widely recognized as a critical component that largely contributes to its performance. Essentially, properties of GDLs are known to vary significantly, depending upon manufacturing techniques employed [1-2]. Recently, many advances have been made in GDLs with an addition of a microporous layer (MPL) on the substrate layer to facilitate water management by preventing water infusion and disallowing surface wetting. This work aims at comparing an MPL layered (34 BC) with a non-layered (34 BA) GDL from SIGRACET by ; (i) ex situ gas transport measurement in which GDLs were stacked in 25cm^2 cell to measure equivalent gas permeability (in terms of viscous permeability and inertial permeability), [1-2] and (ii) electrochemical performance. Results showed a higher viscous permeability by 5 times for 34 BA due to larger pore sizes and the absence of MPL compared to 34 BC. From the polarization curves, 34 BC with lower gas transport capability, showed reasonably decent performance specifically at a higher current density of 0.8 A/cm^2, indicating sufficient control towards water management. In 34 BA, however, which was prone to flooding led to pore blockage, and overall gas transport was compromised, as a consequence early decline was seen at a current density of 0.4 A/cm^2 [1].

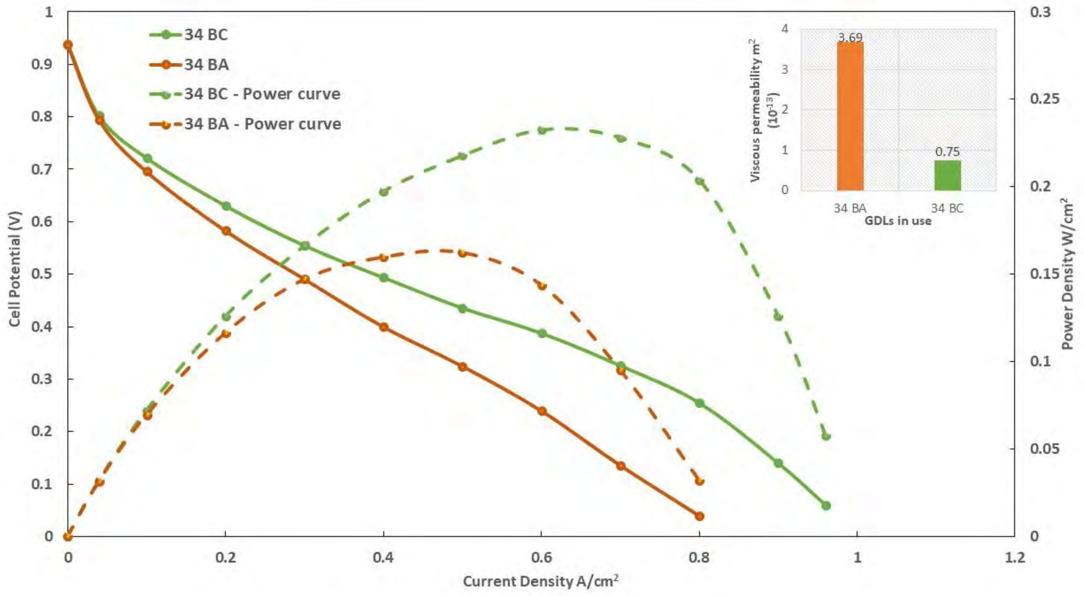

Figure 1. The performance curves on the selected GDLs and viscous permeability values

Simulation of Electrochemical Micromachining by Nanosecond Voltage Pulses

V.M. Volgin[1], V.V. Lyubimov[1], I.V. Gnidina[1], A.D. Davydov[2]
[1]*Tula State University, pr. Lenina 92, Tula, 300012, Russia*

[1]*volgin@tsu.tula.ru*

Electrochemical micromachining (ECMM) with using nanosecond voltage pulses between a tool electrode and a workpiece enables one to form complex-shaped three-dimensional structures with submicrometer precision[1]. The principle is based on the dependence of double-layer charging time on the interelectrode gap (local separation between the electrodes). This results in a highly localized region for electrochemical dissolution or deposition. This technique is used for local anodic dissolution of various metals and silicon as well as for local metal electrodeposition.

The accuracy and productivity of ECMM depends significantly on the operating conditions, in particular, on the interelectrode gap, the pulse-on time and pulse frequency. The pulse-on time can be estimated using an approximate equation for the time constant for electric double layer charging [1]:

$$\tau = CS/\sigma \tag{1}$$

Here C is the specific capacity of electric double layer; S is the interelectrode gap; and σ is the conductivity of electrolyte solution.

The results of modeling and the experimental data [2, 3] give much lower times of double-layer charging. This complicates choosing appropriate machining mode.

In this work, the transport processes in the electrolyte solution and charging-discharging of electric double layer are analyzed theoretically. As a result, an approximate analytical equation for the time constant for double-layer charging is obtained:

$$\tau = \frac{2RTC}{nFi_{\mathrm{F,SS}}} \ln \frac{i_{\mathrm{F,SS}}}{i_0} \tag{2}$$

Here, $i_{\mathrm{F,SS}}$ is the Faraday current density for the charged electric double layer; i_0 is the exchange current density; *n* is the number of electrons involved in the electrochemical reaction; *R* is the gas constant; and *T* is the temperature.

The results of numerical calculations agree well with the approximate analytical equation (2).

Thus, the proposed model of electrochemical micromachining by nanosecond voltage pulses can be used for justified choice of pulse-on time in ECMM.

The work was performed with support of Ministry of Science and Higher Education of Russian Federation.

Acid-Base Electrochemical Flow Battery using Neutralization Energy

Eleana Mundaray-Guilarte, Alfonso Sáez, José Solla-Gullón, Vicente Montiel
Instituto de Electroquímica, Universidad de Alicante
Apdo. 99, E-03080, Alicante, Spain
jose.solla@ua.es

The development of clean, renewable, and affordable energy sources as a consequence of the global warming has become a necessity for society. Consequently, is highly required the development of devices capable of efficiently storing the energy obtained from these sources. In this sense, Hydrogen-based technologies have become a promising candidate both as fuel and transmission element. [1].

A redox flow battery is an electrochemical energy storage device that converts chemical energy into electrical energy through reversible oxidation and reduction of working fluids [2]. Based on this concept an Acid-Base Electrochemical Flow Battery (ABEFB) has been developed. This system is composed of acidic and alkaline solutions, both with a high supporting electrolyte concentration, which are separated by a cationic exchange membrane. Hydrogen oxidation and evolution reactions take place during the charge and discharge processes, which acidifies or basifies the corresponding electrolytes. The neutralization energy obtained from these solutions is used as electromotive force [3]. In this case, HCl and NaOH are used as electrolytes, NaCl as supporting electrolyte, a platinised Pt electrode as cathode, a Pt-catalysed gas diffusion electrode as anode (catalyst loading of 0.5 mg cm^{-2}) and a cationic membrane as ionic separator.

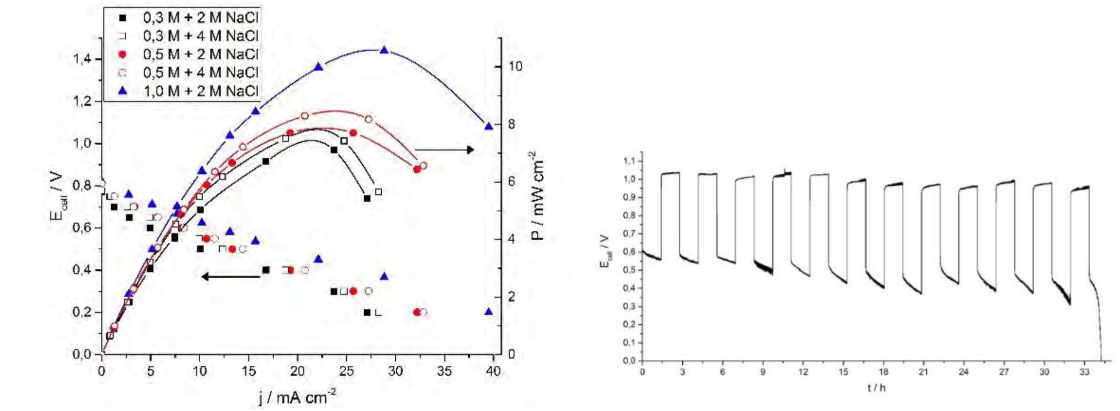

Figure 1:a) Polarization curves and power curves for 0.3, 0.5 and 1.0 M HCl/NaOH, with 2.0 and 4.0 M NaCl. b) Charge/discharge cycles for a charge capacity of 3350 mAh, at 12.5 mA cm^{-2}

In this work, the effect of the supporting electrolyte concentration, the state of charge, and the nature of cationic membrane have been systematically studied. Polarization curves and charge/discharge cycles were obtained to evaluate the performance of the system. We found that this battery can provide a maximum power density of 10.6 mW cm^{-2} at 27.5 mA cm^{-2}, and a coulombic efficiency of around 80 %, depending on the H^+/Na^+ ratio and the membrane thickness. This study reveals a promising energy-storage system, with simple operation and low cost.

Lithium Bonds in Lithium Batteries

Xiang Chen, Qiang Zhang
Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology
Department of Chemical Engineering, Tsinghua University, Beijing 100084, China
chenxiang16@mails.tsinghua.edu.cn, zhang-qiang@mails.tsinghua.edu.cn

Lithium bonds are analogous to hydrogen bonds and are therefore expected to exhibit similar characteristics and functions. Additionally, the metallic nature and large atomic radius of Li bestow the Li bond with special features. As one of the most important applications of the element, Li batteries afford emerging opportunities for the exploration of Li bond chemistry.

In this work, we have briefly summarized the historical development of the Li bond. Especially, the similarities and differences between the Li and H bonds were discussed. Subsequently, the Li bond was described in the context of Li batteries, including discussions of sulfur cathodes, liquid electrolytes, and Li metal anodes. Such discourse on the chemistry of the Li bond can provide fruitful insight into the fundamental interactions within Li batteries and thus deliver a deeper understanding of their working mechanism. In this way, a comprehensive understanding of the Li bond in Li batteries and an outlook on its future developments is presented.

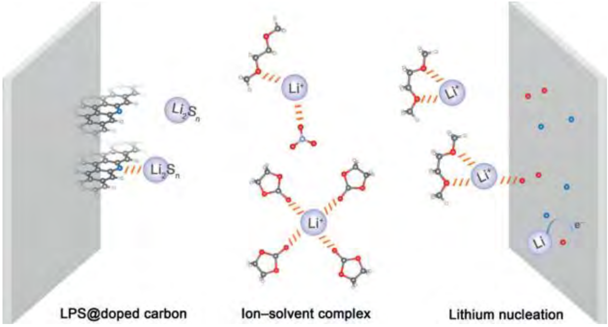

Figure 1. Schematic representation of the Li bond in Li batteries. LPS: Lithium polysulfide.

Automated Investigation of Cyclic Voltammetry Data

Berk Delibas, Burak Ülgüt, Can Berk Uzundal

Ihsan Dogramaci Bilkent University

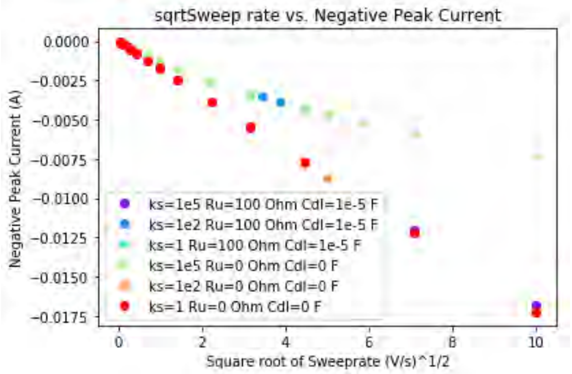
berk.delibas@ug.bilkent.edu.tr, ulgut@fen.bilkent.edu.tr

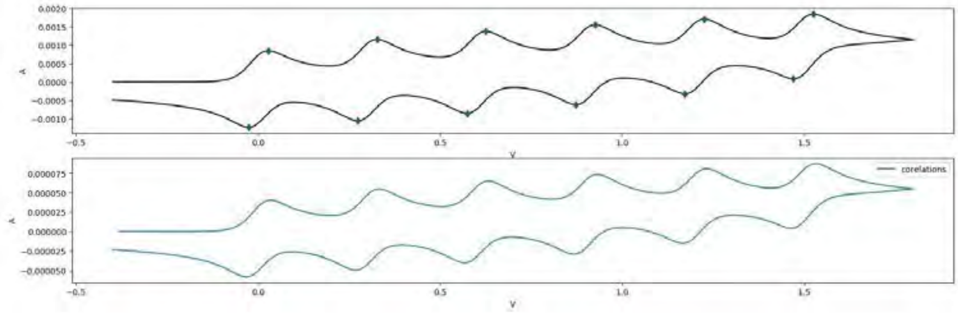
Cyclic voltammetry has been a powerful and versatile tool for every modern electrochemist. It is straightforward to use and can easily grant information on the many properties of the system it is used on.

Interpretation of the cyclic voltammetry data is traditionally done via sweep rate dependence of parameters such as anodic and cathodic peak currents and the separations of the said peaks. A standalone automated system that can do electrochemical analysis requires autonomous detection of electrochemical signals. The idea of autonomous electrochemistry was first introduced by John Arthur Eklund in his thesis supervised by Larry Faulkner. At the time, the experiment used was chronocoulometry and not much progress was made afterwards.

To date, algorithms for finding electrochemical peaks and their respective baselines have used various methods that require many parameters from the operator and/or locate critical points in the data externally. These methods either require human input in real time, or during design time in the form of thresholds. This is mostly due to the potential large noise in the data that may blur the peak locations or baseline locations.

To remedy those problems we have developed a versatile software using Python Programming Language, "AutoCV", which locates the positions of peaks and their respective baselines on the data using little to none operator input while accounting for the noise and artifacts in the data. In order to account for noise and artifacts we have developed a method in which we use the correlation function between an "ideal peak" generated from the work of Nicholson & Shain and noisy data which yields finely clarified peaks and diminished noise and artifacts. Then using these information "AutoCV" can determine many things including; reduction and oxidation peak positions (even if there is more than 1 of each), whether the system is stable or not, whether there are any coupled chemical reactions or not or kinetics of the electrode. Also, in a given set of data it can detect if there is a peak separation and whether it is due to kinetic reasons or not. If the cyclic voltammetry data is inadequate satisfy wanted confidence for the inquisition of the property, software will suggest another experiment to further analyse the property in question. This software is easily modifiable, and its parameters can be adjusted to obtain wanted properties of the system with desired confidence. Also, it can easily be updated to analyse data from many different techniques and do analysis on all the data at the same time.





Tailoring the permeability of chitosan-based coatings deposited on zinc substrates with different methods

Árpád Ferenc Szőke[1], Gabriella Stefánia Szabó[1], Zoltán Hórvölgyi[2], Emőke Albert[2], Attila Gergely Végh[3], László Zimányi[3], Claudine Filiatre[4], Liana Maria Muresan[1]

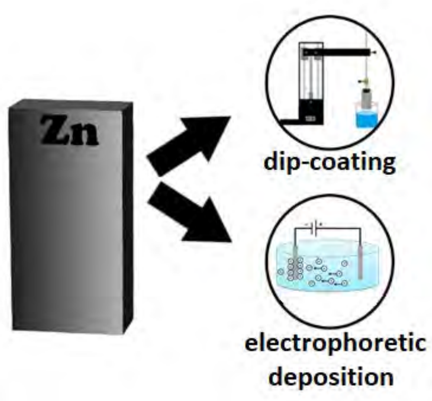
szokearpad@chem.ubbcluj.ro

Chitosan is a highly versatile biopolymer, with applications in various domains, including medicine, agriculture and the packaging industry [1]. Recently, the use of chitosan as an anticorrosive barrier was also studied [2, 3].

Depending on the substrate nature, chitosan can be applied to a surface as a protective coating by multiple techniques. Conventional methods, such as dip-coating have a high success rate due to the simplicity and reproducibility of the coatings [4]. In the case of metal substrates, however, electrophoretic deposition can also yield good results [5].



Our study aims to tailor the permeability of chitosan coatings through different deposition techniques and impregnation/accumulation of additives which could act as corrosion inhibitors. As such, different types of chitosan-based coatings were deposited on zinc substrates and studied mainly through electrochemical methods (electrochemical impedance spectroscopy and potentiodynamic polarization).

The obtained results highlight that in the case of dip-coating, thin, native chitosan layers do not offer any significant protection (in some cases, even a slight reduction of impedance was noted). These highly permeable thin layers can be crosslinked, or used as accumulation matrices, resulting in high corrosion inhibition efficiencies of >90%, suggesting reduced permeability. On the contrary, thick chitosan layers produced from highly viscous solutions can provide some reduced amount of protection (*ca.* 30%), but, due to the thickness of the polymer barrier, in these cases, an effective modification through crosslinking proved to be impossible.

Electrophoretic deposition was an ineffective method in the case of zinc substrates, possibly due to the presence of $ZnO/Zn(OH)_2$ on the metal surface, hindering the production of a uniform layer (proven through microscopy). Electrochemical measurements show a decent inhibition efficiency in these cases, however, due to the non-uniform coverage, leading to increased probability of pitting corrosion, this method was deemed inappropriate for zinc substrates.

Density Functional Theory Analysis of Structural and Electronic Properties of NASICON-structured $Na_xTi_2(PO_4)_3$ (x = 1 – 4)

Linas Vilčiauskas[a] and Denis Gryaznov[a]

[a]*Center for Physical Sciences and Technology (FTMC)*
Saulėtekio al. 3, LT-10257 Vilnius, Lithuania
Linas.Vilciauskas@ftmc.lt

Sodium-ion batteries represent an alternative to current generation of lithium ion batteries due to higher sustainability and potentially lower cost. However, there is still a lack of suitable electrode materials especially on the negative electrode side. Na SuperIonic CONductor (NASICON) type systems demonstrates are among the leading candidates for Na-ion battery applications [1,2]. In the present study, first principles calculations within the linear combination of atomic orbitals and Gaussian basis set formalism were employed in order to study the structural an electronic structure peculiarities in $Na_xTi_2(PO_4)_3$ compounds with different degrees of sodiation (x = 1-4). Hybrid exchange-correlation functionals (HSE06 and B1WC) were used to investigate the band gap changes for different x [3]. We identified the Ti oxidation states and correctly predicted the mixed oxidation state (mixed valence) for x = 2 and 4. Moreover, the mixed oxidation states showed smaller band gaps by ~0.6 eV for x = 2 and 4 vs. 4.1 and 2.2 eV for x = 1 and 3, respectively (Fig. 1). We discuss the nature of this effect based on the analysis of electronic density of states. We demonstrate important role of the electroneutrality condition to find the ground state for each x. Finally, a correlation was found between the bulk electronic properties of $Na_xTi_2(PO_4)_3$ compounds and the symmetry changes due to the variation of sodium content and accompanying charge ordering. The calculations of phonon frequencies at the Γ-point revealed no presence of imaginary frequencies for the ground state structures. These structural peculiarities for $Na_xTi_2(PO_4)_3$ compounds are suggested to have an important effect on their performance in battery applications such as the electrochemical kinetics and polaronic charge transport.

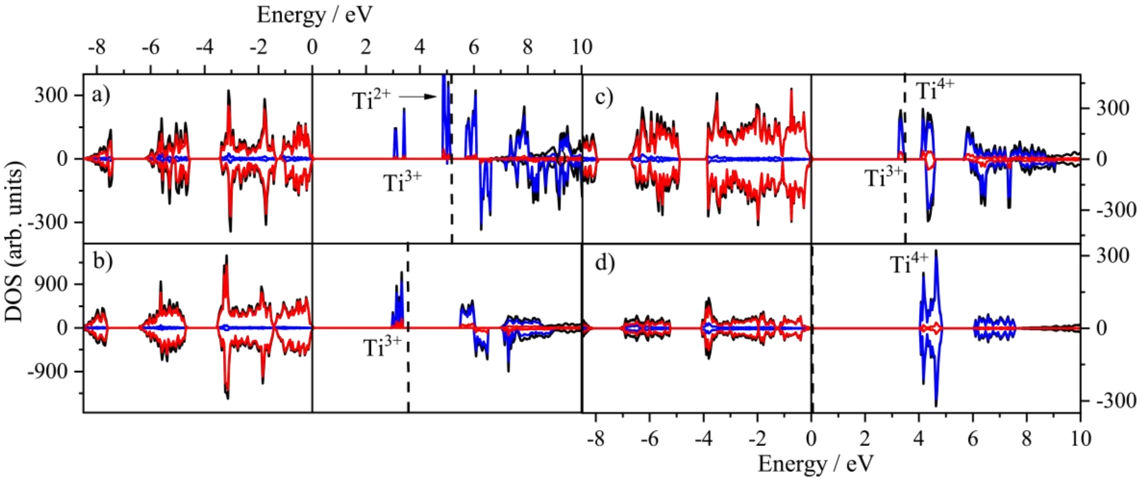

Fig. 1. Electronic Density of States (DOS) for NaxTi2(PO4)3 where (a) x = 4, (b) x = 3, (c) x = 2, (d) x = 1. The Fermi energies are marked by dashed lines.

Layered manganese-based oxides as cathode materials for sodium ion batteries

Kai Zhang[1], Jun Chen[1], Yong-Mook Kang[2]
[1] Affiliation1 Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Nankai University, Tianjin, P. R. China, 300071;
[2] Department of Materials Science & Engineering, Korea University, Anam-ro 145, Seongbuk-Gu, Seoul, Republic of Korea, 02841
e-mail address: zhangkai_nk@nankai.edu.cn

Benefiting from natural abundance and wide distribution of sodium sources, sodium ion batteries (SIBs) demonstrate promising application prospects in hybrid electric vehicles and large-scale energy storage.[1] The capacity of cathode materials is, however, mainly provided by the redox reactions of metal ions, which is difficult to be further improved.[2] Significantly, incorporating a certain amount of lithium ions into the transition metal layer of layered manganese-based oxides can stimulate anionic redox reactions, thus realizing higher capacity.[3] Although layered manganese-based oxides are promising to break through the capacity bottleneck of cathode materials, their capacity and output voltage tend to drastically decay. Therefore, it is imperative to put forward new strategies to stabilize the anionic redox reactions.

In this work, we introduced inactive zinc ions into the sodium layer to synthesize the zinc-doped Na$_{5/6}$[Li$_{1/4}$Mn$_{3/4}$]O$_2$ (NLMO-Zn). A new phase was generated when the undoped sample (NLMO) were charged to the high voltage zone through in situ XRD to observe the phase evolution of zinc-doped and undoped samples during charging and discharging. Interestingly, the NLMO-Zn always maintained single-phase reaction (Fig. a and b), indicating that the Zn-doping could effectively inhibit the phase transformation at high voltage. The charge compensation mechanism analysis of the two samples based on photoelectron spectroscopy (XPS) and X-ray absorption near-edge spectroscopy (XANES) characterization illustrates that NLMO-Zn displayed higher Mn^{4+} content after cycling compared with NLMO (Fig. c). Moreover, the first principles theoretical calculation revealed that the zinc-doped samples had more stable intermediates and lower phase transition probability under different sodium content states (i.e. different charge and discharge states). This doping strategy effectively inhibits the Jahn-Teller effect of Mn^{3+} and avoids phase transition, thus stabilizing the anion redox reaction and greatly improving the electrochemical properties. This study offers considerable application potential toward the development of high-energy SIBs.

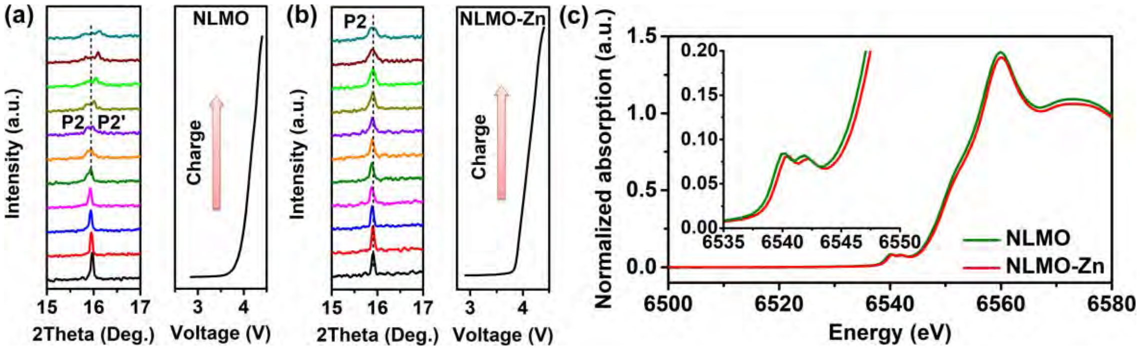

Figure. In situ XRD patterns of NLMO (a) and NLMO-Zn (b) during the 1st charge and the XANES spectra at the Mn-K edge for NLMO and NLMO-Zn at the fully charged states (c).

Construction of inorganic-organic hybrid nanostructures with elaborate design is a promising strategy for advanced oxygen evolution reaction (OER) electrocatalysts with earth-abundant elements. Herein, we have successfully synthesized ultrafine Fe_3O_4 nanoparticles homogeneously immobilized on two-dimensional Ni based metal organic frameworks (MOFs) (Fe_3O_4/Ni-BDC). The functionalized Fe_3O_4 nanoparticles (diameter: 6 ± 2 nm) with abundant surface hydroxide groups are initially fabricated by hydrothermal method, and then anchored on two-dimensional (2D) Ni-BDC layers (thickness: 5 ± 1 nm) with strong non-covalent interactions through a sonication process. The obtained Fe_3O_4/Ni-BDC composites inherit the superior surface structure and physicochemical features of 2D Ni-BDC layers. Meanwhile, the introduction of Fe_3O_4 simultaneously modifies the integral electronic structure and prevents the aggregation of 2D Ni-BDC for enhanced OER performance. In contrast, a mechanically mixed control group shows unmodified electronic structure and unsatisfying activities. We have investigated electronic structure and morphology changes for different amounts of Fe_3O_4 immobilized on the Ni-BDC layers, by a wide range of techniques including XRD, FT-IR, XPS, SEM, AFM and TEM. The optimized Fe_3O_4/Ni-BDC-4 composite demonstrates significantly enhanced OER performance with an overpotential of 295 mV at 10 mA cm^{-2}, a Tafel slope of 47.8 mV dec^{-1} and a superior operational stability for more than 40 h. Furthermore, the reaction mechanism and the valance state of metals species related to OER performance are carefully studied.

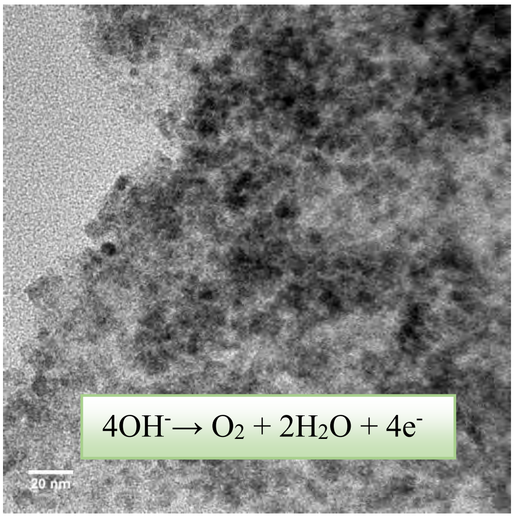

Figure 1. TEM image of the Fe_3O_4/Ni-BDC-4 composite; Inset is the overall reaction for OER.

Paenibacillus dendritiformis within alginate polymer covered graphitized paper with artificial or self-developed redox network

Eleonora Hubenova[1], Mario Mitov[2], Yolina Hubenova[3,4]

Recently, we developed redox-active Ca-alginate polymer for fast immobilization of the Gram-negative bacteria *Pseudomonas putida* [1]. In the present study, we entrapped a Gram-positive strain *Paenibacillus dendritiformis* MA 72, which was proved to form electrochemically active biofilms. Before inoculation and polymerization of the gel, a mixture of 1 mM thiazolyl blue (MTT) formazan/phenazine methosulfate (PMS) was added to form an artificial redox network. The presence of the redox couple was observed on the DPV as a well-defined peak at a potential of -0.05 V (vs. SHE) with a distinguishable Faradaic current in the presence of bacteria, while the abiotic control showed a twice higher capacitive current (Fig.1a). In the absence of redox dyes, no peaks have been observed in the beginning. The polymer covered bioelectrodes (±dyes as additives) have been continuously poised at −0.195 V, and their electrochemical behavior was investigated. The current density in the presence of the redox couple was 6 times higher during the first 70 h, but after ca. 170 h the current of both bioelectrodes became equal (Fig.1b). The registered peak on the DPV suggests that the bacteria have developed a self-produced redox matrix within the alginate which is sensitive to different applied potentials (Fig.1c), indicating that diverse bacterial surface or mobile molecules contact with the electrode and participate in the bacterial response.

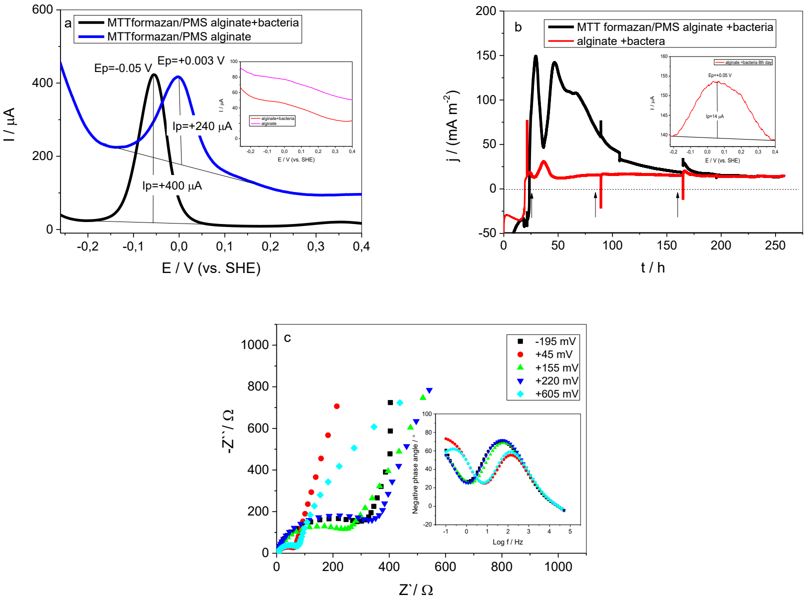

Fig. 1. a) DPV in the beginning; b) Current density generated at −0.195 V applied potential. Inset - DPV of the alginate polymer sample on the 8th day; c) EIS- Nyquist plot of the alginate polymer sample on the 8th day, 50 kHz-15mHz, ac signal 10 mV, different Edc. Inset – the corresponding Bode plot.

The existence of solid-electrolyte interphase (SEI) on the surface of lithium metal is a prominent feature that distinguishes it from other metals, which also inevitably exacerbates the complexity of Li electrodeposition compared to traditional metal electrodeposition at solid/liquid interfaces. Li metal as anode is actually composed of Li (or current collector)/SEI/electrolyte interfaces. Accordingly, Li metal electrodeposition starts always from the desolvation of Li ions at the SEI/electrolyte interface, which is then followed by transportation of Li ions through the SEI to the metal/SEI interface for discharge. Therefore, the SEI and its coupling interfaces in bridging the substrate and electrolyte play key roles, and their structures and properties could directly affect the electrodeposition behaviors of Li metal.

Herein, by adopting the strategy of controlled construction of SEI and metal/SEI/electrolyte interfaces, the investigation by electrochemical impedance spectroscopy (EIS) was carried out to systematically study the processes on Li metal electrodes, especially focusing on the solvation/desolvation processes of Li ions at the SEI/electrolyte interface. First, various kinds of smooth and uniform SEIs with adjustable structure and thickness were fabricated on Li metal and Cu substrates using electrochemical polishing-based method recently proposed by the authors' group[1,2], the well-defined SEI/electrolyte interfaces facilitating accurate EIS analysis. Then, potential-dependent EIS were performed to study the solvation/desolvation kinetics in the electrolyte of LiTFSI/DME-DOL. Meanwhile, the influence of $LiNO_3$ additive was also investigated. Results show that the thickness of SEI and its chemical composition in the outer layer, determining the structures and properties of the SEI/electrolyte interface, significantly affect the solvation/desolvation of Li ions. Our work are beneficial to the understanding of the metal/SEI/electrolyte interfaces and their roles in the solvation/desolvation of Li ions.

Direct methanol fuel cell (DMFC) is one of the most commercialized technology in direct liquid fuel cells due to various advantages of rapid refueling and high energy density, which are crucial characteristics for portable applications. DMFC consists of methanol oxidation reaction at anode and oxygen reduction reaction (ORR) at cathode on PtRu-based and Pt-based catalyst, respectively. Most challenging problem toward DMFC is methanol crossover. Methanol at the anode permeates the cathode and reacts with cathode catalyst, resulting in voltage drop. Pt/C is an excellent catalyst, but it actively reacts with methanol at the cathode. Thus, it is crucial to design a methanol-tolerant Pt-based catalyst to increase the ORR selectivity at the cathode.

In this study, we synthesized Pt/C with heteroatom-doped carbon layer. Heteroatom-doped Pt/C showed both lower activity in the methanol oxidation reaction and higher activity in ORR than pristine Pt/C. The origin of selectivity will be investigated with electrochemical tests such as CO stripping voltammetry and XPS in aspects of oxophilicity and Pt electronic structure. Finally, we will apply heteroatom-doped Pt/C on the cathode and confirm selectivity compared with pristine Pt/C. This approach suggests the way to design a Pt catalyst for ORR to improve performance in DMFC.

CO_2 Electroreduction at $Pt_{0.8}Ru_{0.2}/C$ in a Polymer Electrolyte Membrane Electrolyzer Cell

Shofu Matsuda, Yuuki Niitsuma, Yuta Yoshida, Minoru Umeda
Nagaoka University of Technology, Kamitomioka, Nagaoka, Niigata, 940-2188, Japan
**mumeda@vos.nagaokaut.ac.jp*

Recently, CO_2 reduction is one of the most interesting topics in the field of electrochemistry. There are many reports on the CO_2 electroreduction at transition metal electrodes such as a Cu electrocatalyst.[1] In our previous study, we have proposed an approach that uses a polymer-electrolyte based single cell containing a Pt/C electrocatalyst, which enabled to reduce CO_2 without overpotential. Remarkably, we have demonstrated that CO_2 is reduced to CH_4 with a high efficiency and high selectivity by diluting the CO_2 concentration to be fed.[2,3] Also, we have revealed that the efficiency of CH_4 generation was $Pt/C < Pt_{0.5}Ru_{0.5}/C < Pt_{0.8}Ru_{0.2}/C$ when 100 vol.% CO_2 was supplied.[4] Hence, it is expected that more efficient CH_4 production from CO_2 reduction will be realized by combining the techniques of diluting the CO_2 concentration and using a $Pt_{0.8}Ru_{0.2}/C$ electrocatalyst. In this study, we investigated the stationary-potential CO_2 reduction on a $Pt_{0.8}Ru_{0.2}/C$ under a reduced CO_2 concentration.

We prepared a polymer electrolyte cell equipped with a Nafion®-based membrane electrode assembly containing the 42.5 wt% $Pt_{0.8}Ru_{0.2}/C$ and 45.7 wt% Pt/C as the working and counter electrodes (WE and CE), respectively. Fully humidified H_2 and Ar/CO_2 (CO_2 concentration: 7 vol.%) were supplied to the CE and WE, respectively. Cell temperature was 40°C. The experimental setup in this study is drawn in Fig. 1. The WE potential was stepped from 0.4 V to 0.2 V. After 300-s holding, the potential was stepped to 0.05 V. During the procedures, in-line mass spectrometry (MS) was conducted to analyze the products in real time. All the potentials are shown with the reference to reversible hydrogen electrode (RHE).

Fig. 2 shows MS signals of *m*/*z* 2 (for H_2) and 15 (for CH_4) with applied potential program. The signal of *m*/*z* 15 is observed and almost constant under the potential holding at 0.2 V. On the other hand, the signal of *m*/*z* 2 is observed only after stepping the potential to 0.05 V. Significantly, the faradaic efficiency between 240 s and 299 s for $Pt_{0.8}Ru_{0.2}/C$ was calculated to be 18.2%, which exceeds the efficiency for Pt/C (12.3% at 0.16 V).[3] Overall, this work revealed that the continuous CH_4 production from CO_2 reduction with a high efficiency without overpotential or H_2 evolution was achieved using the $Pt_{0.8}Ru_{0.2}/C$ electrocatalyst under a reduced CO_2 concentration.

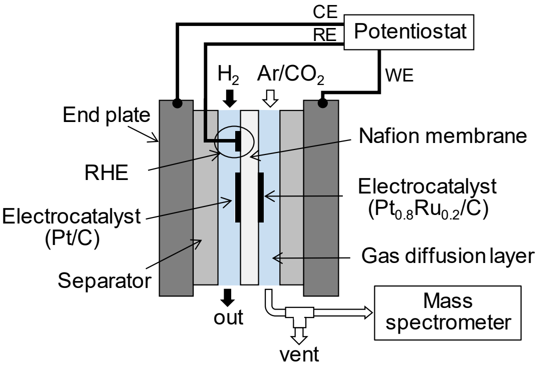

Fig. 1. Schematic diagram of the experimental setup in this study.

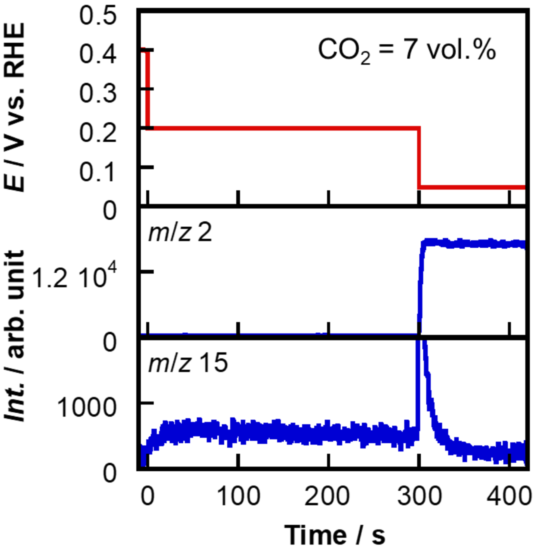

Fig. 2. Potential program applied to the working electrode and MS signals (*m*/*z* 2 and 15) measured simultaneously at $Pt_{0.8}Ru_{0.2}/C$ by feeding 7 vol.% CO_2 at 40°C.

A Diffusion−Reaction Competition Mechanism to Tailor Lithium Deposition for Lithium Metal Batteries

Xiao-Ru Chen, Yu-Xing Yao, Chong Yan, Rui Zhang, Xin-Bing Cheng, Qiang Zhang*
Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology,
Department of Chemical Engineering, Tsinghua University, Beijing 100084 (P. R. China)
E-mail: cxr18@mails.tsinghua.edu.cn

These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated. Li metal is recognized as one of the most promising anode materials owing to its ultrahigh theoretical specific capacity and low electrochemical potential. Nonetheless, Li metal anode has been severely hindered from practical applications by dendritic Li growth. The uncontrollable Li dendrites can result in low Coulombic efficiency (CE) and short cycle life of a working battery. More seriously, the Li dendrites penetrate the separators and reach the cathode to cause internal short-circuits, which even leads to thermal runaway and explosions. However, the continuous conversion between Li metal and Li ions implies the inevitable existence of Li deposition during the plating step. Accordingly, the key to suppress the Li dendrite growth is to tailor Li deposition.

Compared to available deposition morphologies of Li metal anode, spherical Li deposition endows two important merits from its unique morphology. Firstly, spherical Li deposition features well-defined morphology with smooth surface without any sharp tip, thus avoiding serious safety hazards caused by dendritic Li deposition. Secondly, Li sphere exhibits minimum surface area per unit volume among all the other morphologies, which signifies higher CE and longer cycle life because of forming few solid electrolyte interphase (SEI) by the reaction between fresh Li and electrolyte. Many researches have focused on regulating Li deposition into spherical shapes. However, the underlying mechanism of forming Li spherical deposits has not been clarified yet. If the fundamental rationale behind different morphologies of Li deposition can be unveiled, it is conceivable that safe Li metal batteries can be further achieved based on tailoring Li deposition morphology.

In this work, we report a diffusion−reaction competition mechanism which can determine the ion concentration beneath the SEI and therefore tailor the morphology of Li deposition. When maintaining the same electrode reaction rate, through modifying the kinetics of Li diffusion from slow to fast, the ratio of sphere/all deposition (including spherical and dendritic Li) (denoted as S/D) continuously rises due to the progressively higher Li ion concentration beneath SEI. Changing the electrode reaction rate is found to alter the Li plating morphology, since higher reaction rate can induce ion depletion within SEI. This work provides a deep, fundamental understanding of Li deposition morphology that guides the design of future strategies to enable dendrite-free Li deposition.

Graphene Quantum Dots/Gold Nanostructure Chiral Composite for Enantiomeric Sensing

Ruzniza Mohd Zawawi, Nurul Hidayah Mustaffar Kamal, Zakira Imana Abu Mansor
Universiti Putra Malaysia
Department of Chemistry, Faculty of Science, Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia
ruzniza@upm.edu.my

The investigation of chiral compounds has a fundamental significance for understanding the intrinsic properties of the biomolecular building blocks and chemical processes occurring in living organisms. Because of this, the enantioselective detection of chiral species is crucial in drug discoveries, pharmaceuticals and biochemical processes. It is well established that the contrary enantiomers of chiral compounds often differ significantly in their pharmacological, toxicological and pharmacokinetic properties. Previous researches have demonstrated that electrochemical enantioselective sensors have been attracted significant attention owing to various advantages over spectrophotometric and chromatographic techniques. By introducing chirality by organic moieties into solid inorganic materials creates local chiral environments for enantiosensing. Therefore, it is our main objective to investigate the interaction between L-/D-proline with gold nanorods (AuNRs)/graphene quantum dots (GQDs) in order to explain their effect in detecting the racemic mixture. The exceptionally high specific surface area, high conductivity, fast electron transfer kinetics and good biocompatibility of AuNRs and GQDs have attracted attentions from various fields, including biological ones. Due to the simple one-step pyrolysis of citric acid and L-/D-proline to obtain chiral proline-functionalized GQDs and electrostatic self-assembly interaction between negatively charged GQDs and positively charged AuNRs, it is worth exploring the potential of this nanohybrid material as sensing material during fast sweep voltammetry. The characterization of this nanohybrid material was carried out by electrochemical, morphological and spectroscopic techniques. The electroanalysis of chiral compounds by the nanohybrid-modified electrode was studied thoroughly by electrochemical method and its molecular chiral recognition mechanism was modeled by molecular docking method. Successful investigations have produced a new nanohybrid material that suitable as a chiral sensor in nanodevices. The outcome from this research has led to important implications for biosensing, asymmetric syntheses and separation, and significant understanding on the nature of chiral interactions in biological systems.

Earth-Abundant Coal-Derived Carbon Nanotube/Carbon Composites as Efficient Bifunctional Oxygen Electrocatalysts for Rechargeable Zinc-Air Batteries

The exploration of active and robust electrocatalysts for both the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) is the bottleneck to realize the commercialization of rechargeable metal-air batteries and regenerative fuel cells. Here we report facile synthesis of three-dimensional (3D) carbon nanotube (CNT)/carbon composites using earth-abundant coal as the carbon and heteroatom dopant source to grow CNTs. The prepared composite featuring 3D structural merits and multiple active sites can efficiently catalyze both ORR and OER, affording high activity, fast kinetics, and long-term stability. With the additional incorporation of manganese, the developed catalyst afforded an overvoltage of 0.80 V between ORR at the half wave potential and OER at the current density of 10 mA cm^{-2}. The optimized sample has presented an excellent OER performance within a constructed solar-energy water splitting device with continuously generating oxygen bubbles at anode. Notably, it can be further used as a durable air-electrode catalyst in constructed Zn-air battery, delivering an initial discharge/charge voltage gap of 0.73 V, a remained voltaic efficiency of 61.2% after 160 cycles and capability to power LED lamps for at least 80 hours. This study provides an efficient approach for converting traditional energy resource i.e. coal to value-added alternative oxygen electrocatalysts in rechargeable metal-air batteries.

Use of electrochemical method for reduction of carbon dioxide (CO_2) convert into valuable organic compounds, is a great solution to solve the problem of CO_2 accumulation. The most advantage of electrochemical conversion is to elect reaction to produce a few organic compounds from carbon dioxide depending to types of catalyst. Among many types of catalyst, metal catalysts based on Copper element or alloy metals offers the route to synthesize multi-carbon fuels and chemicals from CO_2 (*e.g.*, ethylene, ethanol and n-propanol).

In this study, Copper Phosphide was determined by one of the candidate to solve the problem and it was synthesized by oleate method and used as a catalyst in a near Zero-gap CO_2 gas-phase electrolytic cell for CO_2 reduction reaction at ambient temperature and pressure. By using a hydrophobic gas diffusion layer (GDL), exhibited the formation of three-phase boundary during the CO_2 reduction reaction. The mechanism of the reactions, verified by the onset point of CO and other oxygen-bounded intermediates adsorption with ATR-SEIRAS, *in-situ* surface analysis, which is the intermediate of most products by CO_2 reduction reaction. Headspace GC-MS, UV-Vis, NMR equipment was used to verify gas/liquid product analysis. Their results show that multi-carbon fuels, such as C_4 products, acetaldehyde are produced.

e-mail address : jihyeon1@gist.ac.kr (J. Park), jaeyoung@gist.ac.kr (J. Lee)

Hydrazine fuel cell is one of the promising liquid fuel cells due to its high theoretical voltage, high energy density, and no emission of green gas. However, hydrazine can decompose chemically or electrochemically as a function of the type of catalyst used. Despite being a precious metal, platinum is an ambiguous catalyst because of faradaic reaction catalyst of hydrazine as well non-faradaic reaction. Therefore, in terms of the fuel efficiency, platinum is not suitable for hydrazine oxidation catalyst. Nickel, which is in the same family as platinum, is non-precious metal, and due to its similar structure to platinum, it performs greatly against hydrazine oxidation. In these aspects, hydrazine fuel cells are even more important, not requiring the expensive noble metal. Here, we synthesized Ni nanoparticles via polyol method by changing the type of Ni precursor, since chemical, physical, and electro-chemical properties of a metal nanoparticle depend on its morphology and size. When using nickel nitrate, the size of the Ni nanoparticles is the smallest, amorphous morphology, whereas when using nickel chloride, the size is slightly larger, but the particles spread well on carbon support. Then, in order to confirm hydrazine electro-oxidation reaction, catalyst ink was loaded on the rotating disk electrode (RDE), and cyclic voltammetry (CV) and linear sweep voltammetry (LSV) were carried out.

Precise Anionic Regulation of NiFe Hydroxysulfide Assisted by Electrochemical Reactions for Efficient Electrocatalysis

zhang-qiang@mails.tsinghua.edu.cn

Highly efficient electrocatalysts with high intrinsic activity for oxygen and sulfur redox reactions are strongly required for sustainable energy systems. Generally, cations serve as the real active sites in transition metal compound electrocatalysts, whose electrocatalytic activity is regulated by the surrounding anionic structure. Herein, an electrochemical reaction assisted by an anionic regulation strategy is proposed for precise construction of advanced electrocatalysts with extraordinary electrocatalytic activity. The electrochemical anionic regulation process ensures general release of the regulation reagents for precise substitution of sulfur anions in pristine hydroxide. The as-obtained hydroxysulfide electrocatalyst exhibits a desired electronic structure to afford superb electrocatalytic activity regarding reduced overpotential of 286 mV at 10 mA cm^{-2} for electrocatalytic oxygen evolution and improved polysulfide redox electrocatalytic activity. This contribution not only renders an emerging strategy for precise regulation of the anionic structure for improved electrocatalytic activity, but also provides information for the rational design of advanced electrocatalysts for sustainable energy applications.

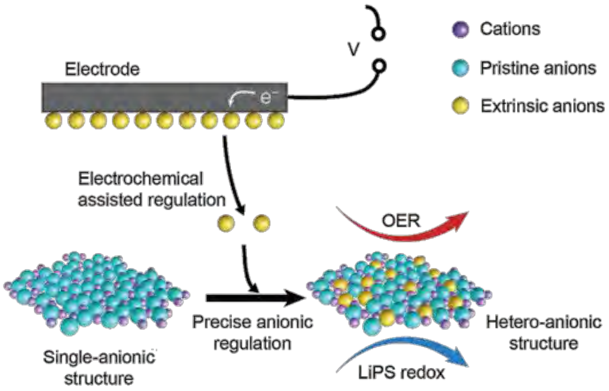

Fig. 1 Schematic of the precise anionic regulation assisted by electrochemical reaction for enhanced electrocatalytic activity.

Multiscale Construction of Bifunctional Electrocatalysts for Long-Lifespan Rechargeable Zinc–Air Batteries

Chang-Xin Zhao, Jia-Ning Liu, Bo-Quan Li, Ding Ren, Xiao Chen, Jia Yu, and Qiang Zhang*
Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology,
Department of Chemical Engineering, Tsinghua University, Beijing 100084, China.
zhang-qiang@mails.tsinghua.edu.cn

Zinc–air batteries deliver great potential as emerging energy storage systems but suffer from sluggish kinetics of the cathode oxygen redox reactions that render unsatisfactory cycling lifespan. The exploration on bifunctional electrocatalysts for oxygen reduction and evolution constitutes the key solution, where rational design strategies to integrate various active sites into a high-performance air cathode remain insufficient. Herein, a multiscale construction strategy is proposed to rationally direct the fabrication of bifunctional oxygen electrocatalysts for long-lifespan rechargeable zinc–air batteries. NiFe layered double hydroxides and cobalt coordinated framework porphyrin are selected as the active sites considering their high intrinsic activity at the molecular level, and the active sites are successively integrated on three dimensional conductive scaffolds at mesoscale to strengthen ion transportation. Consequently, the multiscale constructed electrocatalyst exhibits excellent bifunctional performance ($\Delta E = 0.68$ V), which is even better than the noble metal based benchmarks. The corresponding air cathodes endow zinc–air batteries with a reduced voltage gap of 0.74 V, a high power density of 185.0 mW cm^{-2}, and an ultralong lifespan of more than 2400 cycles at 5.0 mA cm^{-2}. This work demonstrates a feasible strategy to rationally integrate various active sites to construct multifunctional electrocatalysts for energy-related processes.

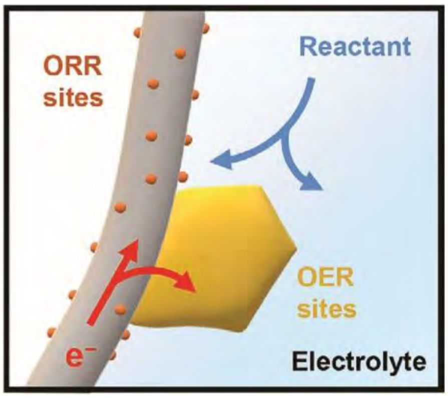

Fig. 1 Schematic illustration of the multiscale construction strategy.

Enzymes can produce highly complex molecules with high efficiency because of their ability to perform cascade reactions via substrate channelling. Using substrate channelling, two different active sites can be connected via a tunnel that allows the diffusion of intermediates to the next active site without diffusion to the bulk solution. Mimicking the architectural features of enzymes in electrocatalytic nanoparticles, called nanozymes, is an approach we have previously applied to single step reactions[1,2] and now seek to apply to cascade reactions.

Electrochemical CO_2 reduction is a suitable model reaction for cascade reactions, given it can be divided into two steps with CO as the key intermediate.[3] In this work, we designed an electrocatalytic nanoparticle, called a cascade nanozyme, comprising a Ag core, where CO_2 can be reduced to CO, and a porous Cu shell, where CO is further reduced to more complex organic molecules.[4] Cascade nanozymes were synthesised and characterised for electrochemical CO_2 reduction using GC and ^{1}H-NMR. We were able to demonstrate a cascade reaction with C_3H_8O formed at -0.6 V vs. RHE on the cascade nanozymes, where experimental controls containing exclusively Cu showed no activity for C_3 products.[4]

Operando TEM, applied for the first time to CO_2 reduction, was used to visualise the electrocatalytic nanoparticles in electrochemical CO_2 reduction conditions. Control experiments were conducted in a variety of conditions to help elucidate the processes. It was found that applied potential and (local) CO concentration had the greatest impact upon structural evolution. This understanding was used to design and synthesise PdCu cascade nanozymes, with a lower rate of CO production and increased stability.

This work demonstrates the capacity of catalytic nanoparticle architecture to confine intermediates from one active site to another in cascade reactions. In electrochemical CO_2 reduction, such substrate channelling can create high local concentrations of important intermediates like CO. We have found that such high local concentrations can enhance the selectivity for longer chain hydrocarbons and influence structural stability, illustrating the trade-off between activity, selectivity and stability that must be considered.

Ni-Fe Hydroxide/Oxide Nanostructures generated on Stainless Steels for Efficient Alkaline Water Electrolysis

Naoto Todoroki and Toshimasa Wadayama
Graduate School of Environmental Studies, Tohoku University,
Sendai 980-8579, JAPAN
naoto.todoroki.b1@tohoku.ac.jp

Developing highly active and durable electrocatalysts for oxygen evolution reaction (OER) have been needed for efficient hydrogen generation by electrochemical water splitting. Various transition metal-based oxides, hydroxides, etc. have been extensively explored as OER catalysts for alkaline water electrolysis (AWE) [1]. Recently, Stainless steels (SS) have much attractive attentions as low-cost, highly active and stable electrode materials at high current density [2]. However, relation between nano-level structures of the surface oxide layers on the SS substrate and OER properties should be clarified. In this study, we investigated changes in OER properties and nanostructures of the surface oxide layers generated on the 316SS electrode during the electrolysis.

316SS (ø = 5mm, t = 4mm) substrate was used as a working electrode after the surface polishing by Emery papers and alumina paste. Polarization curves for the OER with a disk rotation rate of 1600 rpm were measured in N_2-purged 1 M KOH solution at 75 °C at 5 mV/sec. Cyclic voltammograms were collected at 50 mV/sec without disk rotation. After that, constant current density electrolysis (CCE) was conducted at 30 mA/cm^2 for 10 h at 1600 rpm. Nanostructures and compositions of the surface (hydro)oxide layers generated after the electrolysis were investigated by scanning transmission electron microscopy (STEM) with electron dispersive spectroscopy (EDS).

Fig.1 (a) shows changes in the OER overpotentials estimated by the polarization curves at 10 and 100 mA/cm^2 as a function of the CCE times. The overpotentials decreased with increasing the CCE times. In addition, as shown in (b), the cyclic voltammograms indicate the Ni-oxidation peaks of the CCE-5h sample shift to lower potential compared with the pristine substrate (CCE-0h), suggesting the surface electrochemical property of the SS changed during the electrolysis. STEM images of the CCE-5h sample with different magnifications are presented in (c). The surface (hydro)oxide films are composed of 20 nm-thick dense buffer layer (substrate side) and 60 nm-thick nanofiber-like layers. The selected area electron diffraction (SAED) patterns suggests that crystal structures of each (hydro)oxide layers are rock-salt NiO and $Ni(OH)_2$, respectively. Furthermore, corresponding STEM-EDS mappings reveals that Fe and Ni are only metal elements and Cr is almost absent in both the oxide layers. Therefore, increase in OER activity during the CCE probably stems from generation of the specific Ni-Fe hydroxide nanostructures that acting as highly-OER-active sites [3]. The results in this study clearly show that electrochemical synthesis of such the hetero-structured hydroxide/oxide layers on the SS substrate is an effective approach for developments of the practical anode for AWE [4].

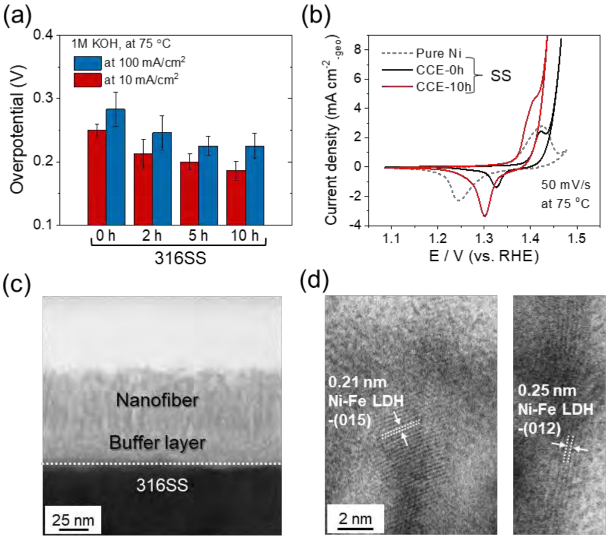

Fig.1 (a) OER overpotentials of 316SS as a function of CCE times. (b) Cyclic voltammograms of CCE-0h, and -10h samples. STEM images (c) and (d) of the CCE-5h sample [4].

Selective CO_2 Electroreduction to Ethylene and Multicarbon Alcohols via Electrolyte-Driven Nanostructuring and Plasma Activation

Dunfeng Gao[1,2], Beatriz Roldan Cuenya[1]
[1]Department of Interface Science, Fritz Haber Institute of the Max Planck Society, 14195 Berlin, Germany; [2]Present address: State Key laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, 116023 Dalian, China
e-mail address: dfgao@dicp.ac.cn

The electrochemical production of fuels and chemicals from CO_2 and water using electricity derived from renewable energy holds promise as a sustainable process that might help to mitigate some of our current energy and climate challenges [1,2]. The CO_2 electroreduction reaction (CO_2RR) is a complicated catalytic process due to the broad range of products that can be obtained at high overpotential. Multicarbon oxygenate and hydrocarbon products (C_{2+}) with high energy density are highly desirable, but severely limited by the slow kinetics of multiple proton and electron transfer steps during C-C coupling. Cu is the only metal able to produce hydrocarbons and alcohols in considerable amounts. However, polycrystalline Cu usually suffers from the need to employ high overpotentials and its low C_{2+} product selectivity. The formation of C_{2+} products during CO_2RR is very sensitive to the catalyst structure [3,4]. It is desirable, therefore, to develop nanostructured electrocatalysts through rational design that could be capable of efficient generation of multicarbon products from CO_2RR.

Surface reconstructions are commonly observed in heterogeneous catalysis, with the most active catalysts dynamically adjusting to the electrolyte, applied potential and other reaction conditions [5-9]. In this work, an efficient electrochemical strategy has been developed, namely, electrolyte-driven nanostructuring, for the synthesis of high surface area nanostructured Cu catalysts for the selective generation of C_{2+} products from CO_2RR [10]. Chlorine-modifications lead to the growth of Cu nanocubes on the polycrystalline Cu surface, while iodine-modifications produce needle-like Cu structures. Interestingly, the newly-created rough Cu catalysts show a suppressed methane formation but improved CO_2RR selectivity towards ethylene and multicarbon alcohols as compared to the flatter pristine Cu foils. The iodine-modified Cu catalyst displays the highest Faradaic Efficiency of ~80% for C_{2+} products at -0.9 V vs RHE. Operando high energy resolution fluorescence-detected X-ray absorption near edge structure (HERFD-XANES) spectra show that some Cu(I) species can still survive in the form of Cu-halide and/or Cu_2O at the negative potentials relevant to CO_2RR. It provides direct evidence of the positive correlation between the presence of Cu(I) species during CO_2RR and improved C_{2+} production. We further study the relative role of Cu oxidation state versus morphology/facet in the case of Cu nanocubes (chlorine-modified Cu) using a low temperature plasma technique [11]. The Cu oxidation state and morphology can be tuned by O_2-, H_2- and Ar-plasma pretreatments. Of them, O_2-plasma treatment destroys the Cu(100) facets of Cu nanocubes but stabilizes Cu^+ species as revealed by quasi in situ XPS developed by our group. Our results demonstrate that the presence of oxygen species in surface and subsurface regions of the Cu nanocube catalysts is key for achieving high activity and hydrocarbon/alcohol selectivity, even more important than the presence of Cu(100) facets.

Electrified solid/liquid interfaces are the key to many physico-chemical processes in a myriad of areas including electrochemistry and colloid science. Despite tremendous efforts devoted to this topic, it is surprising that molecular level understanding of electric double layers is still lacking. In particular, it is perplexing why compact Helmholtz layers often show bell-shaped differential capacitances on metal electrodes, as this would suggest a negative capacitance in some layer of interface water. I will present our latest ab initio molecular dynamics simulations of electrified Pt(111)/water interfaces, aiming at unraveling the structure and capacitive behavior of interface water. Our calculation reproduces the bell-shaped differential Helmholtz capacitance, and for the first time shows that the interface water follows the Frumkin adsorption isotherm when varying the electrode potential, leading to a peculiar negative capacitive response. Our work provides valuable insight into the structure and capacitance of interface water, which can help understand important processes in electrocatalysis and energy storage in supercapacitors.

Hybrid Co_3O_4@CoS nanoparticles in a N/S-doped carbon matrix as An Efficient Bifunctional Electrocatalyst for Oxygen Reduction and Evolution Reactions in Zn-Air Battery

The development of high-performance non-precious bifunctional electrocatalysts for both the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER) is urgently needed to realize the commercialization of rechargeable metal-air battery. Herein, we report a ZIF-67 derived hybrid Co-based carbon composite bifunctional ORR/OER electrocatalyst exhibiting excellent performance and stability in a custom-built Zn-air battery. The catalyst was formed by pyrolytic carbonization of ZIF-67 followed by mild oxidation and sulfurization to a hybrid composite comprised of multiple active sites including Co-N_4, Co-N/S-C, C-N/S-C, Co_3O_4 and CoS, as well as the surface and edge defects in the carbon matrix, that act concertedly yielding a highly efficient bifunctional ORR/OER catalyst for reversible oxygen electrodes. The catalyst affords remarkably low reversible overpotentials and stability not only in a 3-electrode system, but also in a custom-constructed Zn-air battery, exhibiting competitive performance against benchmark bifunctional ORR/OER electrocatalysts reported to-date and thus placing it among the best non-precious metal catalysts for reversible oxygen reactions.

Vanadium redox flow batteries (VRFB) are a rapidly emerging technology for grid scale energy storage and the integration of the renewable energy generation. However, the cost of the electrolyte is a major barrier for implementation of VRFBs [1, 2]. The quality of the electrolyte has a significant impact on the cell performance and cost [1-4]. Thus, understanding the impact of the impurities present in electrolyte on the performance of VRFBs is vital for commercialization of VRFBs [5]. This paper aims to conduct a systematic study on the effect of iron, aluminum and manganese ions (Mn^{2+}, Fe^{2+} and Al^{3+}) on the performance of VRFBs.

A three-electrode system was utilized to conduct cyclic voltammetry (CV) experiments. The battery performance was evaluated in a flow cell using a 'zero-gap' cell design with an electrode area of 5 cm^2. The electrolyte solution (1 M $VOSO_4$ in 3 M H_2SO_4) was circulated through the cell.

The CV results indicate that the rate of side reactions increase with the concentrations of the metal impurities. Comparison of the effect of three transition metal ions (Mn^{2+}, Fe^{2+} and Al^{3+}) showed that the highest VO^{2+} / VO_2^+ peak separation was obtained in the presence of Fe^{2+}. The VO^{2+} / VO_2^+ peak separations for $Mn^{2+}$and Al^{3+} were almost the same. The battery performance over 50 cycles with 0.1 M of each metal was compared at a range of current densities. The highest energy efficiency was observed with the pure electrolyte. Based on the cyclic voltammetry results, the kinetics of the vanadium reaction falls, and the peak separation increased with increasing concentration of the contaminant metal ions Al^{3+}, Mn^{2+}, and Fe^{2+}. The energy efficiencies have the same trend and illustrates that the contaminant metal ions are competitive with vanadium ions for adsorption on the electrode surface and thus affect the vanadium redox reaction kinetics [6]. The side reactions caused by the metal ions can also have a negative influence on the performance of VRFBs.

Ammonia is one of the important chemicals for the global economy, and generally used for the production of fertilizers, refrigerants and other chemical feedstock. Recently, ammonia is also being considered as an energy carrier due to its' high density of hydrogen and carbon-free nature.[1] Haber-Bosch process which is the main route for ammonia synthesis, requires huge energy consumption, high purity of hydrogen and harsh reaction conditions. To overcome such limitations, electrochemical method for ammonia synthesis at ambient conditions has been received much attention.[2] In this study, a molybdenum decorated rhodium electrode (Rh_{Mo}/C) is fabricated using an electrodeposition technique. The Rh_{Mo}/C produces a higher yield of ammonia and shows a higher faradaic efficiency comparing with a commercial Rh/C electrode in alkaline media. The electrochemical ammonia synthesis tests have been also conducted in various reaction conditions such as electrolytes and operating potentials. This study reveals the relationship between the reaction condition and the selectivity of ammonia synthesis.

While alkali metal anodes are considered as the promising alternatives to the ion-hosting materials due to the high energy densities, the nonuniform deposition (dendritic growth) that can lead to internal shorts remains a major obstacle of their practical applications (1,2). Here, according to the *operando* observation in our special capillary cells, we report a shiny-smooth nonporous sodium metal anode that can be cycled reversibly even at high areal capacities, without the formation of any whiskers, mosses, gas bubbles or disconnected metal particles observed in existing studies (3,4). The plating process follows the lateral surface-growing mechanism, which transforms into tip-growing branch-like dendrites at a critical time when applying over-limiting currents (5). The observation reveals the possibility that the solid electrolyte interphases (SEIs) are absent, which is supported by the elemental depth profile analysis. As a result, a reversable high capacity sodium metal anode is achieved in coin cells within a critical penetration-related current density (6 mA cm^{-2}). Our study demonstrates the possibility of plating shiny-smooth reactive alkali metal in liquid electrolytes and provides a reliable option applicable for the next-generation alkali metal batteries.

Bioelectrochemical systems (BESs) are an efficient and flexible platform for energy recovery and wastewater treatment. However, the slow kinetics of the oxygen reduction is one of the main factors that leads to the use of expensive catalysts, such as platinum, limiting the overall performance output of BESs [1,2]. Platinum group metal-free catalysts supported on nanostructured carbon allowed to achieve oxygen reduction reaction (ORR) rate comparable to commercial Pt based catalysts [2]. ORR active sites efficiency and activity are strongly affected by catalyst structure, morphology and carbon scaffold doping chemistry: nitrogen-doped carbon-based materials exhibit a great ORR catalytic activity [3]. We have previously demonstrated that nitrogen-doped nanostructured carbon is an optimal substrate to support FeN4 macroclycles, due to its high surface area, adjustable electronical and mechanical morphology, and tuneable surface [4]. In this study, iron (II) phthalocyanine (FePc) was anchored on carbon black pearls. To introduce nitrogen functionalities in the carbon structure different strategies have been developed, including pre-treatments based on urea as N source and thermal treatments. The catalysts, labelled as FeN4-C, were characterized by combining the use of electrochemical and spectroscopic techniques to correlate the different morphologies and surface chemistry to electrocatalytic activity towards ORR. Figure 1 shows linear sweep voltammetries of a FeN4-C catalyst in neutral environment, together with a schematic of ORR at a surface of a FeN4-C catalyst.

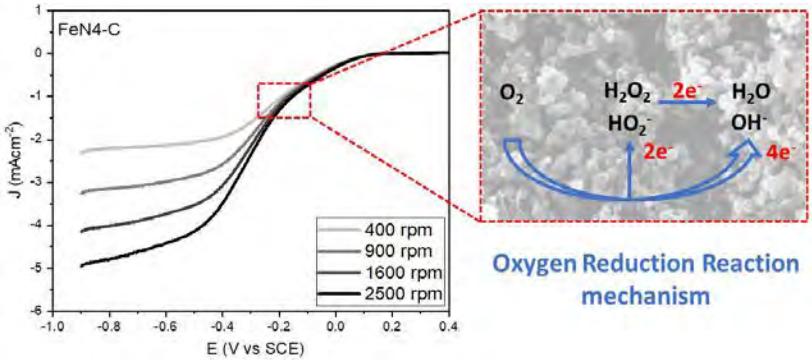

Figure 1. Hydrodinamic linear sweep voltammetries at different electrode rotation rate of FeN4-C catalyst in O_2-saturated 0.1 M phosphate buffer.

As shown in Figure 1, FeN4-N-C onset potential and half wave potential ($E_{1/2}$) were 0.13V and -0.3V vs SCE, respectively, indicating good activity towards ORR. In addition, the application of both Koutecky-Levic theory and rotating ring disk electrode experiments pointed at a charge transfer mechanism close to 4 electrons thus indicating good ORR activity in neutral media. By comparing FeN4-N-C to Pt/C taken as control, the overall performance indicated that FeN4-based electrocatalysts are good candidates to replace platinum for energy conversion in bioelectrochemical systems.

Inorganic binary compounds such as Cu-Se and Zn-Se are precursors for the formation of $CuInSe_2$ (CIS), $Cu(InGa)(S,Se)_2$ (CIGS) and $Cu_2ZnSn(S,Se)_4$ (CZTS(Se)), semi-conductor materials selected for the next generation of photovoltaic devices, owing to their near-ideal photo-electrochemical properties. A proper understanding and a good control of the selenium and its binary compounds electrodeposition is thus required to improve the quality of the semi-conductor materials. Deep Eutectic Solvents are nowadays emerging as promising and cheap alternative media for the electrodeposition of metals or compounds that cannot be easily prepared in aqueous or conventional organic solvents.

In the present work, the electrodeposition of copper selenides thin films has been investigated in the choline chloride-urea (ChCl-U) deep eutectic solvent at a gold electrode using cyclic voltammetry. The strategy is focused on previews results [1, 2] in which the electrodeposition of selenium was conducted at various temperatures. At 110 °C, grey (trigonal) selenium was deposited at a potential of -0.4 V (vs. Ag QRE) using SeO_2 as the precursor. At potentials around -0.7 V (vs. Ag QRE), the electrodeposited Se (0) is reduced to Se (-II) and stripped from the surface. This cathodic stripping forms the basis of our strategy to form a copper selenide compound by electrodeposition.

In the presence of dissolved SeO_2/Cu_2O mixtures as precursors at 110°C, the reduction of Se(0) to Se(-II) proceeds at less negative potentials, being coupled with the formation of copper selenide in one step by a proper choice of the deposition potential. The voltammetric responses obtained by varying the deposition potential showed that the electrodeposition of Cu_2Se can be carried out at -0.4 V.

XPS and XRD characterisations point to the formation of Cu_2Se. Photoelectrochemical measurements have been conducted to characterize the semiconductor behavior and the photochemical stability of the electrodeposited material.

The performance of conventional solvent-based and newly developed waterborne coating systems was assessed via the electrochemical impedance spectroscopy (EIS) on the surface and Scanning Vibrating Electrode Technique (SVET) at the cut-edge and then benchmarked with natural exposure results [1-2]. It was observed that the developed environmental-friendly coating system has a slightly poorer performance via EIS compared with the conventional coating system in the coil-coating industry. The undercutting corrosion in the waterborne coating was also slightly more noticeable in comparison with the conventional solvent-based system at the cut-edge. The most important outcome of the study, however, was the ability to predict the long-term performance of these coatings by matching the trends obtained via EIS and SVET to the natural exposure results. Correspondingly, the results from the same coating systems after two years of exposure suggest that the conventional system tends to be more corrosion resistant compared to the environmental-friendly coating system. The reasons for different performances have also been discussed based on the inhibition efficiency of corrosion inhibitors doped within the organic coating, and also the effect of substrate chemical composition on corrosion performance of the system.

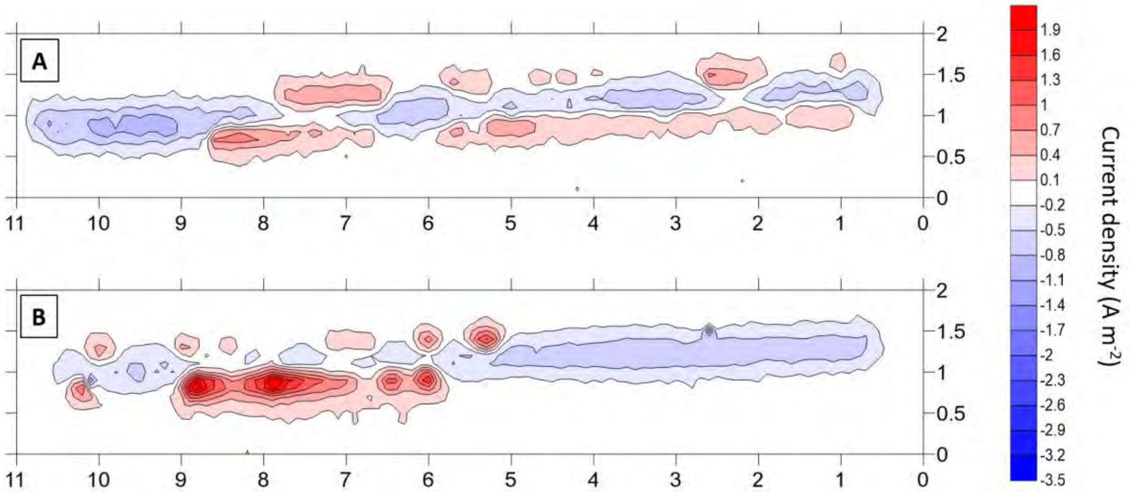

Figure 1 – SVET current density maps: (A) conventional solvent-based coating, and (B) environmental-friendly waterborne coating systems after 12 hours in 5 wt.% NaCl solution

In recent years, the installed power of renewable energy sources plants has considerably grown increasing [1]. One of the main drawbacks of renewable sources is their unpredictability, consequently they need a storage system that can efficiently manage the produced energy. In this scenario, the electrochemical production of hydrogen could play an important role in the future. However, the electrochemical hydrogen production cost is still too high in respect to other technologies. For this reason, research is focused on improving the electrolyzers performance, through the use of more efficient and less expensive materials, such as transition metal alloys [2].

In water alkaline electrolyzer field, the development of Nickel-based nanostructured electrode is one of the possible ways to improve the water electrolysis efficiency [3]. In particular, through the use of a simple manufacturing method, template electrosynthesis, it is possible to realize high density surface area electrodes. In previous works, Ni nanowires electrodes for water-alkaline electrolysis covered by nanoparticles of IrO_2 as an anode and Pd as a cathode have shown good and stable performance also at room temperature [4-5].

In this work, using the template electrosynthesis for nanostructures fabrication, the attention has been focused on the electrodeposition of Ni-based alloys. Several different alloy electrodes were manufactured starting from different aqueous solution containing various transition metal, such as zinc, cobalt and tungsten. Tuning the elements concentrations in the solutions and the electrodeposition operating conditions, alloys with different compositions have been obtained. Morphological and chemical nanostructured electrodes features will be presented and discussed. Moreover, electrochemical and electrocatalytic test carried out to evaluate the best alloy composition will be shown. Then, long term test conducted at a constant current density in aqueous solution of potassium hydroxide (30% w/w) at room temperature will be also reported.

The vertical alignment of pores in hexagonal mesoporous silica films can be achieved through the electrochemically assisted self-assembly method (EASA).[1,2] An appropriate negative potential is applied to a solution containing the surfactant and inorganic precursors solubilized in an ethanol/water mix. This results in the generation of hydroxide ions in solution, whereby, the pH swings from acidic to alkaline at the electrode surface. The electric field plays a pivotal role in the self-organization of the cationic surfactant into hemi-micelles and the pH change catalyses the polycondensation of the silica sol.[3,4] Our interest in well-ordered vertically aligned EASA films is the possibility of utilizing them as feasible templates for the electrodeposition of few nm-diameter metal and semiconductor nanowires. Previous works reveal that it is possible to electrodeposit nanowires into porous silica templates[5,6]. However, the stability of very small nanowires is poor in pore diameters below 2 nm.[7] Here we demonstrate that systematic increases in the pore diameter ($>$ 2 nm) are achievable by EASA, utilising larger surfactants formed by extending the single straight alkyl chain. Additionally, replacing the methyl substituent of an ammonium polar head group is another route to pore diameter expansion.

The demand for greener sources of energy resulted in a higher production of biodiesel, and consequently glycerol, since it is a co-product of the biodiesel synthesis that has surpassed the industrial demand. Due to this issue, many research groups have been investigating alternatives to use this excess[1]. In this context, the electro-oxidation of glycerol (EOG) is an interesting option towards the chemical valorization of this compound, generating value-added products and high purity H_2 in electrolysers[2].

The EOG has been studied in Pt in both acidic and alkaline media[3-5], however, at least to our knowledge, there is any study about the effect of the temperature in the activity and selectivity of the reaction. Thus, herein we study the EOG on Pt polycrystalline (Pt_p) and Pt single crystals electrodes of the main crystallographic orientations: Pt(111), Pt(100) and Pt(110) at 5 °C and 35 °C. *In situ* FTIR and electrolysis coupled to HPLC will be performed to understand the electrochemical results in terms of products and/or intermediates that are formed during the EOG.

Figure 1 shows results obtained in alkaline media. Interestingly, this preliminary results suggests that the temperature acts increasing the rate of all the parallel processes occurring at each electrode, generating changes in the current densities, but not changing the I-V response shape. For Pt(110), the increase in the current density was approximately fourfold, threefold for Pt(100) and twofold for Pt(111), i.e., as more open the surface is, higher the temperature activation. It is well-known that as more open the surface is, more prone to poisoning it becomes, then we suggest that the increase of the temperature help to detach strongly adsorbed adsorbates, contributing more to the enhancement of the currents of the more poisoned electrodes.

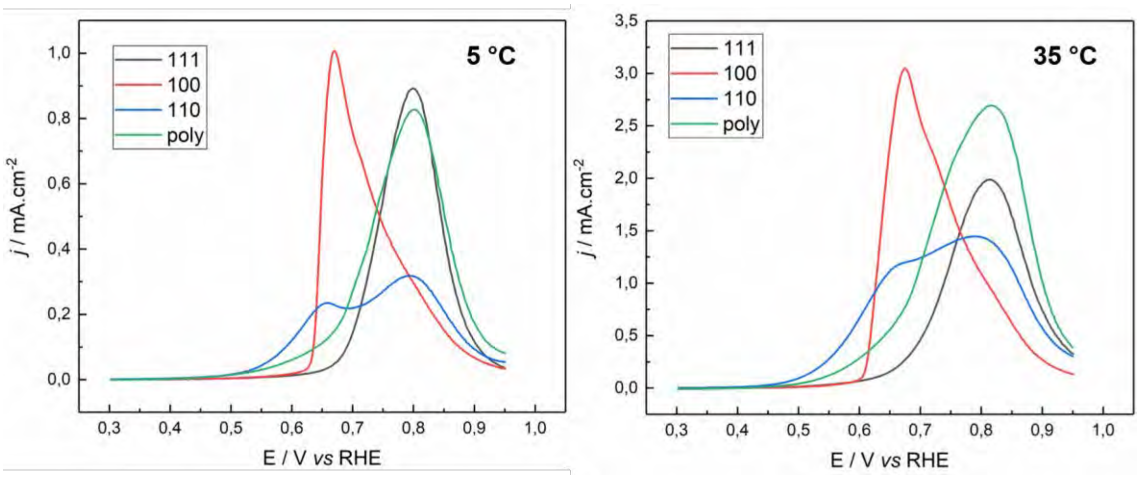

Figure 1 – 10th positive scan of the EOG in 0.1 M NaOH + 0.1 M GlOH for all the electrodes at 10 mV/s.

Electrochemically Addressable Nanofluidic Devices based on the Integration of Electroactive Polymers into Solid-State Nanochannels

Solid-state nanochannels have attracted the interest of the scientific community due to its controlled mass transport properties. Particularly, the ionic transport through these nanometer-sized channels is strongly dependent on the geometry and surface charge of the channel walls. The modulation of the surface charge density allows modifying the permselectivity and consequently the conductance of solid-state nanochannels which has huge implications in fields such as electronic, biosensing, and filtration.[1] Considering this fact, there has been an increasing interest in the development of nanofluidic devices with the capability of controlling the surface charge density, and therefore the ionic transport, by experimentally controllable stimuli, such as temperature, pH, electrical potential, light, or the presence of an analyte in solution.[2] However, most of these conditions are difficult to control in confined spaces. In this context, the electrochemical stimuli-based strategy is especially promising since it enables to regulate the ionic currents by an external and easy to control experimental input. In this sense, the integration of electroactive polymers into solid-state nanochannels offers a suitable option to accomplish this aim. Thus, the use of redox-active bistable molecules that can be switched between different oxidation states by addressing an external electrical potential would allow an easy modulation of the surface charge on the nanochannel walls and, consequently, to govern the nanofluidic readout with a fast and highly efficient response.

Within this framework, we present our recent results concerning the integration of electroactive polymers into solid-state nanochannels for developing electrochemically-addressable nanofluidic devices.[3–6] We show how the combination of electroactive polymers and solid-state nanochannels can lead to a myriad of new designs of switchable nanofluidic devices with potential applications in different fields such as biosensing, drug delivery, or filtration.

The term “Nanoarchitectonics” involves the integration of molecular building blocks into well-defined organized assemblies via a variety of approaches, where the intimate connection between the materials gives origin to improved functionalities or even creates new ones. Among the vast spectrum of available strategies, Layer-by-Layer (LbL) and electropolymerization are two of the most employed approaches for creating functional materials for electrochemical applications. While LbL allows for an accurate manipulation of film architecture and the incorporation of numerous building blocks; electropolymerization offers a precise control of film thickness, morphology, and composition, thus allowing the inclusion of desired moieties for further surface functionalization.

On the other hand, Oxygen Reduction Reaction (ORR) is an essential electrochemical process in many energy conversion devices, taking particular relevance in facing the increasing global demand for clean energy sources and vectors. Desirable features for ORR-based catalysts are operability under environmentally friendly conditions, biocompatible electrolytes, and the reduction of metal loadings. [1]

Having in mind the above discussion, we hereby present examples of the integration of Conducting Polymers (CPs) and Metal Organic Frameworks (MOFs) through different approaches in order to construct assemblies featuring improved ORR performance. In this way, the O_2 adsorption ability and high porosity of the Zn-based MOF ZIF-8, and the electroactivity of polyaniline-like CPs are effectively brought together by making use of LbL assembly and electropolymerization techniques.

In the first example, the LbL strategy is employed in order to perform the sequential assembly of colloidal suspensions of the polyaniline/polystyrene sulfonate complex (Pani-PSS) and polyallylamine hydrochloride-coated ZIF-8 nanocrystals (PAH-ZIF-8). The LbL-assembled films are found to be electrically connected and feature promising increases in the ORR current in neutral pH aqueous environments.[2]

On the other hand, we introduce the use of electropolymerization as synthetic strategy for producing electroactive films featuring $-NH_2$ moieties. Then, a MOF coating is integrated by induced growth on the amino pending moieties from the methanolic precursor solutions. This strategy generated a composite film with improved ORR performance due to the effective combination of the electroactivity of the CP and the MOF capacity of acting as an oxygen reservoir.[3] Moreover, this approach also allows the incorporation of metallic nanoparticles (NPs) in order to improve the overall electrocatalytic performance of the nanocomposites. In this way, the in-situ reduction of the Pt NPs precursor on the CP not only keeps the electroactivity of the conducting matrix but also improves its electrocatalytic efficiency. Subsequent deposition of the MOF coating further increases the ORR performance, by adding the O_2 preconcentrating effect. [1]

Finally, nanoarchitectonics can be seen as a toolkit from which different strategies can be taken in order to construct complex interfacial architectures with improved ORR features arising from the combination of the different building blocks.

Selective Recognition by Nanoparticle-Imprinted Matrices

Sweety Ann Samuel, Gunther Wittstock
Carl von Ossietzky University of Oldenburg
Department of Chemistry, 26129 Oldenburg/DE
sweety.ann.samuel@uni-oldenburg.de

Nanoparticles (NPs), being the suitable candidates for various commercial and domestic applications due to their unique physical and chemical properties are now widely used in medical, automotive and ecological arenas. A major drawback is their uncontrolled release to the ecosystem paired by inadequate detection techniques selective to size, shape and chemical nature of core material as well as shell. Those parameters decisively determine the toxicity of NPs. This calls for facile tools to detect NPs based on the above factors. We work towards the development of simple, inexpensive and miniature sensing layers capable to selectively enrich NPs on surfaces. The work follows the idea of nanoparticle-imprinted matrices (NAIM), with some analogy to the well-known molecularly imprinted polymers (MIP). Electrochemistry is used to deposit a thin film, which is homogeneous, highly stable and thick enough to provide size-selective recognition of nanoparticles [1].

Electroreduction of 4-((triisopropylsilyl)ethynyl) benzene diazonium salt followed by the electroreduction of 4-nitrobenzene diazonium salt yields a matrix, which is 7-9 nm thick on an indium tin oxide (ITO) coated glass substrate. The initial layer is formed from a diazonium salt with a bulky substituent to induce steric hindrance, thereby preventing inhomogeneous, highly rough film formation [2]. The films are characterized by scanning force microscopy, photoelectron spectroscopy and infrared reflection absorption spectroscopy. Such a film entraps the template NPs on the substrate and forms a matrix. Later, the template NPs are removed by chemical etching which forms a cavity complementary to the template NPs used, forming a NAIM. This NAIM is then exposed to analyte NPs, expected to selectively recognize them based on their shape, size and shell.

Statins are a group of drugs that are responsible for lowering cholesterol levels by inhibiting the reductase 3-hydroxy-3-methyl-glutaryl-enzyme A (HMG-CoA). They are widely used to prevent cardiovascular diseases [1,2] and can be divided according to their origin into natural and synthetic ones [3]. These drugs interact not only with proteins but also have an effect on the organization and surface properties of lipid membranes.

Preparation of model biological membranes at the air-water interface by means of Langmuir technique allowed us to assess the influence of selected statins on the lipid packing in the membranes and the fluidity of the layers. The lipid systems used consisted of phosphocholines (DOPC), sphingomyelin and cholesterol which are the main components of lipid rafts. The effect of the three selected statins (pravastatin, fluvastatin and cerivastatin) on muliticomponent monolayers was first investigated. The effect of statins strongly depends on the properties of the drug itself, since molecular differences between statins' structures may lead to the changes in functions that affect cellular processes [1]. It has been shown that pravastatin changes the surface properties of the layers only slightly. More lipophilic fluvastatin penetrated the model membranes much easier while cerivastatin had a fluidizing effect, but only slightly changed the packing of the polar headgroups in the lipid monolayer. The second stage of the research involves the transfer of layers from the air-water interface to a solid substrate by the Langmuir- Blodgett/Langmuir-Shaefer method. The effect of selected statins on multicomponent layers forming lipid rafts (DOPC:SM:Chol), was studied using electrochemical impedance spectroscopy. Biological membranes by their structure act as capacitors, hence impedance experiments allowed us to assess changes in their capacity and barrier properties following exposure to statins.

Our experiments showed the specific nature of the interaction of cerivastatin with model membranes and its negative effects upon the membrane organization which may explain why this drug was withdrawn from the market. Based on the performed measurements it is possible to understand better why these drugs, so effective in decreasing levels of cholesterol, can also lead to unwanted disorders of the nervous system and myopathy, threatening the proper functioning of our body.

Electrochemistry for Climate Change:

CO_2 Capture by An Electrochemically Mediated Amine Regeneration Process

Mohammad (Mim) Rahimi, T. Alan Hatton*

Department of Chemical Engineering, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge MA 02139, USA
** Corresponding author: tahatton@mit.edu*

Abstract

Global warming resulting from the emission of greenhouse gases, especially carbon dioxide (CO_2), has become a major concern in recent years. The global concentration of CO_2 in the atmosphere is increasing rapidly; in May 2019, atmospheric CO_2 reached 415 ppm, which is the highest level in more than 800,000 years. This prompted research activity to develop various approaches that could effectively mitigate emissions by capturing CO_2, especially from large-point sources such as post-combustion flue gas. It is believed that electrochemistry, a key part of the 2019 Nobel Prize in Chemistry, is a powerful, emergent tool for the design of different approaches to directly or indirectly assist in achieving the goals in the action plan by effectively mitigating CO_2 emissions. Electrochemistry will offer a unique advantage in the future, when the electrical energy is mostly generated by renewables. The carbon footprint and the cost of the electrochemical processes would be minimized, making them an attractive solution for addressing climate change. In this context, different approaches based on electrochemical processes have been proposed to drive CO_2 capture and release. We recently demonstrated an electrochemically-mediated amine regeneration (EMAR) process as a low-energy, efficient, and potentially scalable method of capturing CO_2 from flue gas. The EMAR process scheme is similar to that of the amine-based thermal approach, but the high-temperature scrubbing stage is replaced with a two-compartment electrochemical cell that operates at a moderate temperature. During the EMAR process, a CO_2-rich amine stream from the absorber is introduced to the anode compartment of an electrochemical cell, in which copper ions are electrochemically generated from a copper plate anode (i.e., $Cu^0 \rightarrow Cu^{2+} + 2e^-$) to drive the dissociation of amine-CO_2 toward CO_2 desorption (i.e., Cu^{2+} + n amine-$CO_2 \rightarrow$ Cu(amine)$_n^{2+}$ + n CO_2). Once the gas is flashed off through a flash tank located after the anode compartment, the CO_2-lean stream is regenerated via the electrochemical plating of copper on the cathode from the copper-amine complex (i.e., Cu(amine)$_n^{2+} + 2e^- \rightarrow Cu^0$ + n amine). Therefore, CO_2 capture and release can be achieved by chemical absorption followed by electrochemical regeneration of the absorbent through the EMAR process.

To determine the best combination of metals and amines for the EMAR process, a systematic analysis of several transition metals together with monoamines, diamines, and polyamines was performed. A combination of copper as the metal and a mixture of ethylenediamine (EDA) and aminoethylethanolamine (AEEA) as the amine absorbent was found to be the most effective chemistry for the EMAR cycle, mainly due to the high stability constant of the copper complexation with the amines, a suitable reduction potential of the complex, high CO_2 capacity, good reversibility, high electrochemical performance, and low cost. Based on this chemistry, we scaled up the EMAR process to a level at which continuous CO_2 capture and desorption from flue gas was achieved over longer than 100 hours. We also showed that electrical energy can be efficiently translated to CO_2 desorption, with an electron utilization (i.e., moles of CO_2 desorbed per mole of electrons transferred) of ~0.8 over more than 50 cycles. To date, the EMAR system is the most advanced and scaled-up system in terms of gas desorption rate and efficiency among all the electrochemical processes developed for CO_2 capture from flue gas streams.

Gas Diffusion Electrode Setups:
A New Testing Platform For Electrocatalyst Evaluation

Accurate testing platform and efficient electrochemical characterization method play a key role in development of electrocatalysts in fuel cells and CO_2 electrolyzers. Currently, two approaches are well-established: rotating disk electrode (RDE) or H-type half-cell setups with liquid electrolyte as well as single-cell tests with membrane electrode assemblies (MEAs) [1]. The former has the disadvantage of mass transport limitations, which significantly limits the “accessible reaction rate” that can be analyzed, and the latter requires specialized equipment and large quantities of catalyst, making them less ideal for early-stage development [2]. Recently we introduced a gas diffusion electrode (GDE) setup to overcome these limitations [3]. This setup allows the investigation of the electrocatalysts under realistic conditions so it can be considerd as a link to bridge fundamental and applied investigations. In the presented work, we discuss the application of GDEs for investigating the stability of high surface area fuel cell catalysts under realistic reaction conditions in acidic [4] and alkaline media. In addition, we show the identical location transmission electron microscopy (IL-TEM) images which were taken before and after the accelerated degradation test (ADT). Moreover, we implemented the characterization of the catalysts by small-angle X-ray scattering (SAXS), which establishes the particle size distribution in the catalyst layer. In contrast to IL-TEM, SAXS is an integral method which probes changes in the entire catalyst layer before and after performing the ADT [5]. Furthermore, we demonstrate how the carbon dioxide reduction reaction (CO_2RR) can be studied with simple minor changes to the setup [6].

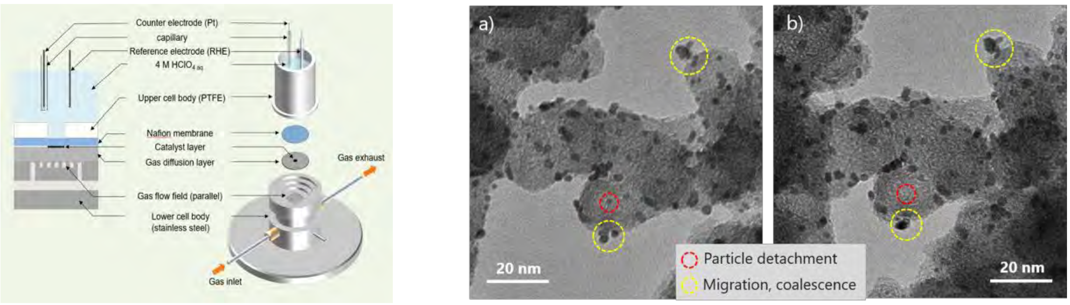

Fig.1 The sketch of the GDE cell (left) and IL-TEM micrographs of a commercial 20 wt. % Pt/C catalyst (HiSPEC 3000) before and after load-cycle ADT treatment for 1200 cycles at 60 °C (right).

Acid mine drainage treatment by means of bioelectrochemical technology

Luis Fernando Leon-Fernandez, José Villaseñor, Francisco Jesús Fernández
Dept. of Chemical Engineering. Faculty of Chemical Sciences and Technologies. Ciudad Real. Spain
Avda. Camilo José Cela S/N, 13071, Ciudad Real, Spain
LFernando.Leon@uclm.es

Acid mine drainage (AMD) is an environmental problem mainly associated with the mining activity. AMDs are characterized by high concentrations of a wide variety of metals, high concentration of sulphates and low pH.

This work has studied the sequential cathodic removal of four metals (Cu^{2+} 500ppm, Fe^{3+} 500ppm, Ni^{2+} 50ppm and Sn^{2+} 50ppm) from a simulated AMD by using a bioelectrochemical system, first working as a microbial fuel cell (MFC) and then as microbial electrolysis cell (MEC).

Operating as MFC, Fe^{3+} was reduced to Fe^{2+} and Cu was deposited onto the cathode. All the Cu was recovered after 4 days and generating about 0.12 mA/cm2. When operating as MEC the Fe^{2+}, Ni^{2+} and Sn^{2+} were simultaneously removed by fixing the cathode potential at -0.7 V vs Ag/AgCl, getting a current density of 1.75 mA/cm2. This stage recovered all the Sn, 60% of the Fe and 75% of the Ni in 3 days.

Financial support from projects EQC2018-004240-P, SBPLY/19/180501/000254 "Rehabilitación de entornos abandonados de minería metálica y recuperación de recursos mediante tecnologías bio-electroquímicas" and from the FPI grant to L.F. León through the reference BES-2017-081718 from the Spanish Ministry of Economy, Industry and Competitiveness are gratefully acknowledged..

Enhancement of the cathodic dechlorination of 2,4-DCP in bioelectrochemical systems

Luis Fernando Leon-Fernandez, Ignacio Ramos, José Villaseñor, Francisco Jesús Fernández
Dept. of Chemical Engineering. Faculty of Chemical Sciences and Technologies. Ciudad Real. Spain
Avda. Camilo José Cela S/N, 13071, Ciudad Real, Spain
LFernando.Leon@uclm.es

The use of organochlorinated pesticides and herbicides to enhance the production of crops may produce soil and groundwater pollution. 2,4-dichlorophenol (2,4-DCP) is one of these compounds, mainly used as precursor of 2,4-dichlorophenoxyacetic acid (2,4-D), a commercial herbicide. In this work, a novel treatment of 2,4-DCP by using bioelectrochemical systems (BESs) was studied.

This work studies the influence of the cathode pH and energy input on the electroreductive hydrodechlorination of 2,4-dichlorophenol (24DCP) in an abiotic cathode. When operating as BES as Microbial Fuel Cell (MFC), the results showed that more acid cathode pH enhances the electrocatalytic hydrodechlorination (ECH), reaching a total dechlorination after 72 h. Also, ECH was further enhanced by operating under Microbial Electrolysis Cell (MEC) mode, where the cathode was poised towards more negative potentials and higher current densities were achieved. The dechlorination was directly linked to the toxicity reduction and biodegradability increment, allowing to a subsequent biological treatment of the effluent generated which reduces the treatment cost of this kind of recalcitrant pollutants

Abstract

P53 gene plays a vital role in regulating cellular processes and its accurate quantification is of great significance to the early screening of cancers.[1, 2] Here, we proposed a simple and label-free electrochemical DNA biosensor based on the gold nanoparticles (GNPs) mediated electron transfer (ET) across different DNA monolayers modified on (gold electrode) GE surface and we also introduce nicking endonuclease-assisted signal amplification (NESA) into the bio-sensing system. Additionally, hairpin DNA (HPDNA) was first employed in our work for better understanding of the how the different status of DNA strands monolayers on electrode surface affect GNPs mediated ET process. The working principle of p53 gene biosensor is illustrated in Scheme 1. Specifically, compared to single-strand DNA (ssDNA), the HPDNA is a relatively rigid structure[3] which can prevent the adsorption of GNPs onto the GE surface, such blocking events cannot introduce enhanced ET between electrode and redox species. However, the nicking endonuclease could bind to and nick the recognition site embedded into the loop portion of the HP after its hybridization with p53 gene. After nicking, the HP would be cleaved into two pieces. The resulting ssDNA on the GE could adsorb GNPs because of the electrostatic interaction between gold and nitrogen-containing bases.[4] Thus, the negative electrochemical species $[Fe(CN)_6]^{3-/4-}$ can transfer electrons to electrode through adsorbed GNPs. The charge-transfer resistance (R_{ct}) will dramatically decrease with the increase of cleavage of HPs. Consequently, the change of R_{ct} is directly proportional to the hybridization of p53 gene. Additionally, with the assistant of nicking endonuclease, p53 gene can be reused and hugely lower the detection limit. The proposed biosensor toward p53 DNA achieves a detection limit of 0.0835 fM with a linear calibration range of 0.1 fM ~ 1 fM. Moreover, the prepared biosensor also exhibited excellent sequence selectivity and reproducibility, demonstrating this strategy was promising for enormous potential application in clinical diagnostics and biomedical research.

Urine and struvite are promising organic fertilizers that can replace conventional fertilizers[1]. However, these fertilizers may contain some emerging organic contaminants, such as hormone. One of the most common hormones is the ethinylestradiol, which can be found in aquatic environments and can cause several changes in living organisms, including deregulation of fish endocrine glands, which can promote the feminization of some species[2]. Thus, the present work developed a fast, sensitive, and portable method for determining ethinylestradiol in urine and struvite, using square wave voltammetry (SWV) and screen-printed carbon electrodes modified with nickel film (SPCE-Ni).

SPCE modification was performed by cyclic voltammetry (CV) and the variables of interest (number of cycles (NC), scan rate (SR) and nickel ion concentration ($[Ni^{2+}]$)) were optimized using factorial design 2^3 and central compound design (CCD). The application of factorial design demonstrated that the variables NC and $[Ni^{2+}]$ are significant. Therefore, these variables were submitted to CCD planning (SR was set at 5 V s^{-1}). Fig. 1 shows the results obtained by CCD, the optimal values chosen for NC and $[Ni^{2+}]$ were 1000 and 9.4 mmol L^{-1}, respectively.

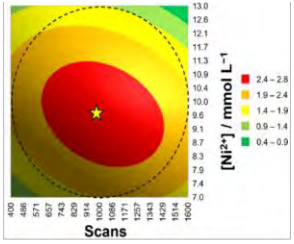

Fig.1. Level curve obtained for the optimization of the variables: number of cycles and concentration of nickel.

The SPCE-Ni and SPCE were characterized by Raman spectroscopy, to identify the modification performed on their surfaces. Fig. 2 shows Raman peaks at 304, 450, 473, 490, 526, and 552 cm^{-1}, what can be attributed to the presence of $Ni(OH)_2$ and NiOOH[3,4]. The results demonstrate the possible presence of different nickel compounds on the surface of the SPCE, especially NiOOH which has electrocatalytic activity in the oxidation of organic molecules[5]. The pH effect on the voltammetric response of ethinylestradiol was evaluated by CV, in the pH range of 3.0 to 10.0, using KCl and BR buffers in the presence of 10.0 µmol L^{-1} of the analyte. The results demonstrate that 0.1 mol L^{-1} BR buffer solution (pH 8.0) was the best support electrolyte. The optimization of the SWV operational parameters was also performed by factorial design (2^3) and CCD. The optimal values found were: 10 mV (step potential), 40 mV (modulation amplitude) and 20 Hz (frequency).

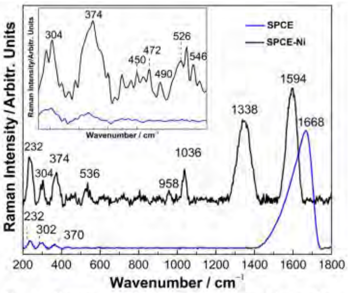

Fig. 2. Raman spectrum of the screen-printed carbon electrode surface (—) SPCE and (—) SPCE-Ni.

The analytical curve was constructed in a linear range of 0.23 to 30.0 µmol L^{-1} (Fig 3). The method presented a limit of detection (LOD) and quantification of 0.067 and 0.228 µmol L^{-1}, respectively, and R^2 of 0.996. The determination of ethinylestradiol in struvite and urine samples indicated that the concentration of the hormone is below of LOD in both. The recovery tests in different matrices showed values between 93.9 and 107.5%, demonstrating that there is no matrix effect. Based on all of these results, the developed procedure can be considered a viable and sustainable alternative to promote green chemistry in the determination of the ethinylestradiol in urine and struvite.

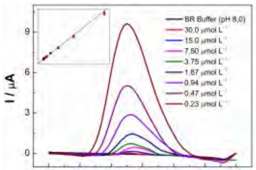

Fig. 3. Square wave voltammograms for the addition of eight solutions of ethinylestradiol (0.23 to 30.0 µmol L^{-1}) in 0.1 mol L^{-1} BR buffer (pH 8.0).

Electric double-layer structure and adsorption of halides on Au (111) electrode in organic solvent - SEIRAS, XPS and EIS

Ahmed S. Shatla, Pawel P. Bawol, Helmut Baltruschat *

Universitaet Bonn, Roemerstrasse 164, 53117 Bonn, Germany

e-mail: Baltruschat@uni-bonn.de

Specific adsorption of ions on the electrode surface has a significant impact on the electric double layer (EDL) structure and the kinetics of electrode processes[1]. This has a substantial effect on many disciplines, such as corrosion, galvanic deposition, electrosynthesis, and electrocatalysis[2]. The ion adsorption at aqueous solution interfaces[3] on various metals has been examined intensively, but much fewer studies from non-aqueous solvents have been conducted[4]. Such studies are important because the metal-solvent [5] and ion-solvent interaction energy [6] depend on the chemical nature of the solvent.

In this study, three organic solvents (propylene carbonate (PC), diglyme (DG), and dimethyl sulfoxide (DMSO)) were investigated for the adsorption of iodide and bromide ions on Au(111) single crystal electrode. This analysis was conducted by using differential capacity measurements, cyclic voltammetry (CV), Electrochemical Impedance Spectroscopy (EIS), surface-enhanced infrared spectroscopy (SEIRAS), and X-ray photoelectron spectroscopy (XPS) techniques.

During SEIRAS measurements, a bipolar band is observed at around 1800 cm^{-1} which correlates to the C-O-vibration of PC as reported on silver electrodes from SERS measurements[7]. Its intensity enhances with going to negative potentials with shifting to lower wavenumbers because of increasing field and highly orientation of PC molecules. While the presence of iodide in the electrolyte results in the shift in the pzc in the negative direction, which leads to stronger alignment of PC molecules in the direction of positive potentials. Anion adsorption charge in DMSO is approximately half the charge in propylene carbonate. Quantification of the adsorbed iodide amount from XPS spectra confirms the calculated adsorption charge from the CVs. The magnitude of anion adsorption on Au(111) electrode increases in the series of halides $I^- > Br^-$ due to better solvation [8] and in the solvent order PC > DG > DMSO.

Electrochemiluminescence (ECL) is a leading technique in bioanalysis.[1] Since the excited species are produced with an electrochemical stimulus rather than with a light excitation source, ECL displays improved signal-to-noise ratio compared to photoluminescence, with minimized effects due to light scattering and luminescence background. The most challenging breakthrough in the development of analytical electrochemiluminescence (ECL) applications was reported from Bard and co workers that presented for the first time the generation of ECL with a coreactant.[1] This finding opened the application of ECL to large literature and transformed ECL from an academic curiosity to a real application and industrial success. In this context, the only real used materials for the ECL analytical and commercial application are tripropylamine (TPrA) as sacrificial "oxidative-reductant" coreactant and Ruthenium(II)-tris(2,2'-bipyridine) ($[Ru(bpy)_3]^{2+}$) as emitting species. In this case the mechanism for the ECL generation was proposed by Bard and still nowadays the only one accepted.[2],[3]

Here we show an additional, and very efficient, mechanism pathway for the generation of ECL by using TPrA as coreactant. Thanks to the combination between ECL and microscopy we experimentally prove the alternative mechanism with the standard $[Ru(bpy)_3]^{2+}$/TPrA system.[3],[4] These mechanistic findings allow us to propose alternative amines as coreactant enhancing the ECL signal of more than one order of magnitude.

The reported results, besides contributing to a better understanding of the mechanisms operating in the chemiluminescence generation, also pave the way for the development of very highly efficient ECL coreactants for ultrasensitive bioanalysis.[5]

Regulating Li-Ion Migration in Solid-State Electrolytes for Li Metal Anodes

Chen-Zi Zhao, Xin-Bing Cheng, Rui Zhang, Qiang Zhang*
Department of Chemical Engineering, Tsinghua University
Beijing 100084, China
zhang-qiang@mails.tsinghua.edu.cn

Lithium (Li) metal batteries are strongly considered one of the most promising candidates for next-generation rechargeable batteries due to their high theoretical specific capacity and low reduction potential. However, Li metal anodes are suffering from limited cycle life, low cycling efficiency, and severe safety concerns resulting from sharp Li dendrites and electrolyte degradation.

The uncontrollable Li dendrite growth caused by the uneven distribution of Li ions is an extremely complicated issue coupled with the transport of anions, cations and electrons, as well as the chemical and electrochemical reactions at the anode-electrolyte interphase. In terms of the ion migration, space-charge theory indicates that the electrolyte is divided into a quasi-neutral region and a space-charge region. The quasi-neutral region approaches the cathode side, at which the ion transfer is governed by diffusion. In contrast, when ions travel close to the anode side, the ion transport is mainly driven by the electric field, leaving a space-charge region that accounts for ramified Li metal growth. Consequently, it is rewarding to design electrolytes that can regulate the ion distribution (including both Li cations and the counter anions) to inhibit Li dendrite growths.

Immobilizing anion has been theoretically proved to influence cation distribution, where a portion of immobilized anions (even as small as 10%) contribute to stable Li electrodeposition. Here, we develop an anion-immobilized solid-state composite electrolyte for Li metal anodes. Garnet-type $Li_{6.75}La_3Zr_{1.75}Ta_{0.25}O_{12}$ (LLZTO) ceramic particles are well dispersed in a polymer matrix to synthesize a polyethylene oxide (PEO)–lithium bis(trifluoromethylsulphonyl)imide (LiTFSI)–LLZTO (PLL) solid electrolyte. In contrast to routine electrolytes with mobile anions, the PLL solid electrolyte contributes to effective immobilization of anions for uniform ion distribution and dendrite-free Li deposition. Chemical and mechanical interactions between ceramic particles and the polymer matrix result in reduced PEO crystallinity and pinned TFSI−anions, enabling relatively fast Li^+ conduction. We further demonstrate the application of this flexible membrane in all–solid-state $LiFePO_4$ (LFP) || Li and $LiNi_{0.5}Co_{0.2}Mn_{0.3}O_2$ (NCM) || Li batteries.

Moreover, ion migration in batteries can be analogized to the fluid transportation in packed towers in the field of chemical industry. Redistributors are used to intensify the heat and mass transfer processes in a packed tower. Solid-state electrolyte LLZTO, with abundant 3D ion conduction channels, can act as a redistributor to regulate Li-ion distribution. We propose a concept of ion redistributors to eliminate dendrites by redistributing Li ions with LLZTO coated polypropylene (PP) separators in Li metal batteries. The standard deviation of ion concentration beneath the LLZTO composite separator is 13 times less than that beneath the routine PP separator. This approach enables a high specific capacity for $LiFePO_4$|| Li pouch cells and prolonged cycle life span of 800 hours for Li || Li pouch cells. This strategy is facile and efficient in regulating Li-ion deposition by separator modifications and is a universal method to protect alkali metal anodes in rechargeable batteries.

Oxygen reduction reaction on rough massive gold electrodes – Surface roughness as adjusting screw

Andreas Köllisch-Mirbach, Helmut Baltruschat

Rheinische Friedrich-Wilhelms-Universität Bonn

Römerstraße 164, 53117 Bonn, Germany

koellisch@pc.uni-bonn.de

Surface roughness is a parameter, which is scarcely addressed in current publications, despite the fact, that the surface structure can strongly affect the product distribution of an electrochemical reaction. In this work, we show the change in ORR product distribution in Li^+ and Ca^{2+} containing dimethyl sulfoxide (DMSO) on gold. In case of Ca^{2+} containing DMSO we furthermore investigate the possibility of using the surface roughness as tool to get additional insights into the reaction kinetics. This investigation is supported by methods like Differential electrochemical mass spectrometry (DEMS) and rotating ring disk electrode (RRDE) generator collector experiments. It is already known that on gold electrodes in Li^+ containing DMSO soluble superoxide is formed prior to insoluble Li_2O_2 during ORR.[1-3] We found, that in case of Li^+ containing DMSO on gold electrodes, the amount of generated O_2^- is constant for all roughness factors (f_R) during a cycle, while the amount of insoluble Li_2O_2 increases linearly with f_R corresponding to a slope of approximately $660\frac{\mu C}{cm^2}$, finally leading to a complete deactivation of the electrode. In case of Ca^{2+} containing DMSO a continuous generation of soluble superoxide, even at CaO_2-saturated electrodes is already known ond gold electrodes.[4, 5] We furthermore found diffusion limited formation of soluble CaO_2 on rough Au electrodes. From the change in half –wave potential with electrode roughness, we were able to estimate the transfer coefficient $\alpha = 0.56$, while the usual approach using the Tafel slope from the current voltage relationship gives $\alpha = 0.46$, both for $z = 1$. This indicates a one electron process as rate determining step for the ORR in Ca^{2+} containing DMSO.

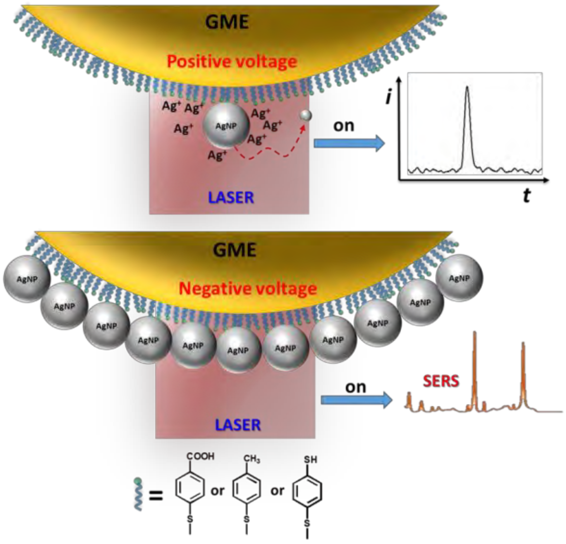
Abstract

Understanding of the chemical interaction and junction formation under molecule level brings remarkable interest to molecular electronics and molecular plasmonics,[1, 2] but still remains elusive. In this work, we studied the effect of the surface chemistry of the collector electrode on nanoparticle (NP) collisions and the molecular junctions through simultaneous electrochemical and surface-enhanced Raman spectroscopy (SERS) measurements. Different plasmonic molecular junctions were formed through the random collision events of silver NPs (AgNPs) in electrolyte with a gold microelectrode (GME) modified by benzenethiols with different terminal groups (-SH, -COOH and CH_3). As shown in the Scheme 1, when we applied a positive bias to a GME, due to the faradic oxidation of AgNPs, typical current spikes can be observed when a AgNP collides on the electrode surface. However, when negative bias was applied at the electrode, the AgNPs could stick on the electrode surface and formed the AgNP-on-GME geometry. The AgNP-on-GME geometry is analogous to the widely used "NP-on-Mirror" (NPoM) geometry,[3] in which extremely high Raman signal enhancement and single molecule sensitivity has been achieved due to the gap surface plasmon mode.[4] Moreover, different from NPoM approach, continuous bias can be applied in the AgNP-on-GME configuration. Using time-resolved electrochemical current measurement and SERS, we successfully observed the effect of various electrode surface chemistry on the transient electrochemical current changes and the evolution of newly formed molecular junctions through AgNP-GME collision events.



Scheme 1. Schematic diagram for the voltage-controlled formation of silver nanocap for efficient SERS of probe molecules on GME.

Lithium-Sulfur Batteries: From Electrochemistry to Materials Practices

Qiang Zhang

Department of Chemical Engineering, Tsinghua University, Beijing, 100084
**zhang-qiang@mails.tsinghua.edu.cn*

Among various promising candidates with high energy densities, lithium-sulfur (Li-S) batteries with a high theoretical capacity and energy density are highly attractive;[1-2] while the commercial application of Li-S batteries still faces some persistent obstacles, such as the low electrical conductivity of sulfur and lithium sulfide and the dissolution of polysulfides. The introduction of nanocarbon into the field of Li-S batteries sheds a light on the efficient utilization of sulfur by improving the conductivity of the composites and restraining the shuttle of polysulfides. In this presentation, the concept for the rational design of nanocarbon for energy storage is explained. The advances in the use of advanced energy materials in the cathode, separator, and anode is explained.[3-14] New insights on the relationship between the nanostructure and the electrochemical performance are presented.

Li metal is considered as the "Holy Grail" of energy storage systems. The bright prospects give rise to worldwide interests in the metallic Li for the next generation energy storage systems, including highly considered rechargeable metallic Li batteries such as Li-O2 and Li-sulfur (Li–S) batteries. However, the formation of Li dendrites induced by inhomogeneous distribution of current density on the Li metal anode and the concentration gradient of Li ions at the electrolyte/electrode interface is a crucial issue that hinders the practical demonstration of high-energy-density metallic Li batteries.

In this talk, we review energy chemistry of lithium metal anode in safe batteries. Firstly, the importance and dilemma of Li metal anode issues in lithium–sulfur batteries are underscored, aiming to arouse the attentions to Li metal anode protection. Specific attentions are paid to the surface chemistry of Li metal anode. Next, the proposed strategies to stabilize solid electrolyte interface and protect Li metal anode are included. Finally, a general conclusion and a perspective on the current limitations, as well as recommended future research directions of Li metal anode in rechargeable batteries are presented.

Electrochemically Assisted Surfactant Assembly in the hard X-ray beam: an in situ GISAXS study

Gilles E. Moehl, and Andrew L. Hector
Chemistry, University of Southampton
Southampton, SO17 1BJ, UK.
g.e.h.k.moehl@soton.ac.uk

Under the Advanced Devices by Electroplating EPSRC programme grant (EP/N035437/1) we are working on the integration of nanowire semiconductor structures into electronics, using aligned mesoporous templates as host for the electrodeposition of high quality chalcogenide semiconductors. This necessitates the making of porous hosts for template electrodeposition, such as mesoporous silica structures. Mesoporous silica films are typically produced by evaporation-induced self assembly (EISA)[1], but vertical alignment of the pores to the substrate is very difficult to achieve. Hexagonal arrays of vertically aligned mesopores can be achieved by electrochemically assisted surfactant assembly (EASA)[2]. The self-assembly of a cationic surfactant (typically cetyltrimethylammonium bromide) close to the substrate surface relies on the application of a negative potential to an electronically conductive substrate, but also leads to the formation of spheroidal surface aggregates, limiting the obtainable film thickness to a few hundreds of nm[3,4]. Grazing incidence small angle X-ray scattering (GISAXS) allows for the non-destructive structural analysis of thin films with high statistical relevance in lateral and vertical direction. In this work, we show the results obtained from in situ GISAXS experiments done during the EASA of silica, following the evolution of the structure formation in real time with sub-second time resolution. From this, suggestions to a more detailed mechanism of formation are made.

Metal corrosion has caused huge waste and serious threats to the economy and the safety of human life. Cathodic protection is the most commonly used method for metal corrosion protection in marine engineering, however it can cause waste of energy and anodes. In recent years, triboelectric nanogenerator (TENG) cathodic protection technology has shown good application prospects. In this work, polydimethylsiloxane (PDMS) and Al foil with different electronegativity were selected as the friction layer to construct a vertically separated TENG (PDMS-Al). In addition, the chitosan and AAO were used to topologically modify the PDMS and construct the micro-nano structure, and it was combined with Al to form PDMS/CS-Al and PDMS/CSr-Al TENG. The electrical output performance of TENG was evaluated. It was found that PDMS/CSr-Al TENG has better electrical output performance. The PDMS/CSr-Al TENG was selected to build a TENG cathodic protection system under the condition of simulating mechanical external force (Fig. 1). Driven by a simulated mechanical force of 5 Hz, it was found that the maximum output open-circuit voltage of the TENG can reach 77.1 V, and the surface potential of the exposed area of 1 × 1 cm^2 304ss can be reduced by about 0.1 V (Fig. 2), indicating that it forms a cathode for 304ss polarization protection. Furthermore, it explored and evaluated the application potential of TENG cathodic protection technology.

Volatile organic compounds (VOCs) are characterized by their high activity in atmospheric photochemical reactions. In addition, human health can also be importantly affected, because VOCs can be easily absorbed by the skin and the mucosa, damaging the metabolic system and, in some cases, they can even be carcinogenic. Therefore, their removal is very important. A very promising technology for the treatment of gaseous polluted streams is electro-scrubbing [1], which consists of the combination of an absorption process with a mediated electrochemical oxidation. Its purpose is to retain gaseous contaminants into a liquid stream and then oxidize them using metal pairs as catalysts. This work focuses on the removal of toluene using a packed column and a one compartment electrolyzer. An electrolyte, based on the pair Co (II)/Co (III) in an acid medium, is used to capture toluene and degrade it. This electrolyte is circulated throughout an absorption column and the cell. The activation of the metallic catalyst and the efficiency in the contact between the phases are parameters that have been carefully analyzed. The recirculation of the washing solution through the electrochemical system allow the oxidant species to be regenerated and keep the treatment active. Reaction intermediates have been monitored by GC-MS and HPLC.

Ozone is a very powerful oxidant with many applications in water and wastewater treatment. Despite it is typically produced by non-electrochemical methods, its electrochemical production is becoming a topic of the major interest nowadays. Ozone can be generated by the oxidation of oxygen contained in water throughout different types of electrode materials and cell designs. Use of diamond anodes can be very important to reach high efficiencies in a process in which the low solubility of oxygen in water is one of the main drawbacks. To face this important problem, reactor design is very important and PEM electrolyzers seems to be promising options which allow the production of ozone at low voltages, and, hence, with high cost-effectivity. In this work, is evaluated the influence of pressure and use of mechanical microbubbles generators on the ozone electro-generation using different of PEM electrolyzers. Results highlight the great influence of these parameters which are of a great significance for the treatment of wastewater polluted with different organics, as it is also confirmed in different tests shown in this presentation.

Javier.Llanos@uclm.es

Ozone (O_3) and hydrogen peroxide (H_2O_2) are two environmentally friendly oxidants that have been used in several applications regarding wastewater treatment, purification of water loops used in the pharmaceutical and semiconductor industries, wood pulp bleaching process, treatment of textile wastewaters, and other applications [1]. It is well known that these two reactions can be performed in aqueous solutions by cathodic and anodic reduction using different cathodes and anodes, and using air coming from the air [2]. The performances of these two different reactions can be increased upon enhancing the pressure from 0 to up to 30 bar and, on the other hand, increasing the current density and modifying the composition of the electrolyte solution in which the reactions take place [3]. In this work, we have designed a reactor that works in high pressure conditions to facilitate the absorption of O_2 in an aqueous solution to react in an electrochemical reaction (Figure 1) using Boron Doped Diamond as anode material and PTFE-Carbon Black Reticulated Vitreous Carbon (RVC) as cathode material to achieve the production of O_3 and H_2O_2 in two different reactions, that would increase the efficiency using high-pressure conditions, using O_2 in a closed chamber. It is expected a dramatic effect of the pressure on the efficiency of these reactions, along with other parameters such as electrolyte composition, electrode materials and current density applied to the system.

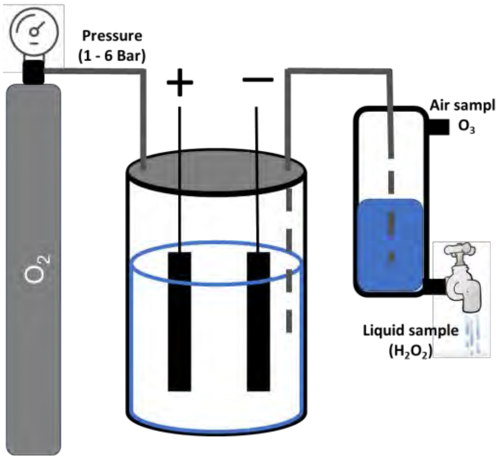

Figure 1. Schematic representation of the experimental setup to produce H_2O_2 and O_3 under pressure conditions.

CO_2 Fixation via Carbonation of NaOH Generated by an Electrochemical Reactor

Gustavo Acosta, Erika Bustos, Lidia Utrilla, Pablo Cañizares, M.A. Rodrigo and Javier Llanos
Chemical Engineering Department, University of Castilla-La Mancha
Avenida Camilo José Cela 12, 13071, Ciudad Real, Spain
Javier.Llanos@uclm.es

The ability to convert carbon between different oxidation states in order to store and release energy relies on biological metabolism and in the center of human energy infrastructure and chemical industry. A potential approach to reduce CO_2 emissions and fossil-fuel consumption that has attracted nowadays attention is the recycling of CO_2 into fuels and chemicals [1]. One of the several strategies to mitigate CO_2 emissions is Electrochemical CO_2 reduction (CO_2R), these processes for the fixation of CO_2 have been the focus of many research activities mostly for the necessity of dealing with the increment of this compound in the atmosphere, which is correlated with global warming and pollution in many industrialized countries and worldwide [2]. Carbon atoms in CO_2 molecules are in their highest oxidation state, whereas those in common fuels and chemicals such as hydrocarbons, alcohols, and acids are in lower states, and for the synthesis of these compounds an energy input is required, which is one of the main reasons why CO_2 is not extensively used in current chemical industries [3]. In this work, we aimed to fixate CO_2 in an adsorption glass column coupled to an electrochemical reactor (Figure 1), which consists of two electrode chambers separated by an ionic membrane, that produces Cl_2 in the anode (MMO) chamber and NaOH and H_2 in the cathode chamber (stainless steel), which is connected to the adsorption column to generate $NaCO_3$ and $NaHCO_3$. Our results show that CO_2 fixation in this reactor depends on the electrolyte concentration, the intensity applied, which is correlated to the amount of NaOH and Cl_2 electrogenerated in both chambers, and on the velocity and concentration of CO_2 that is injected to the adsorption column. This technology can be used to produce secondary added value products (hydrogen, chlorine) and help to mitigate CO_2 emissions.

Impedance Measurements on QLED Devices: Analysis of High-Frequency Loop in Terms of Material Properties

Chen You,[1] Alex Titov,[2] Baek Hyun Kim,[2] Mark E. Orazem[1,*]
1. Department of Chemical Engineering, University of Florida, Gainesville, FL 32611 USA
2. NanoPhotonica Inc. Research Lab, UF Innovate / The Hub, Gainesville, FL 32601 USA
* meo@che.ufl.edu

Quantum-dot light-emitting diodes (QLED) are used in the new generation of electronic displays. A QLED based display can offer superior performance, including brightness, color purity, color gamut, and efficiency, at a lower cost as compared to existing technology. Electrochemical impedance spectroscopy (EIS) has been applied over the decades to study the light-emitting diode (LED) devices and could provide an ability to characterize the electrical properties of the material. However, work is needed to improve the interpretation of the EIS response of QLED devices.

Constant-phase-element (CPE) behavior is often observed in EIS response of electrochemical and solid-state systems. The CPE can be used to improve the fit of the equivalent circuit model to the impedance data. However, interpretation of the CPE parameters to extract physical meaning requires an understanding of the time-constant distribution in each individual system. Hirschorn et al.[1,2] developed a power-law model that could relate the CPE parameters to the physical properties of the film by regression of the measurement model[3-5] to synthetic data. The distribution of resistivity was identified by assuming a uniform dielectric constant.

The objective of the present work is to interpret the high-frequency impedance response on red and green QLED devices in terms of the physical properties of the device. Impedance measurements were performed on red and green QLED devices under current densities chosen to yield specified luminescence. A circuit model was developed for the observed high-frequency loop in terms of the thickness, dielectric constant, and resistivity distribution of the hole-injection layer. dielectric constant and resistivity were extracted with a known layer thickness obtained from Scanning Electron Microscopy (SEM) analysis. Impedance measurements performed on hole-transport only devices were used to verify the interpretation of the high-frequency capacitive loop in terms of the properties of the hole-injection layer.

kroner@icvt.tu-clausthal.de

The vanadium redox flow battery (VFB) is a promising energy storage system, due to its durability and intrinsic safety. Several studies on the kinetics of the VFB reactions are already available, however mainly on model electrodes such as platinum or glassy carbon [1]. The kinetics at these model electrodes can deviate significantly from real electrodes, since different overpotentials and reaction mechanisms might occur. Besides that, the electrode structure of real materials is neglected when using model electrodes.

For understanding the interplay between the electrolyte and the electrode, investigations on commercial electrode materials, such as porous carbon felts are necessary. Because of the complex structure of the porous electrodes, especially due to the strong influence of the morphology and pore volume on the results, the interpretation of the electrochemical data is highly complex [2]. In addition, the low conductivity of the electrolyte results in inhomogeneous current density distributions in the porous electrode, which makes an exact determination of kinetic parameters very difficult [3].

Therefore, neither a model electrode nor a complete commercial porous electrode was applied in our studies. Instead, we used single carbon fibre microelectrodes (similar to [4], see figure 1, left), which were detached from commercial electrode materials, connected to a copper wire and isolated with a heat-shrink tubing. These electrodes were operated under technically relevant electrolyte concentrations and examined by electrochemical impedance spectroscopy (EIS) and polarization curves. The results were used to determine the reaction rate constants, the transfer coefficients, and the reaction orders of the vanadium ion reaction kinetics. For example, the exchange current density was determined depending on the state of charge of the electrolyte (see figure 1, right). In addition, different fibres out of one single piece of electrode were investigated to analyze the variation of kinetic activity within the material, which can occur due to irregularities in the production process or during activation.

The gained precise kinetic parameters allow to improve electrode materials for VFB. Furthermore, they are useful for electrode models, which are applied to study the influence of mass transport and current density inhomogeneities in porous electrodes. Thereby, the influence of activation methods on the electrode materials can be investigated and better understood.

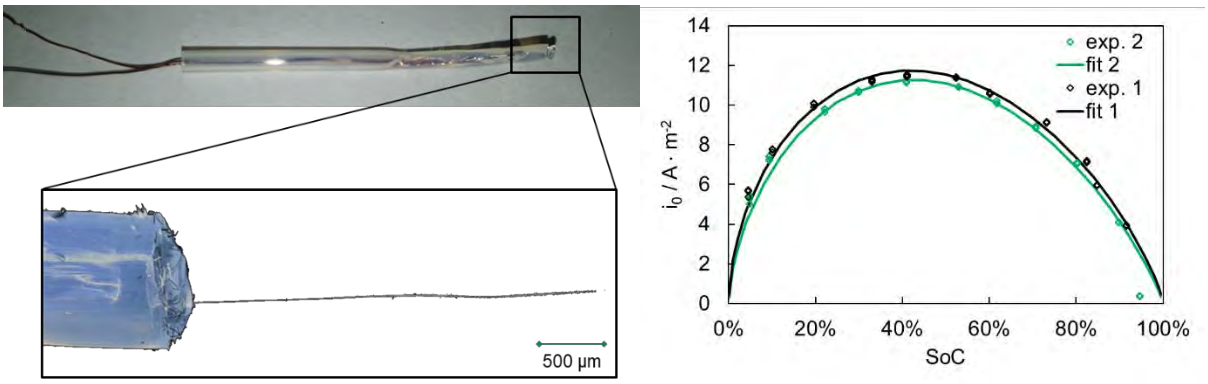

Figure 1: Carbon fibre microelectrode (left) and experimental results from two subsequent experiments in negative electrolyte compared to mathematical fit of reaction order (exchange current density at different SoC).

INTEMA, CONICET, Av. Colón 10850, 7600 Mar del Plata, ARGENTINA
mvazquez@fi.mdp.edu.ar

Reinforced concrete is a reliable building material due to many excellent properties such as strength and durability. However, marine environments and chloride-contaminated aggregates accelerate deterioration and failure[1]. Inorganic inhibitors are frequently considered to mitigate steel corrosion [2,3]. In this work, silicate ions were tested as corrosion inhibitors in concrete pore simulating solutions contaminated with chloride ions. The electrochemical evaluation included cyclic voltammetry and polarization curves. Weight loss tests were implemented to follow the inhibitor performance over long exposure times. Micro-Raman spectroscopy and X-ray photoelectron spectroscopy (XPS) were used to investigate the composition of the surface film.

Steel is tested in an alkaline solution simulating the composition of pore solutions in concrete (pH 13) contaminated with 0.3 mol/L chloride ion, which also contains 0.3 mol/L silicate ion (Cl-PSS-Inh). Compared to Cl-PSS, the improvement in behavior and the difference in response when silicate ions are present is clear from the results of all the techniques used to evaluate the electrodes.

Anodic polarization curves show no sign of pitting or any form of localized corrosion and very low passive current densities when silicate ions are present in solution. These results are promising in terms of the ability of these inorganic ions to be used as corrosion inhibitors.

When chloride and silicate ions are present simultaneously in an Inhibitor/Chloride = 1 ratio, complete inhibition of the localized attack is observed after 60 days of immersion.

Cyclic voltammograms and XPS spectra indicate that the presence of silicate ions affects the composition of the passive film (see Figure 1). However, further study is needed to understand the mechanism of action of silicate ions as inhibitors and to explore their effectiveness when used in mortars, concrete or to pre-treat the steel bars.

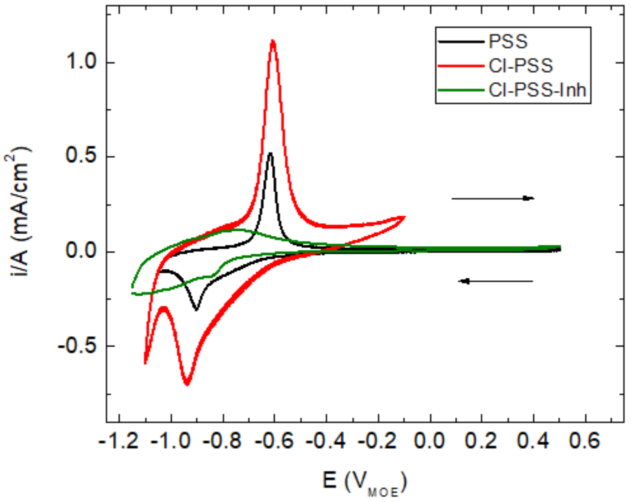

Figure 1: Cyclic voltammograms recorded for steel in pore simulating solutions (pH=13) showing the effect of chloride ions and chloride plus silicate ions. Silicate ion concentration is 0.3 mol/L and Inhibitor/Chloride = 1. Scan rate = 10 mV.s^{-1}. The tenth cycle is presented.

Recurrence Quantification Analysis as a Tool to Investigate Current Oscillations Observed During the Mass-Transport Controlled Electrodissolution of Fe in Sulfuric Acid Solutions

Chrysanthi Gkili, Dimitrios Valavanis, Dimitra Sazou
Department of Chemistry, Aristotle University of Thessaloniki
Thessaloniki, T.K. 54124, Thessaloniki, Greece
e-mail address: chrysagkili@gmail.com

Recurrence is a fundamental property of nonlinear dynamical systems, which can be utilized in order to characterize the system dynamics in phase space. A visual tool for exploiting the recurrence behavior of phase space trajectories is the recurrence plot (RP) introduced in 1987 by Eckman et al [1]. On the basis of the RP, recurrence quantification analysis (RQA) can be carried out to identify different dynamical regimes and characterize transitions between them. Recurrence plots (RPs) and recurrence quantification analysis have been widely used in many scientific fields from chemistry, physics and engineering to life sciences, ecology and economy [2, 3]. RQA was also turned out to be a key issue revealing complex dynamics, phase and generalized synchronization in non-phase-coherent and even non-stationary time series of electrochemical systems and characterizing different corrosion states of metals and alloys [4-6]. This study aims in exploring non-linear quantifiers based on RPs and RQA in order to investigate complex current oscillations observed during the mass-transport controlled electrodissolution of iron in sulfuric acid solutions (Fe|0.75 M H_2SO_4 interfacial system). Under the potentiodynamic operation mode, Fe|0.75 M H_2SO_4 is a well-known electrochemical system exhibiting multiple oscillatory potential regimes depending on various control parameters [7]. Our focus here is on oscillations appeared in the limiting current region beyond a critical value of the ohmic potential drop and when proper hydrodynamic conditions are established across the interfacial region [8]. By applying two system configurations comprising an upward and a downward-facing Fe-disc electrode, visual changes in RPs plots and RQA measures, such as the average diagonal line (ADL), the trapping time (TT) and the longest vertical line (LVL) along with a new entropy quantifier, reveal different nonlinear correlations. The new entropy quantifier was based on recurrence matrix microstates that represent more general properties of the recurrence space as compared with the entropy quantifier based on just diagonal or horizontal lines of the recurrence space [9]. Indeed, the microstate-based entropy quantifier reflects correctly the system complexity in agreement with ADL, TT and LVL. All RQA measures indicate that the enhancement of the mass transfer affects the complexity and the transitions between different nonlinear dynamical regimes.

The long-term use of conventional chemotherapeutics leads to damage of healthy cells and adverse side effects. To minimize the side effects of the drugs, achieve their sustained release or improve their stability they can be delivered encapsulated in appropriate drug carriers. Here we propose tailored liquid crystalline structures (LCP) and their nanoparticles (LCNP) that incorporate an anti-cancer drug together with complexed radioconjugates in order to obtain more effective action towards the cancer cells.

Lipidic liquid-crystalline phases, such as cubic phases, are promising as drug carriers since they have large interfacial area of 400 m^2/g and their structure consists of bicontinuous lipid bilayer surrounding two systems of non-contacting aqueous channels. A wide range of drugs can be encapsulated in this biocompatible amphiphilic environment resembling that of a biological membrane. Cubic phases are stable in the excess of water and can be dispersed in the presence of stabilizer into colloidal nanoparticles – cubosomes. Cubosomes are less viscous and exist as a suspension which makes them easier to handle and deliver to the appropriate site.[1-4]

We prepared cubic phases and cubosomes with doxorubicin (DOX), a drug with particularly negative side effects, and we characterized the mesophase structure by small angle X-ray scattering (SAXS) and DLS (for cubosomes). To investigate the behavior of the drugs incorporated in the carrier and to determine drugs release profile we used electrochemical methods and UV-Vis spectroscopy. We considered Korsmeyer-Peppas and other mathematical models in the evaluation of the drug release kinetics. In order to obtain more effective action, the cubosomes containing DOX were also doped with an amphiphilic ligand complexing ^{177}Lu radionuclide. We used MTT assay to evaluate cytotoxic effect of the cubosomes with single and two components upon selected cancer cell lines.

Vanadium-redox-flow batteries (VRFB) have been intensively developed and commercialized since the last decade. This electrochemical processes in VRFB are based on conversions of vanadium redox couples in highly acidic media: V(III)/V(II) at the anolyte and V(V)/V(IV) at the catholyte. In practice, the kinetics of both of these reactions are known to be sensitive to the electrode pretreatment. For this reason, the widely used graphite felt electrodes for VRFB usually undergo thermal pre-oxidation or oxidative chemical pretreatment. However, the detailed mechanism of these electrode reactions is unknown and the interpretations of the effect of electrode surface pre-treatment are controvercial[1].

n this work we present the compairison of the literature data on the kinetics of the V(III)/V(II) and V(V)/V(IV) electrode reactions, considerations about the effect of the electrode surface and the cyclic voltammetric experimental data at glassy carbon electrode material. Special attention is given to the pre-treatment protocol. To characterize the state of the electrode surface, the potassium hexacyanoferrate is used as a reference redox-active probe.

Electrochemical impedance spectroscopy protocol for detection of Norfloxacin at a polyamic acid modified electrochemical sensor

PGL Baker, Clementine Louw
SensroLab research group, Chemistry department, University of the Western Cape, Robert Sobukwe drive, Bellville 7530, South Africa
pbaker@uwc.ac.za

Pharmaceuticals are introduced into the environment through many different pathways including production and consumption waste, ineffective water treatment, improper disposal of even as unused pharmaceutical waste. Pharmaceutical contaminants are on the WHO critical list as priority emerging pollutants in water, since in many countries, disposal remains unregulated. Norfloxacin is a hemotherapeutic antibiotic agent which is used to treat urinary tract infections and respiratory infections, among others. Due to the high water solubility required of antibiotics, antibiotics are able to pass through all the typical filtration systems employed in water treatment plants and reach surface water, groundwater and even drinking water.

Electrochemical sensors are devices that change electrochemical information into an analytical signal that is useful for quantification. Conducting polymers are widely used as transducers in the design of chemical sensors, however they have some disadvantages such as low sensitivity, poor selectivity and surface poisoning due to adsorbed intermediates or interfering species. The aromatic polyimides typically exhibit good thermal and chemical stability, mechanical strength, and low dielectric constants. Among them, polyamic acid (PAA) was used for different applications, including sensor modification. PAA is a polymer with cation complexing properties, due to its carboxyl groups. Integrating metal nanoparticles into polymers to form polymer nanocomposites tends to improve the physical and chemical properties of the sensor. The unique optical, electrical, magnetic and catalytic properties of cobalt nanoparticles have made desirable in applications of nanoelectronic devices, nanosensors and catalysts. In this work we have shown how the unique combination of Co-nanoparticles incorporated into a deposited polyamic acid thin film has been advantageously employed for the sensitive detection of Norfloxacin. Following the use of a variety of techniques including microscopy and small angle X-ray measurements to verify the topography and morphology of the sensing layer, electrochemical impedance spectroscopy was employed to extract the mechanism of interaction between Norfloxacin and the modified transducer.

Nanostructured Silicon as Anode for Lithium-ion batteries

The enhancement in the morphology of anode materials leads to better capacitance properties. Nanostructure design is an effective way to improve battery cycling because nanostructures provide short diffusion length for Li$^+$ ions and electrons with better resistance to fracture [1]. The most widely used anode is graphite whose lithiated compounds have stable phases up to the LiC$_6$ stoichiometry corresponding to a theoretical specific capacity of 372 mAh / g [2]. In contrast, silicon possesses a very high theoretical capacity of 4200 mAh / g and can intercalate 4.4 Li into Si at high temperature to form Li$_{15}$Si$_4$ [3]. Silicon also features a working potential around 0.4 V vs. Li / Li$^+$ which is safer than operating potential of graphite (0.05 V vs. Li / Li$^+$). Although silicon possesses all of these advantages, silicon-based anodes suffer from huge volume expansion upon cycling (≈400%) causing electrode fracture and electrical isolation during repeated cycling [4]. Continuous volume changes cause the breaking-reformation of the solid electrolyte interphase (SEI) film which leads to the consumption of lithium-ions and electrolyte.

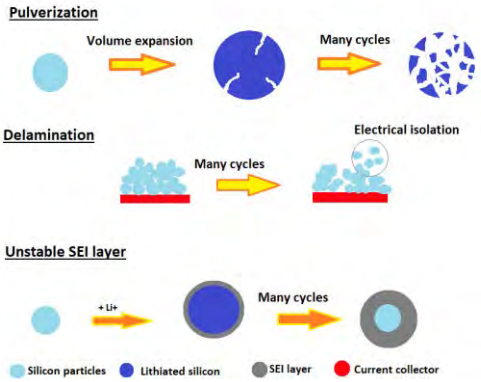

Fig. 1 Cell failure mechanisms of silicon

There are two strategies to avoid this problem, first one is combining Si with different kinds of carbon materials such as amorphous carbon, conductive carbon black, carbon nanotubes and graphene and secondly, by designing nanoscale silicon with different structures. In the present work, we represent nanostructured composite anodes. Structural and microstructural changes in silicon nanomaterials were examined using several methods: X-ray powder diffraction combined with the results of Raman spectroscopy, FT-IR spectroscopy, UV-Vis spectrometry, Nitrogen adsorption measurements, and TEM analysis. Electrochemical performances were investigated by cyclic voltammetry and galvanostatic charge-discharge measurements.

One promising way to store and distribute renewable energy like solar and wind energies is the electrochemicals production of fuels like hydrogen (H_2), hydrogen peroxide (H_2O_2) and methane (CH_4)[1]. The reported most promising electrocatalysts are based on rare and expensive noble metals as they are highly efficient and stable, therefore the recent researches have been focusses on the substitution of noble metals with earth abundant elements[2,3] or metal-free catalysts[4,5]. A major drawback of currently available electrocatalysts for the large-scale application, is poor long-term stability due to decomposition or delamination. To overcome those limitations, mechanically interlocked carbon nanotubes (MINT) has been investigated due to its strong immobilization of the organic compound in a rotaxane-type while still maintaining the desired properties of the carbon nanotube as well as the organic catalyst.

The successful synthesis and characterization of non-covalent rotaxane-type MINT with various organic molecules was demonstrated[6]. Motivated by tunable chemical catalytic capability of anthraquinone MINT's (AQ-MINT)[7], we investigated AQ-MINT as an electrocatalyst toward oxygen (O_2) to H_2O_2 reduction, as quinones in general are known for their capability of O_2 to H_2O_2 transformation[8].

This work studied the electrochemical behaviour of AQ-MINT's in comparison to supramolecularly adsorbed species (AQ@SWCNT) in aqueous and organic solutions[9]. Thereby, the versatility as well as superior stability of the MINT immobilization could be demonstrated. Furthermore, the electrocatalytic O_2 reduction to H_2O_2 was studied in neutral and basic aqueous media over 8 h. The results revealed that oxygen was reduced electrochemically using AQ-MINT in basic solution yielding 7.0 µmol of H_2O_2 after 8 h electrolysis, which correspond to a maximum catalytic activity of up to 12 $\mu mol_{(H2O2)}\ mg_{(AQ\text{-}MINT)}^{-1}\ h^{-1}$ or a turnover number (TON) of 417.

Templated Electrodeposition of Nanoscale p-Block Materials

Li Shao, Andrew Hector, Philip Bartlett, Kees De Groot, Gilles Moehl, Samantha Soulé, Lingcong Meng,
Wenjian Zhang, Yasir Noori
University of Southampton, Southampton SO17 1BJ, UK
School of Chemistry, University of Southampton, University Road, Southampton, SO17 1BJ, UK
L.Shao@soton.ac.uk

Our project (ADEPT, EPSRC EP/N035437/1) aims to intergrade electrodeposition into device fabrications including thermoelectric devices, infrared detectors and phase change memories. This work focuses on producing nanowires by templated electrodeposition, the schematic is displayed in Fig 1. Silica thin films with well-ordered three-dimensional (3D) mesoporous structures were used to be the templates for electrodeposition. They were synthesised by evaporation-induced self-assembly (EISA) process using Pluronic F127 triblock copolymer as a structure-directing agent. FE-SEM showed that most of the pore diameters were between 6 and 10 nm. Grazing incidence small-angle X-ray scattering (GISAXS) showed that pore structure of the template adopted Fmmm space group with [010] orientation, as shown in Fig 2 (a). Bismuth and tellurium were grown through the 3D mesoporous channels by conducting two-step pulsed electrodeposition in a non-aqueous electrolyte system. Fig 2 (b) shows the Te nanowires grow through the mesostructure of the silica films. Electrodeposition conditions were controlled to optimise the nucleation and growth process and to maximise pore filling. *In-situ* grazing incidence small-angle neutron scattering was used to follow Bi electrodeposition into the pores and to link variations in nucleation to differences in the grown material.

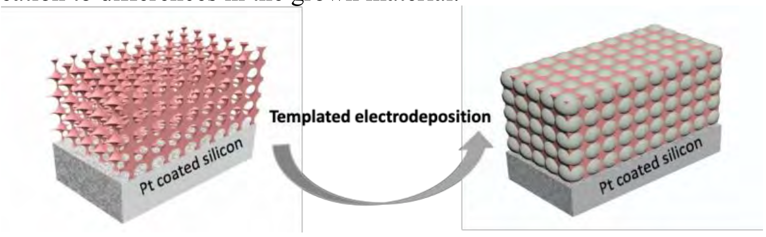

Fig 1 The schematic of templated electrodeposition

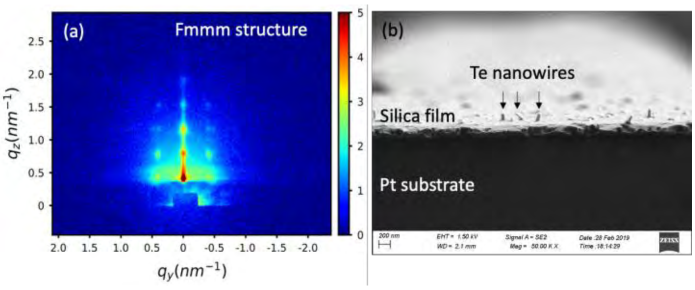

Fig 2 (a) The GISAXS pattern of the silica film as the template; (b) The cross-view SEM image of Te nanowires grow through mesostructure of the silica film.

An additional mechanism of extracellular electron uptake by microorganisms: Can the maintenance of low H_2 partial pressures favor the H_2 reaction on a cathode or metallic iron?

Jo Philips
Department of Engineering, Aarhus University
Hangøvej 2, 8200 Aarhus N, Denmark
jo.philips@eng.au.dk

Several anaerobic microorganisms, e.g. acetogenic bacteria and methanogenic archaea, are capable of using solid electron donors, such as a cathode or metallic iron (Fe(0)). Such microorganisms are of interest for novel applications such as microbial electrosynthesis (cathode as electron donor), while they could also cause detrimental microbial induced corrosion (Fe(0) as electron donor). Intriguingly, similar microorganisms can differ strongly in their capacity to use solid electron donors, which likely relates to their extracellular electron transfer (EET) mechanism. Different EET mechanisms have been proposed for acetogens and methanogens (Figure). Recently, I proposed an additional mechanism: the maintenance of low H_2 partial pressures by microbial H_2 consumption, which thermodynamically favors the H_2 evolution reaction on the cathode or Fe(0) surface (Philips, 2020). I will elaborate in my presentation how H_2 consumption affects the H_2 evolution on a cathode, as well as the anoxic corrosion reaction. In addition, I will discussed that microorganisms strongly differ in their H_2 consumption characteristics. Furthermore, I will explain my hypothesis that the difference in the capacity of microorganisms to use solid electron donors is likely related to differences in their H_2 consumption characteristics. Finally, I will discuss how the EET mechanism I propose relates to other EET mechanisms. My presentation will mainly focus on acetogenic bacteria, but similar considerations are also relevant for other hydrogenotrophic microorganisms.

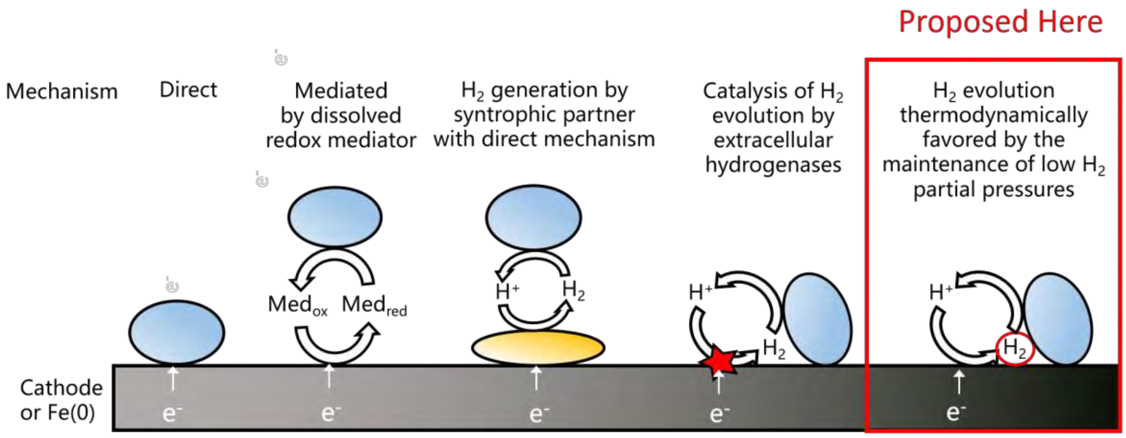

Figure: Overview of the different EET mechanisms previously proposed for microorganisms capable of using a cathode or Fe(0) as electron donor and the additional mechanism that I will discuss (Figure adapted from Philips (2020))

Keywords: Tetracycline, anodic oxidation, electro- Fenton process, Ti_4O_7-ceramic anode, carbon felt, TOC removal efficiency

ABSTRACT

The exploration of electrochemical advanced oxidation processes (EAOPs) have become popular for the degradation of pharmaceutical pollutants in wastewater treatments. This work investigated the degradation of tetracycline (TC), toxicity and intermediate studies using EAOPs. Carbon felt and Ti_4O_7 layer deposited on Ti substrate were used respectively as cathode and anode. Electro-Fenton (EF), anodic oxidation (AO) and electro-Fenton coupled with anodic oxidation (EF/AO) systems were used to degrade TC and their performances were compared. EF/AO performed most efficiently, with removal efficiency of 64.89±0.17% and 68.27±0.43%, at 20 ppm and 50 ppm TC, respectively, as compared to EF and AO. Then different applied currents were investigated for 20 ppm and 50 ppm TC, using EF/AO. Optimal conditions were established for 20 ppm and 50 ppm TC to investigate the intermediate products using HPLC and toxicity tests. The toxicity of the solution was less than initial stage of treatment, corresponding to the formation of less toxic by-products. EF/AO process using Ti_4O_7 anode and CF cathode provides low energy and high mineralization current efficiency (MCE) with high removal efficiency, because of the production of hydroxyl radicals at the surface of the anode and also a large surface area and porosity of CF. The ceramic sub-stoichiometric Ti_4O_7 anode with CF (EF/AO) can be used to degrade pharmaceuticals successfully.

The polymer electrolyte membrane fuel cell (PEMFC) is a simple power device but inside it a complex and coupled mass transport phenomena are key factors in governing its performance and durability [1]. Over operation time membrane electrode assembly degrades, the diagnosis is usually done by a popular technique called electrochemical impedance spectroscopy (EIS). It gives out information on the cause of degradation, but it fails considerably to comment on and distinguish between mass transport processes with comparable time constants [2]. The PEMFC offers gas pressure as a non-electric variable to observe. When combined with current or voltage it gives us additional definitions of impedance and using this technique in harmonic conditions is called electrochemical pressure impedance spectroscopy (EPIS) [3,4].

Niroumand et al [5], made the first attempt to analyze the dynamic relationship between pressure and voltage by examining pressure-induced voltage oscillations in polymer electrolyte fuel cells. It has been demonstrated that cell voltage exhibits oscillations with an identical frequency of the cathode outlet pressure modulation and concluded that a spectrum of such relationship over a range of 0.1 Hz to 20 Hz frequency can be used as a diagnostic tool to understand transport processes such as water transport, limitations in electrode gas flow transport. Hartmann et al [4] applied EPIS to sodium-oxygen batteries by monitoring pressure amplitude in relation to electric current and obtained vital information about hydration imbalance, changes in reactant distribution, their effects on mass transport and concluded that EPIS was significantly sensitive to oxygen transport properties of porous electrodes. In addition, Rho et al. [6] showed that the significant control by diffusion of the reacting gas in the inert gas can be specifically examined by comparing the phase shift of the system with inert gas-oxygen mixture (e.g. air) to that with pure oxygen.

In this work, the focus is on applying EPIS to PEMFC and developing it for better understanding the transport process having comparable time constant inside PEMFC. A sinusoidal variation in the cathode backpressure was applied and the voltage response of the fuel cell was recorded at constant current in a frequency range of 1 mHz to 1 Hz with pressure amplitudes of a few mbar. In order to better resolve the transport processes, experiments with varying oxygen mole fraction were carried out. It was observed that the impedance modulus decreases rapidly with increase in oxygen mole fraction (beyond 0.4) and it is the lowest in case of pure oxygen. In case of pure oxygen, it was observed that the absence of nitrogen contribution in diffusion causes the overall impedance to reduce dramatically over whole spectrum and phase shift in low frequency region (below 50 mHz) depicting the detection of diffusion when compared to air. These observations about oxygen sensitivity are in accordance with results obtained by Hartmann et al [4] and Rho et al [6]. Experiments with reduced stoichiometry of pure oxygen at high polarization and 100 % RH are underway for possible detection of flooding by EPIS, enabling the proper resolution of the diffusion and water transport inside PEMFC.

Electrochemiluminescence – Counter Claims

Lynn Dennany[1], Ashton Theakstone[2], Paul Francis[2]

lynn.dennany@strath.ac.uk

Electrochemiluminescence (ECL) analytical applications have been increasingly exploited in recent years. The majority of these applications are based upon the tris(2,2'-bipyridine)ruthenium(II), $[Ru(bpy)_3]^{2+}$ system with various secondary or tertiary alkylamine co-reactants such as tri-*n*-propylamine (TPrA) which generally follows the oxidative-reductive or anodic co-reactant ECL mechanism.[1,2,3] However, the mechanisms at the counter electrode have largely been ignored. This offers a unique opportunity to further exploit ECL based systems, particularly for multiplexed analysis, by examining the electrochemical processes occurring at the counter electrode. Indeed, this work highlights the importance of considering this in the elucidation of ECL reaction mechanisms. Not surprisingly, the processes observed at the counter electrode were dependent on the configuration of the electrochemical cell, as (i) the voltage at the counter electrode is adjusted by the potentiostat to account for any change within the system to maintain the desired potential at the working electrode, and (ii) the position and geometry of the counter electrode will determine the portion of emitted light that is measured by the photodetector.[4]

Beyond the implications for investigation into ECL reaction mechanism, the recognition of processes at the counter electrode resulting in intense ECL and the development of our instrumental approach to distinguish the source of the emission creates exciting possibilities for analytical applications involving a dual ECL response at the working and counter electrode. A new approach to examine electrochemiluminescence (ECL), in which the potentials at both the working and counter electrodes are measured and the emitted light is detected by a photomultiplier tube, camera and then a charge-coupled device (CCD) spectrometer, provides unequivocal evidence that the purported cathodic ECL of [Ru(bpy)3]2+ and tri-n-propylamine actually arises from anodic reactions at the counter electrode.

Synthesis and electrocatalytic reduction of CO_2 on nanostructured materials

Anand Kumar
Department of Chemical Engineering
College of Engineering, Qatar University, P O Box 2713, Doha, Qatar
akumar@qu.edu.qa

Fossil fuels accounts for a large portion of the total energy required for human beings over the past decades as they produce higher current density than other energy systems, resulting in an exponential growth in CO_2 emission to the atmosphere. This causes environmental pollution as CO_2 is considered to be one of the major contributors to global warming. On the other hand, CO_2 is also an essential material for the growth of all plants and many industrial processes. In order to maintain the ecosystem stability, the total release of CO_2 in the environment by all sources should be balanced with what is consumed in an ideal scenario. Considering the worldwide total energy consumption trends, it is challenging is to stop using fossil fuels until environmentally clean energy systems are invented and adopted. Another possible approach is to capture and sequestrate CO_2 geologically or to convert CO_2 into useful chemicals such as low-carbon fuels. All over the word, many research groups are working on green technologies for the environmental friendly energy such as solar, wind, tidal and biomass energies whereas other research groups throughout the world are attempting to convert CO_2 into useful chemicals such as H_2, HCHO, HCOOH, CH_3OH, C_2H_5OH, CH_4 and CO with photo- or electro-catalysis and others or to capture and sequestrate with different adsorbents.

Herein, I plan to discuss the novel strategies adopted for synthesizing nanostructures for metallic and bimetallic catalysts and their performance for electrocatalytic reduction of CO_2. Some selected catalysts are also evaluated for thermal catalysis to compare the differences in activity and the nature of product when two different platforms are used. Catalysts are primarily composed of transition metals and their alloys (Cu, Ni, Zn, Co etc. and alloys with Ag). Combustion synthesis, hydrothermal techniques and galvanic exchange methods were adopted to fine-tune the surface and structure of the catalysts [1,2]. Some selected catalysts, e.g. Ni, Cu and Ag, were also deposited on fumed silica and calcined at high temperature to obtain supported catalysts for thermal-catalytic reduction of CO_2 [3]. Electrocatalytic results indicate selectivity towards formic acid, and formate species; whereas thermal catalytic results show a greater tendency towards methane and CO formation. All the catalysts were characterized in detail using XRD, XPS, SEM/TEM before and after the reaction to understand the structural changes owing to the reaction. Reaction pathway studies were also performed by using in-situ FTIR studies in DRIFTS mode to monitor the reaction intermediates with temperature.

Introduction Electrical stimulation is a therapeutic technique aiming at restoring impaired biological functions by injecting a controlled amount of charge in the body. Commonly used planar stimulation electrodes exhibit a non-uniform current density distribution (j) that can lead to locally exceeding the safe stimulation threshold[1]. An electrode can be recessed into an insulating part, which results in a different j [2], thus a different injection of charge, which can induce damage or insufficient stimulation. However, few studies[3] have focused on the influence of the recess parameters on j and how it could be used in electrode design. *Material & Methods* A finite element model was used to calculate j at recessed and non-recessed planar disc platinum electrodes in saline in response to an applied potential (COMSOL 54 Electrochemistry module). Recess shape (tubular and conical) and aspect ratio (AR), defined as recess depth divided by electrode diameter, were varied. Fig. 1 (c) shows a transverse view of a conical (left) and tubular (right) recess with the electrode covering the entire base of the recess. *Results* The tubular recess presents a uniform j at the electrode surface and at most depths throughout the recess, except at the open end of the recess, where the apparent j is more similar to the one of a non-recessed electrode, fig. 1(a, c). The conical recess presents a distribution more similar to a non-recessed electrode at the electrode surface, which becomes more uniform towards the recess end, fig. 1 (b, c). Increasing the AR makes j more uniform, both at the electrode surface and at the end of the recess, fig. 1 (a, b, d). At a given AR, varying the dimensions of the recess does not affect j, with relative standard deviations typically smaller than 0.5% (7 ARs tested, 3 pairs of dimensions per AR). *Discussion* The non-uniformity of j depended only on the recess shape and AR. Understanding this relationship will allow finetuning the current density profile at the electrode surface and at the recess end. For instance, a tubular recess with an AR larger than 2 will yield a uniform distribution at the electrode surface. Similarly, a conical recess of AR = 1/3 will reproduce the current density profile of a non-recessed electrode with less than 6% error, while being straightforward to manufacture. This study used a purely resistive model under steady-state conditions, which is a simple model for charge injection at an electrode-electrolyte interface. Further studies will consider a more realistic charge-transfer model and conditions closer to real dynamic electrical stimulation experiments.

In recent decades, direct alcohol fuel cells have been interested due to their advantages over hydrogen fuel cell. Alcohols such as methanol, ethanol and ethylene glycol are the most common types of fuel used in direct liquid-feed fuel cells. Moreover some of fuels are especially attractive as they can be produced from renewable biomass. Main advantages of liquid, low-molecular weight alcohols as fuel are that they can be easily handle storage and transported compared with hydrogen fuel.

One more important thing is research based on the development of new, various rare earth metals and metal oxides compositions, the improvement of known materials such as carbon with various additives with the aim to reduce or completely refuse of noble metal and to find low cost, more efficient and greater performance catalysts. Nanoparticles-based catalysts are usually heterogeneous catalysts broken up into metal nanoparticles in order to speed up the catalytic process. Metal nanoparticles have a higher surface area so there is increased catalytic activity because more catalytic reactions can occur at the same time. Pt is known as one of the best electrocatalysts for alcohols oxidation. However, among the many various catalysts studied for oxidation of alcohols in alkaline media Au was noticed to have high electrocatalytic activity towards the oxidation of alcohols and great tolerance for surface poisoning.

This paper presents comparison of electrocatalytic activities of $AuCo_3O_4/C$ and $PtCo_3O_4/C$ catalysts towards methanol, ethanol and ethylene glycol oxidation reactions in an alkaline medium. The Au and Pt nanoparticles were deposited on the Co_3O_4/carbon (Co_3O_4/C) substrate using microwave irradiation method. The composition, morphology and structure of the prepared catalysts were characterized using Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES), Transmission Electron Microscopy (TEM), X-ray Photoelectron Spectroscopy (XPS) and X-ray diffraction (XRD). Electrochemical analyses were performed using a cyclic voltammetry and chrono-techniques.

The amount of Au and Pt in the catalysts was evaluated by ICP-OES and equal to 0.105 and 0.147 mg cm^{-2}, respectively. The electrochemically active surface area of Au and Pt nanoparticles was calculated from the cyclic voltammograms recorded on the investigated catalysts and was equal to 0.23 and 1.1 cm^2, respectively. It has been determined that the $AuCo_3O_4/C$ catalyst showed 3, 8 and 5 times higher electrocatalytic activity towards methanol, ethanol and ethylene glycol oxidation compared with that obtained for the $PtCo_3O_4/C$ catalyst. The $AuCo_3O_4/C$ and $PtCo_3O_4/C$ catalysts also showed an enhanced electrocatalytic activity towards the oxidation of all investigated alcohols compared with the bare Au/C and Pt/C catalysts and Co_3O_4/C substrate.

Investigation of Electrochromism Process through Ultrafast Broadband Spectroelectrochemistry

Musah Zakaria, Hamza Kahri, Mohammed Ahmed Zabara, Can Berk Uzundal, Gozde Karaoglu, Burak Ulgut

Department of Chemistry, Bilkent University, Ankara 06800, Turkey

musah.zakaria@bilkent.edu.tr

Electrochromism is the reversible change in optical properties such as absorbance and transmittance of an electroactive material as a result of an induced redox reaction [1]. Electrochromic materials have gained much research attention since the discovery of organic conducting polymers with high prospects for diverse applications. The redox reaction leading to a color change in electrochromic materials is accompanied by doping/dedoping steps. Considering the oxidation of a neutral conducting polymer (for simplicity), first, the polymer loses electrons in a heterogeneous electron transfer leading to net positive charge creation. To achieve further oxidation, electroneutrality is restored by anions that diffuse from the bulk solution into the polymer. Since the diffusion rate of counterions is much slower than electron transfer, it is widely assumed that the oxidation process is limited by ion transport [2].

To test this assumption we employ Ultrafast Cyclic Voltammetry and broadband UV-visible spectroscopy to decouple ionic charge transfer from heterogeneous electron transfer during electrochromism in poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) thin films. We will present cyclic voltammetric experimental results at sweep rates up to 50kV/s obtained with a home-built fast potentiostat equipped with IR compensation. At such high sweep rates, the period for a full voltage sweep is reduced to the order of microseconds in which counterions do not have enough time to diffuse into the diffusion layer and we effectively exclude their contribution towards electrochromism in the PEDOT:PSS films. At these fast sweep rates, we monitor the electrochromic behavior of the polymer by in situ UV-visible spectroscopy. The collected spectra are compound or averaged spectra (because the spectrometer cannot keep up with the rate of conversion between the redox forms of the polymer during Ultrafast Cyclic Voltammetry). Using principal component analysis algorithm, we will decompose the compound spectra and calculate the time the polymer spends in each of its redox forms during the Ultrafast Cyclic Voltammetric experiments. We will also present the dependence of absorbance of the PEDOT:PSS thin films on sweep rate.

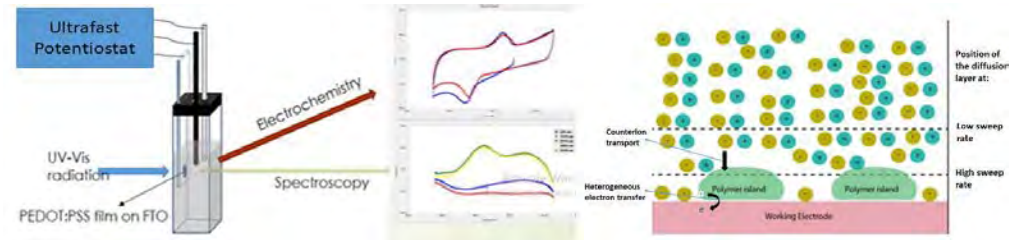

Fig 1. a) Spectroelectrochemistry setup b) Effect of sweep rate on diffusion layer thickness.

In a world that urgently needs to redress the balance of energy derived from fossil fuels, an efficient transformation of CO_2 into valuable chemicals (e.g., formic acid, methanol, methane) has become the key towards combatting climate change, environmental pollution and natural resource challenges. However, being a thermodynamically stable molecule, the ideal concept of a direct conversion of CO_2 into chemical energy has to overcome several limitations such as kinetic barriers to lower overpotentials, increase faradaic efficiency and promote products selectivity [1,2]. As such, its conversion into added value chemical feedstocks and fuels demands highly efficient catalysts. Noble metals are among the most performing catalysts, although they face challenges related to a high cost, sustainability and scarcity of precious metals. For this reason, the research in metal-free catalysts as sustainable and low-cost alternatives is attracting many efforts; advances in the development of highly performing non-metallic catalysts can make possible to overtake metal-based catalysts in the race towards the technological marketplace of carbon dioxide conversion into chemicals [3].

In this context, the objective of the study is to screen metal-free carbon materials as sustainable and efficient electrocatalysts for the conversion of CO_2 into fuels. Despite some carbon materials have been successfully used for this purpose, yet the origin of their electrocatalytic activity and/or the nature of the active sites capable of reacting with the CO_2 molecule remain unclear. Thus a smart design of carbon-based catalysts with adequate electroactive sites is needed**.** For this reason, we have selected a series of carbons with different chemical, structural and textural properties, and analyzed their response as electrocatalysts for the reduction of carbon dioxide under different polarization conditions. A detailed rationalization of the conversion yields and selectivity towards different products will be discussed considering the interactions CO_2-carbon material, analyzing the effect of the pore confinement, the presence of specific surface bonds that might control charge transfer reactions and/or electrochemical features necessary to activate a stable electrocatalytic transformation of carbon dioxide.

Acknowledgments. This project has received funding from the European Research Council through a Consolidator Grant (ERC-CoG PHOROSOL, grant agreement 648161).

Comparative Study of the Electrical Conductivity of Carbon Materials Measured Using Various Approaches

Eder Amayuelas, Hafssa Arraghraghi, Ana Casanova, Encarnacion Raymundo, Conchi Ania
CEMHTI, CNRS (UPR 3079), Université d'Orléans, 45071 Orléans, France
eder.amayuelas-lopez@cnrs-orleans.fr

Carbon-based electrodes are largely used in many electrochemical applications over a wide variety of competitors owing to the diversity of existing carbon materials with good chemical and mechanical stability, relatively high electronic conductivity, and low cost and sustainability [1-3]. Although some carbons present electronic properties close to those of metallic electrodes (e.g., graphite, graphene and derivatives), this is not the case for many other members of the carbon family, since the heir conductivity depends strongly on the spatial arrangement of the carbon atoms. One example is the case of nanoporous carbons which usually display a low structural order, as a result of which their electronic conductivity is about 4-5 orders of magnitude lower than that of graphite or graphene [4]. For such materials, measuring the electrical conductivity is complex, and despite various methods have been reported in the literature, the comparison of the values obtained by different authors is not straightforward [5,6]. Considering this, the objective of this study was to determine the electrical conductivity of a selection of carbon materials with different structural order, chemical composition, and porous features using various methodologies: four-point probe technique, impedance spectroscopy, Van der Pauw method. Gathered data has shown that the dispersion in the conductivity values is quite low when the carbons display high electron mobility (e.g., graphite, graphene, carbon black). In contrasts, when carbons with moderate to low electron mobility are measured (e.g., amorphous and functionalized porous carbons, graphene oxide, reduced graphene oxide), the differences between the values obtained with different methods become more pronounced. The values obtained using the four probe methods are reliable for carbon materials with a low level of anisotropy, provided that the pellets are homogenous at a macroscopic scale. In contrast, the values obtained by impedance spectroscopy of thin pellets seemed to be quite consistent in all cases.

Acknowledgments. This project has received funding from the European Research Council through a Consolidator Grant (ERC-CoG PHOROSOL, grant agreement 648161).

Zinc oxide (ZnO) is a n-type semiconductor with numerous applications in photocatalysis due to its abundance, non-toxicity, versatility and unique photoelectrical properties, as a wide band gap of 3.37 eV and high electron mobility, from 10 to 100 times higher compared to titanium dioxide.

In the present study, ZnO nanostructures were synthesized by anodization method in an aqueous bicarbonate electrolyte with different amounts (10, 25 and 50 v/v %) of ethanol (E) under controlled hydrodynamic (H) and stagnant (S) conditions followed by thermal annealing. Morphology, crystallinity, and vibrational properties of the samples were studied by means of Field Emission Scanning Electron Microscopy (FE-SEM) and Confocal Laser-Raman Spectroscopy. Finally, photoelectrochemical water splitting measurements using ZnO nanostructures as photoanodes were performed.

According to the results, the synthesized ZnO nanostructures presented high photosensibility during water splitting experiments in aqueous Na_2S/Na_2SO_3 electrolyte as it is shown in Figure 1. In particular, the sample anodized in 10 v/v % ethanol electrolyte at stagnant conditions (S-E-10 in Figure 1 (a)) presented the highest photocurrent density response with a value of 0.34 mA/cm^2 at an applied potential of -0.46 $V_{Ag/AgCl}$.

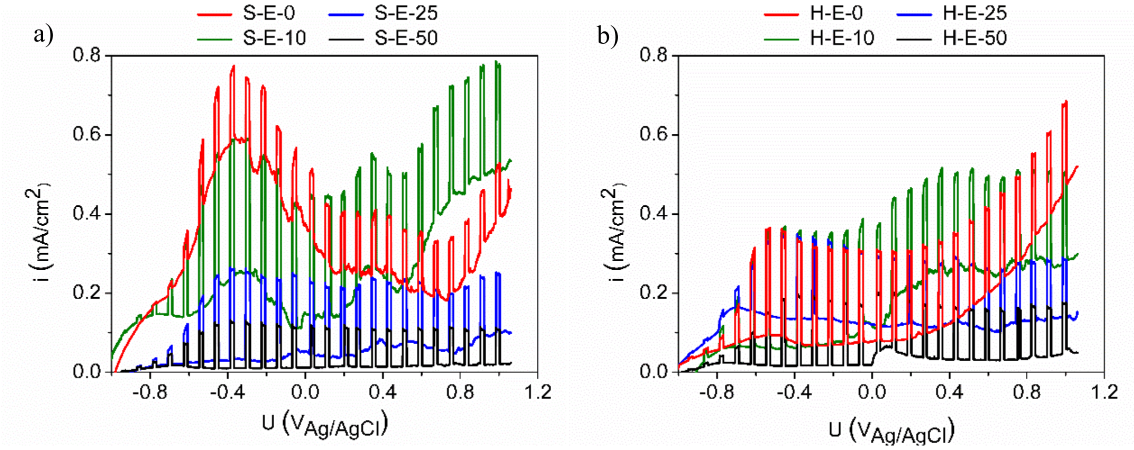

Figure 1. Current density under on/off simulated sunlight as a function of the applied potential for the nanostructures anodized at stagnant (a) and hydrodynamic (b) conditions.

Wastewater usually contains a large amount of recalcitrant pollutants and its composition is complex. The wastewater pollutants include textile dyes, pharmaceuticals, pesticides, heavy metals, pulp and paper, surfactants, and other chemicals. Therefore, it is crucial to apply clean, environmentally friendly, and efficient wastewater treatment technologies that can remove these pollutants.

Nanostructures of different materials are interesting for being used as photocatalysts in advanced oxidation processes like the one known as photoelectrocatalysis (PEC). Tungsten oxide is one of the best options due to its properties, such as suitable band gap, non-toxicity, high chemical stability in low pH values and ability to absorb a reasonable fraction of the solar spectrum.

In this work, the synthesis of WO_3 nanostructures by electrochemical anodization has been optimized by means of an experiment design 3^3 in which three factors of the process have been varied with three different levels. These factors have been the electrolyte used during anodization, the annealing temperature and the annealing atmosphere in the post-anodization thermal process. The acids used as electrolyte have been sulfuric acid (H_2SO_4), methanesulfonic acid (CH_4O_3S) and nitric acid (HNO_3). The heating temperature varied between 400 °C, 500 °C and 600 °C, while the atmospheres tested were air, nitrogen and argon.

In order to analyze the properties of each sample obtained, different morphological, structural, electrochemical and photoelectrochemical techniques were used to characterize the nanostructures.

Once the optimal nanostructures were obtained, they were used to degrade fenamiphos, a harmful and toxic organophosphate pesticide. For this purpose, the technique known as photoelectrocatalysis was used, where the nanostructures obtained previously acted as photoanodes. This process was monitored using UV-Visible and HPLC to verify that the entire process was going as expected and to subsequently analyze the percentage and kinetics of degradation.

The obtained results showed that the optimal conditions for the synthesis of nanostructures are as follows: use of CH_4O_3S and subsequently heat the nanostructures in an air atmosphere at 600 °C, since a better photoelectrochemical behaviour was obtained. The fenamiphos degradation was achieved at 2 h of experiment and the intermediate formation was noticed at 1 h of PEC experiment.

Synergic Effects between Carbon and Redox Couples Dispersed in Electrolytes for Zn-air Batteries

E. Pujades-Otero, D. Tonti, N. Casañ-Pastor
Institut de Ciència de Materials de Barcelona (ICMAB, CSIC)
Campus UAB, E-08193, Bellaterra, Barcelona, Spain
epujades@icmab.es

The use of nanocarbons as dispersed conducting particles can bring interesting advantages in the electrolyte of electrochemical storage devices as this material can ensure a high conductivity and area. Moreover, the introduction of multiredox couples dispersed in the electrolyte can also lead to remarkable improvements, as seen in Li/air batteries[1], [2]. These redox couples can act both as redox mediators and catalysts for the oxygen reduction or evolution reactions (ORR, OER) that take place during the battery cycling. Polyoxometalate clusters or other nanoparticles such as IrOx are already known by their catalytic activity in O_2 reduction and reoxidation processes[3].
Herein, the influence of carbon and redox couples in aqueous alkaline and organic media has been studied for Zn-O_2 cell electrolytes. Furthermore, the interaction between carbons and the redox compounds have also been tested, as a significantly enhanced catalytic activity is expected being the redox particles coupled to the carbons. We do observe a synergy between the redox and the conducting species giving rise to enhanced currents and lower overpotentials. The relevant parameters and hypothesis for a mechanism will be discussed.

Nitrogen-doped Nanoarrays Modified 3D Hierarchical Graphene as Co-Function Host for High Performance Flexible Li-S Battery

Ruichao Lu, Meng Cheng, Lijuan Mao, Miao Zhang, Yuena Meng,* Zhixiang Wei*
National Center for Nanoscience and Technology
No. 11, Beiyitiao Zhongguancun, Beijing 100190, P. R. China

Lithium-sulfur (Li-S) batteries with high energy density and low cost are regarded as promising candidates for the next-generation energy storage systems.[1] Practical application of Li-S batteries is still hindered by both the shuttle effect of polysulfides and the severe Li dendrites growth. To overcome challenges in Li-S batteries, various ways have been thoroughly explored for Li anode or S cathode separately with little attention to the co-function hosts for both Li and S.[2, 3] We believe that the co-function hosts are prospective with simultaneous promotion for both Li anode and S cathode. Luckily, there are various similarities in the design of structures and properties, such as highly conductive skeleton to effectively host active materials and uniformly polar surface to improve the performances, which makes it possible to use the same material to improve performances simultaneously. Therefore, to build an approach of co-function hosts for Li anode and S cathode simultaneously, a rational design of 3D hierarchical skeleton is highly desired.

Herein, we designed and fabricated a 3D, freestanding and hierarchical porous reduced graphene oxide with N-doped nanoarrays (3DRGO/NC) as the co-function host for Li anode and S cathode. The 3D freestanding porous RGO forms the main skeleton structure to hold the Li metal and elemental S, and heteroatom N doping can lower the Li nucleation overpotential and immobilize the polysulfides. More importantly, the well-aligned nanoarrays can effectively confine Li-ions flux and provide an optimized ion-diffusion pathway for better Li plating/stripping behavior and enhanced S utilization/conversion. Particularly, an ultrathin graphene barrier layer was built on RGO with N-doped nanoarrays (3DRGO/NC-BL) which can effectively retain intermediate polysulfides staying in the cathode through physical confinement. As a result, the 3DRGO/NC shows a perfect Li plating behavior without growth of Li dendrite or "bulk" Li deposition, high CE of 98.0% for 300 cycles with low nucleation overpotential (14 mV), long cycle lifespan (500 h) and perfect rate performance. The 3DRGO/NC-BL exhibit high initial discharge capacity of 1185 mAh g^{-1} with excellent CE and present a long stability up to 500 cycles with high-reversible specific capacity of 927 mAh g^{-1}. Most importantly, a flexible battery is demonstrated with excellent performance in flat, bent, and even rolled states by combining 3DRGO/NC@Li anode and 3DRGO/NC-BL@S cathode, which provide a promising strategy for flexible energy-storage devices.

The compounds of the so-called MAX phases class (where M is a transition metal, A is an element of the main subgroup of the III-V groups of the periodic system, X is carbon or nitrogen), which were firstly synthesized in the 1970s are widely used as the basis of structural materials due to high mechanical strength, outstanding heat and electroconductive properties, as well as chemical stability [1]. We used one of such compounds – Ti_3SiC_2 (TSC) [2] for the particles surface modification of polyanionic cathode materials for lithium-ion battery e.g. $Li_3V_2(PO_4)_3$/carbon composite (LVP/C). TSC modified LVP/C demonstrates improved electrochemical behavior (Fig. 1) [3].

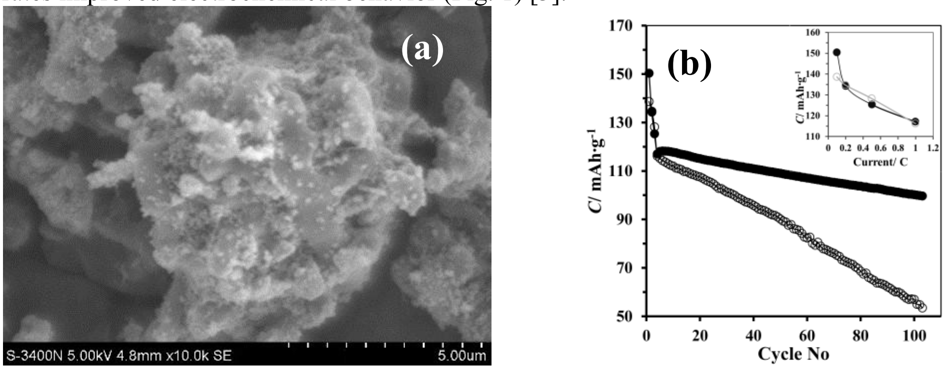

Fig. 1: Scanning electron micrograph (*a*) and galvanostatic charge/discharge capacity behavior (*b*) of the TSC-modified LVP/C-electrode. Empty markers of (b) correspond to the material with bare particles, filled markers – TSC-modified particles.

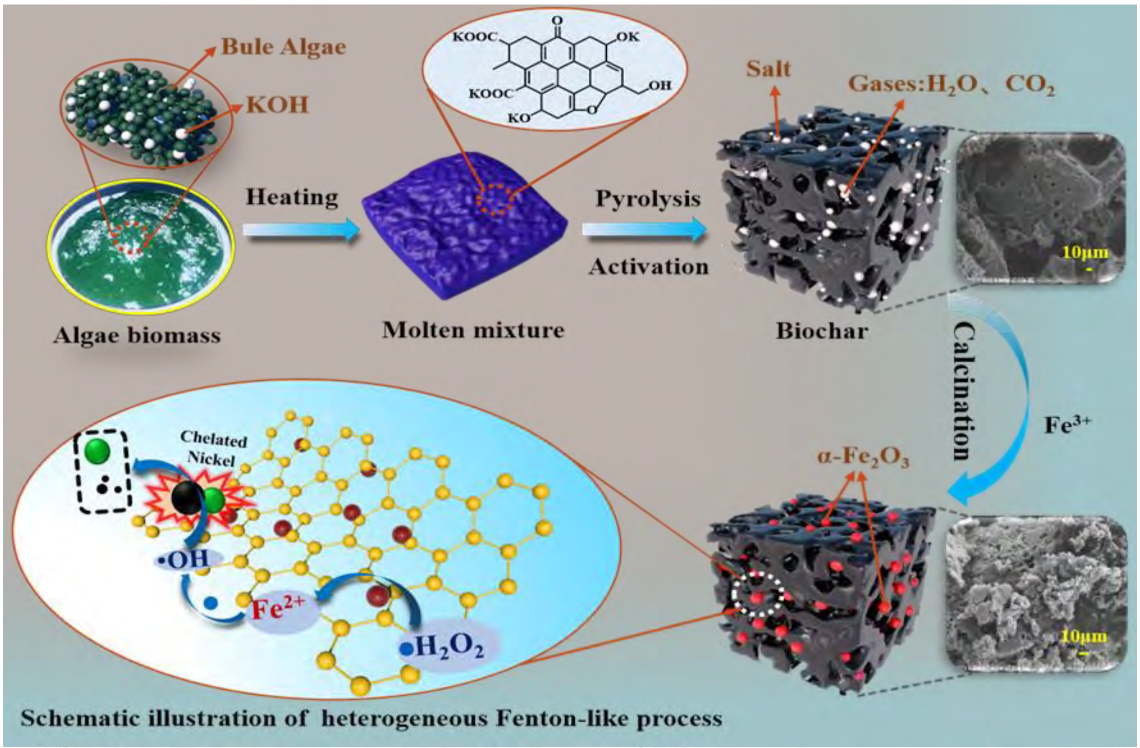
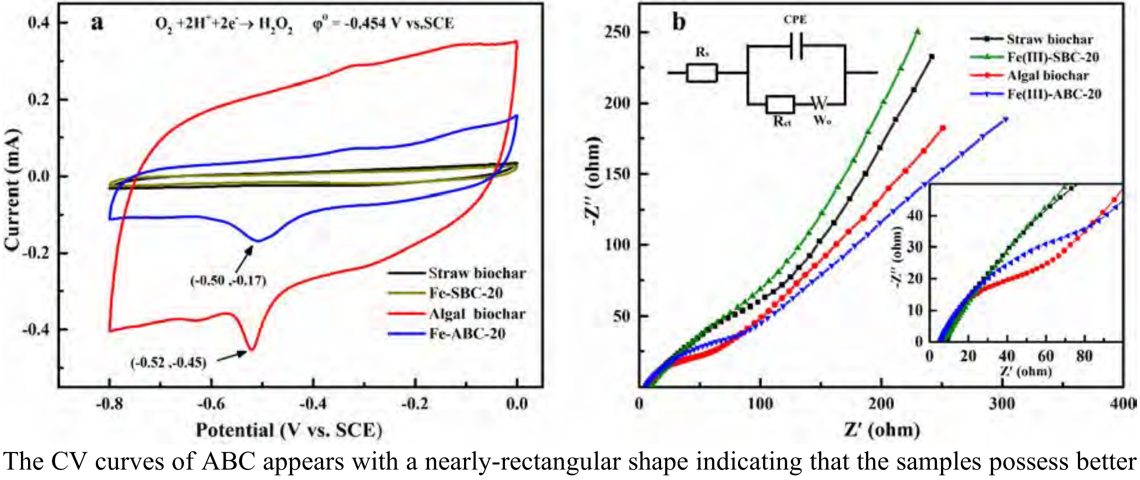
Modified Blue Algae Biochar Electrode for CO2RR

Qun Yan, He Wang
Jiangnan University
School of Environmental and Civil Engineering, Jiangnan University, Wuxi 214122, China.
yanqun@jiangnan.edu.cn s



Schematic illustration of heterogeneous Fenton-like process



The CV curves of ABC appears with a nearly-rectangular shape indicating that the samples possess better capacitance traits and smaller internal resistance. After the iron loading, the CV curve is significantly narrowed and the current peak shifts to -0.5 V. This is due to the iron loading blocked the porous algal biochar structure, thereby reducing the electric double layer capacitance. In addition, the right shifting and widening of the current peak could be attributed to the reduction of Fe(III) via the presence of ligand to metal charge transfer (LMCT).

EIS curve of the ABC electrode appeared as an approximate semicircular arc with smaller diameter than that of Fe(III)-ABC-20, SBC and Fe(III)-SBC-20 electrodes, implying the ABC based electrode possess lower electron transfer resistance than their SBC based counterparts.

Nitrogen-doped graphenic materials: towards platinum-free catalytic layers in PEMFCs

Lilian Moumaneix[12*], Sébastien Fontana[1], Claire Hérold[1], François Lapicque[2]

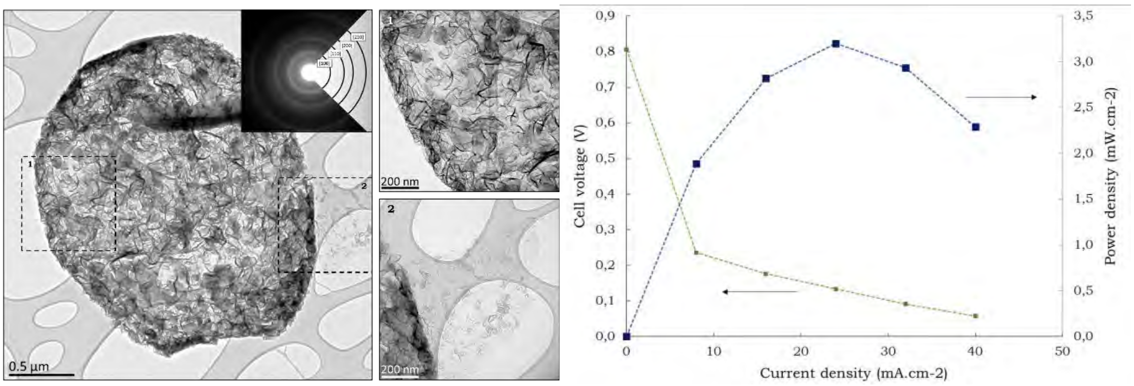
Platinum nanoparticles dispersed over porous carbon materials are still widely used as catalysts for oxygen reduction reaction in polymer fuel cells. However, platinum resources are diminishing rapidly, and the lack of recycling solution will aggravate the situation for this critical metal during the next century. Nitrogen-doped graphenic materials are investigated as cheap alternative to platinum since nitrogen is able to catalyze oxygen reduction by partially redistributing the electric charges of the neighboring carbon atoms.

An original synthesis route to nitrogen-doped graphenic foam has been developed, this material exhibiting both polycrystallinity with surface area up to 2200 $m^2.g^{-1}$, and electrochemical properties brought by the nitrogen doping (1-3 at.%).

Recently, our materials have been tested in a complete PEMFC setup in impedance and potentiometric measurements, to assess their performance in energy production and their kinetic capacities. First tests showed that N-doped graphenic foam as cathode catalyst, allows current density over 30 $mA.cm^{-2}$, a power density of 3.2 $mW.cm^{-2}$, approximately 50-fold larger than with nitrogen-free graphenic foam. While nitrogen atoms appear essential to catalytic activity, intrinsic carbon defects nature, pore size or oxygen functions content could also play an essential role for catalysis purpose, as currently studied to optimize furthermore our materials.



TEM micrographs of N-doped graphenic foam; electrochemical performance of N-doped graphenic foam as cathode catalyst during PEMFC operation

Photoremoval of Cyanobacteria and Cyanotoxins by Magnetic ZnO-based Photocatalysts

Promoted by rising global temperatures and anthropological trends such as water pollution, the formation of harmful cyanobacterial algal blooms and, in turn, the release of cyanotoxins are becoming major problems worldwide. In response, the development of efficient, effective strategies and technologies for treating cyanobacteria and cyanotoxins, especially in drinking and recreational water, is urgently required. In the study reported here, a circular process (**Figure 1**) for water decontamination and biofuel production to minimize the generation of residues and improve the efficiency of photocatalysts was proposed. Spirulina was cultivated using microalgal ashes while carbon dioxide was fixed and oxygen was released, and microalgal ashes generated during the combustion of microalgal pellets were recycled as a supplement for the cultivation media. Next, magnetic hybrid ZnO-based photocatalysts were synthesized following a biotemplating process involving Ni electroless deposition, ZnO deposition, and sulfidation, which led to the formation of onion-shape Ni@ZnO@ZnS-microalgae hybrids. Ultimately, the hybrids, which exhibited excellent photocatalytic activity for the degradation of cyanotoxins (i.e., anatoxin-A) and two species of cyanobacteria, were implemented for water decontamination using sunlight irradiation and recycled after their effective lifetime for the manufacture of microalgal biopellets as biofuel.

Using 4-aminophenol as an intermediate in manufacturing analgesic and antipyretic drugs has given the product important commercial value. Currently, several methods are available for synthesizing 4-nitrophenol, the most relevant being the multistep iron-acid reduction of 4-nitrochlorobenzene or 4-nitrophenol, the catalytic hydrogenation of nitrobenzene, and the electrochemical reduction of 4-nitrophenol. However, the necessary use of highly corrosive mineral acids and dangerous toxic reducing agents, poor chemoselectivity and yields, and the growing demand for 4-aminophenol demonstrate the need for developing or optimizing green, efficient routes for preparing 4-aminophenol. Among possible options, organic electrosynthesis can realize an environmentally friendly, chemoselective redox transformation under conditions free of exogenous reductants due to the use of electric current. However, the optimization of efficient electrocatalysers and electrochemical media conditions needs to be further studied to propose such a route for synthesizing 4-aminophenol.

In the study reported here, the electrosynthesis of highly accessible, well-defined porous Au micropillars for use as electrocatalyzers in the chemoselective electroreduction of 4-nitrophenol was optimized. Using the double shape-controlled electrodeposition of Au based on the combination of 3D laser lithography and colloidal lithography allowed the reproducible synthesis of porous Au micropillars with highly accessible surface areas. Additionally, using the porous Au micropillars in moderately acidic conditions realized the electrosynthesis of 4-aminophenol, both in high yields and with high chemoselectivity. Porous Au micropillars can thus also contribute to an efficient, environmentally friendly method of removing 4-nitrophenol from wastewater. The electrosynthesis of porous Au micropillars as electrocatalyzers for 4-nitrophenol reductions can offer a competitive, ecofriendly strategy for electrosynthesizing 4-aminophenol and decontaminating wastewater.

Polyoxometalates (POMs) are composed of cations and polyanion clusters with structural diversity. POM anions in their ground states can be excited by UV or near- visible light.[1, 2] The essence of excitation is the charge transfer from an oxygen atom to the d^0 TM (transition metal) in the presence of light with abundant energy. In order to expand its application scope, we expect it to be connected with porphyrins, a common photosensitizer, and applied to the visible region.[3] Here, a non-noble Fe-based POM (Anderson) with ZnT_2P porphyrin was synthesized by electropolymerization. This process was also monitored by EQCM (Electrochemical Quartz Crystal Microbalance). The copolymer was characterized by UV-Vis-NIR spectroscopy, electrochemistry.

Their electrical properties have been studied by electrochemical impedance spectroscopy and their photovoltaic performances have been investigated by photocurrent transient measurements under visible-NIR light irradiation. The photocurrent for the $Fe^{III}POM\text{-}ZnT_2isoP^{\bullet}$ copolymer can be up to 200 μA/cm^2.

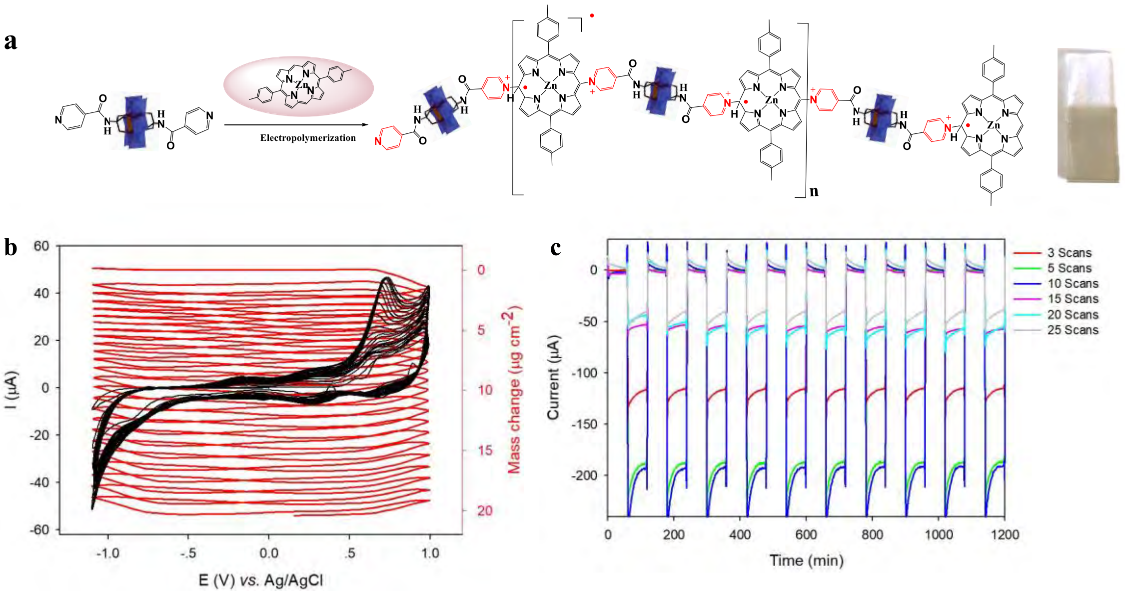

Figure 1. a) Structure of $Fe^{III}POM\text{-}ZnT_2isoP^{\bullet}$ copolymer. **b)** Consecutive cyclic voltammograms (first 25 scans) and electrochemical quartz crystal microbalance measurements (Δm) for the first 25 scans during the electropolymerization. **c)** Transient photocurrent study for $Fe^{III}POM\text{-}ZnT_2isoP^{\bullet}$ copolymer.

The development of efficient catalysts is significant in order to achieve the shift from fossil fuels to sustainable alternatives, such as hydrogen energy.[1] One of the promising ways to synthesize electrocatalysts is to combine metal nanostructures with supports that possess high electrical conductivity as well as high surface area.[2,3] Here, we reported a general method for the synthesis of metal nanoparticle/nanocarbon composite, denoted as M(nP)/nC, which included generation of graphenide solution from graphitic carbon source and reaction between graphenide solution and metal salt. Electrocatalytic performance of the prepared materials were measured for reactions in water electrolyzer and fuel cell, such as the hydrogen evolution reaction (HER), oxygen evolution reaction (OER), and oxygen reduction reaction (ORR).

On the one hand, starting with various carbon sources, graphenide solutions with carbon flakes differing in lateral dimension were achieved; after reaction with iron salt, iron nanoparticle/nanocarbon composites were generated with controllable size of iron nanoparticles. Electrochemical measurements showed that the choice of initial carbon was crucial for determining the scale of carbon flake and simultaneously tailoring the size of iron nanoparticles, which had a major impact on electrocatalytic performance for the ORR and OER. On the other hand, following the same synthetic method, when tuning metal species from transition metal iron to noble metal rhodium, nanocarbon with decoration of rhodium nanoparticles was also successfully synthesized and displayed efficient electrocatalytic activity for the OER and HER in alkaline condition.

Herein, Vulcan XC-72 was functionalized with the home-obtained mesityl copper (Cu-mes) organometallic compound. $C_{Cu\text{-}mes}$ was characterized by FTIR, and Raman. The results showed the successful incorporation of organometallic compound and structural modification of Vulcan. Afterwards, Pd nanoparticles were dispersed on the novel supports by the polyol method, obtaining 20 wt. % $Pd/C_{Cu\text{-}mes}$. The nanocatalyst was characterized by XRD, where a shift towards higher 2θ angles indicated the formation of alloyed Pd-Cu phases. The crystallite size was estimated using the Scherrer equation, obtaining values of 2.9 and 6.9 nm for $Pd/C_{Cu\text{-}mes}$ and conventional Pd/C, respectively. Chemical composition analysis showed that the organometallic compounds are chemically stable, maintaining a high Cu concentration after the synthesis of the nanocatalyst. XPS analysis of $Pd/C_{Cu\text{-}mes}$ indicated mainly the presence of Cu^0 and Cu^{+2} in the Cu 2p region. At the Pd 3d region, the Pd^0, Pd^{+2}, Pd^{+4} species have been identified. In the case of Pd/C the three species were also observed. Moreover, there was a shift to higher BE of the doublets in $Pd/C_{Cu\text{-}mes}$ compared Pd/C, attributed to the chemical interaction between Pd and Cu. The electrochemical characterization was performed in 0.5 mol L^{-1} KOH. The ECSA values of $Pd/C_{Cu\text{-}mes}$ and Pd/C were 118.72 and 24.55 $m^2\ g^{-1}$, respectively. A higher value was obtained for $Pd/C_{Cu\text{-}mes}$, indicating a large number of active sites that participate in the electrochemical reaction, which can also be related to the electrocatalytic activity of the nanocatalyst. The catalytic activity of the nanocatalyst in CO-stripping tests showed that the CO oxidation occurs at more negative potentials in $Pd/C_{Cu\text{-}mes}$ compared to Pd/C. The polarization curves of the EOR at the nanocatalysts showed that $Pd/C_{Cu\text{-}mes}$ promotes the reaction at a more negative onset potential, i.e., E_{onset} = 0.38 V/RHE, compared to 0.41 V/RHE of Pd/C. The mass current density (j_m) was considerably higher at $Pd/C_{Cu\text{-}mes}$ (1234 mA $mg^{-1}{}_{Pd}$), compared with Pd/C (665 mA $mg^{-1}{}_{Pd}$). An electrolysis test was carried out for 4 h where is important to remark that the nanocatalysts supported in functionalized Vulcan consumed a higher percentage of ethanol (61%) during electrolysis than Pd/C (47%), which indicated a higher catalytic activity and stability over time. In AEM-DEFC tests, the cell equipped with a $Pd/C_{Cu\text{-}mes}$ nanocatalyst anode showed the highest open circuit voltage (OCV) 0.60 V, compared to 0.50 V at the cell having a Pd/C anode, respectively. The maximum power density value was 0.14 W cm^{-2} at 0.5 A cm^{-2} by $Pd/C_{Cu\text{-}mes}$. The results of this study clearly showed an enhanced behavior for the EOR in alkaline media by the nanocatalysts supported on functionalized Vulcan with Cu-mes, attributed to the formation of alloy phases between Pd and Cu and therefore the combination of the bifunctional mechanism, as well as ligand and strain effects. In summary, $Pd/C_{Cu\text{-}mes}$ showed a high catalytic activity in AEM-DEFC applications.

Electrochemical Investigation of Gramicidin Reconstituted into Liquid Crystalline Cubic Phases

A. Buta,[a,b] E. Nazaruk,[a] R. Bilewicz[a]
[a]Faculty of Chemistry, University of Warsaw, Pasteura 1, 02-093 Warsaw, Poland.

e-mail: abuta@chem.uw.edu.pl

Liquid crystalline phases composed of lipids, water and incorporated ionophores such as gramicidin, provide a useful tool for the study of membrane transport. Lipidic cubic phase (LCP) consists of interpenetrating but noncontacting aqueous channels surrounded by a lipid bilayer. These compartments are continuous in three dimensions, so the mesophase is called "bicontinuous". Specific features of lipid cubic phase structure make them convenient for electrochemical measurements: they are stable in the presence of excess of water, highly viscous, and can be easily placed at the electrode surface. The amount of protein sample needed for the measurements is small and its stability is increased. Such membrane is biomimetic and the conditions resemble those typical for biological bilayers - therefore the incorporated proteins and peptides can maintain their activity.

Gramicidin is a polypeptide antibiotic, a dimer that forms small pores in the membrane and allows the movement of monovalent cations. The antibacterial effect of gramicidin is based on increasing the permeability of e.g. potassium ions through membranes, which ultimately leads to the death of the bacterial cell. In the literature there are other examples of the pore forming peptides applied as drugs[1] and a number of studies on diseases in which the formation of pores occurs in the cell membrane including bacterial infections[2] or Alzheimer's disease[3]. Gramicidin, due to its small size and easy accessibility, can serve as a good model of transmembrane channels.

The goals of our study were to prepare a stable monoolein cubic phase (*Pn3m*) with and without incorporated gramicidin. The phase identity and structural parameters of the lipid samples were determined by Small-Angle X-ray Scattering (SAXS). The ion transport of gramicidin incorporated into LCP was studied by cyclic voltammetry (CV) and chronoamperometry (CA). The glassy carbon electrodes covered with a film of cubic phase with and without gramicidin were exposed to solutions of different concentrations of KCl and the currents were recorded upon application of potential steps towards positive and negative values of potential. The electrode capacitance and resistance of the films were evaluated by impedance spectroscopy (EIS).

The project is implemented under the Operational Program Knowledge Education Development

2014 - 2020 co-financed from the European Social Fund.

Disulfide Bridges-based Polymer as Cathode for Rechargeable Li and Mg Batteries

Anh Ngoc Tran, Jean-Claude Leprêtre, Fannie Alloin

Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, Grenoble INP, LEPMI, 38000 Grenoble, France

E-mail address: ngoc-anh.tran@grenoble-inp.fr

The new technological era to take over from Li battery system is currently investigated at a fast rate.[1] In this regard, the Mg based battery system has gained considerable popularity as an alternative system since they proffer to provide one of the best economical solutions for electrical storage.[2,3] Contrary to metal-based inorganic active materials, organic materials seem very well adapted to the divalent character of Mg^{2+}, and the performance obtained with Mg^{2+} opening a wide window of investigations for the development of organic positive electrodes with high capacity using Mg as negative electrode. In this study, polybenzoquinonyldisulfide (PBQDS) in lithium and magnesium-based electrolytes were investigated using cavity micro-electrode technic and galvanostatic cyclic tests. In this study, diglyme and sulfolane solvents, associated with both LiTFSI and $Mg(TFSI)_2$ were used. The electrochemical characteristics of PBQDS are truly similar in term of potential and ΔE_{peak} in both lithium and magnesium systems at a relative high scan rate, i.e. 1 mVs^{-1}. An improvement of the redox couple reversibility seems to be observed in Mg form, with a ΔE_{peak}= 400 mV with $E_{1/2}$ near 3 V *vs* Mg^{2+}/Mg. Based on this interesting behavior, PBQDS was investigated in a coin cell configuration as active material in the present of glyme or sulfolane based electrolytes. The cell achieved a stable capacity of 140 $mAh.g^{-1}$ in sulfolane + LiTFSI at C/20, whereas a value of 105 $mAh.g^{-1}$ in sulfolane + $Mg(TFSI)_2$ can be obtained. The electrochemical process involved in both Mg and Li based electrolytes was compared.

Mental disorders like schizophrenia affect about 0.7% of the world population[1]. Nowadays, the treatment consists of atypical anti-psychotic drugs, mainly olanzapine (OLZP) and quetiapine (QTP)[2]. It was observed a chemical interaction between both OLZP and QTP ~~, anti-psychotic drugs,~~ with dopamine (DA) in phosphate buffer solutions at physiological pH using cyclic and differential pulse voltammetry techniques. DA electrochemical oxidation was hindering in the presence of both OLZP and QTP. ~~A solution containing both anti-psychotic drugs and DA presented a shift of DA's redox processes, hindering its electrochemical oxidation. We investigate the chemical interaction voltametrically and obtained that b~~Both drugs presented ~~a first~~ first-order kinetics with DA, presenting kinetic rate constants of 1.54 10^{-2} s^{-1} and 7.78 10^{-3} s^{-1} for OLZP and QTP, respectively. To further evaluate the ~~the~~ chemical reaction, a minimalist model ~~between~~ was proposed using PIPES buffer ~~molecule~~ and ~~cathecol~~catechol to simulated the DA- drug interaction. ~~was proposed and tested.~~ The model presented a similar signal decrease and kinetic rate constant with those observed for both OLZP and QTP reaction with DA, suggesting that a chemical interaction occurs between piperazine and catechol moieties.

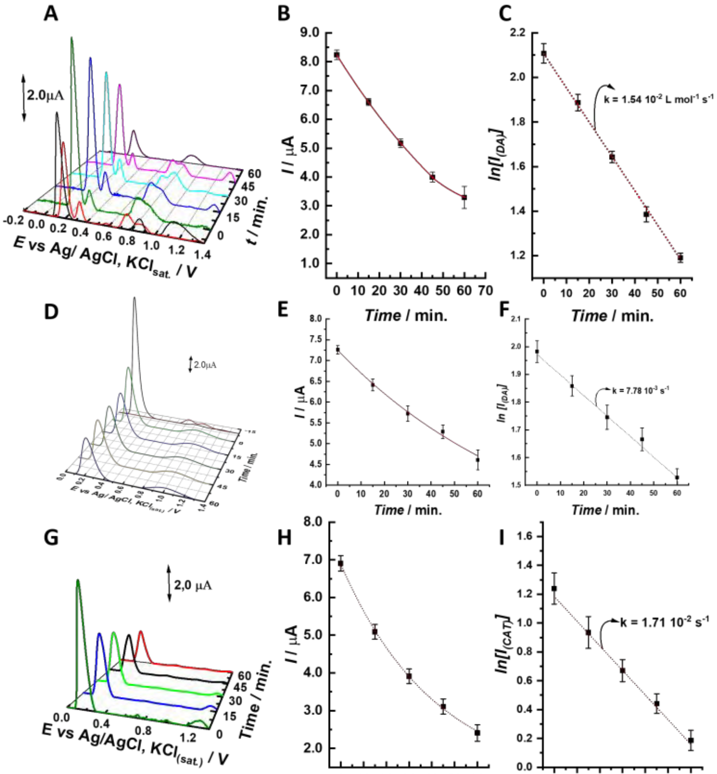

Figure 1: DPV of solutions containing A) 1.0 mM, each, of OLZP and DA; D) 1.0 mM, each, of QTP and DA; G) 1.0 mM, each, of Pipes and CAT in PBS 0.1 M, pH = 7.4; I x t plots of the respective DPV (B-A; E-D; H-G); lnI x t plots of the respective DPV (C-A; F-D; I-G).

PEDOT Nanotubes: From Synthesis to Energy Storage and Electrocatalysis Applications

Bruna M. Hryniewicz, Larissa Bach-Toledo and Marcio Vidotti
Federal University of Paraná, Chemistry Department
CP 19032, 81531-980, Curitiba, PR, Brazil
brumahry@gmail.com

Nanostructured conducting polymers have been extensively studied to improve properties and achieve new characteristics when compared to bulk polymers. In this work, poly-3,4(ethylenedioxythiophene) nanotubes (PEDOT-NTs) were successfully electrodeposited onto flexible stainless-steel mesh electrodes in the presence of methyl orange (MO) template [1]. It was found that the pH of the reaction medium is an important parameter to tune up the final morphology (Fig. 1). The modified electrodes were characterized by scanning electron microscopy (SEM) and transmission electron microscopy. To better understand the mechanism of nanotube formation, the current-time transients obtained in the synthesis were fitted according to a theoretical model.

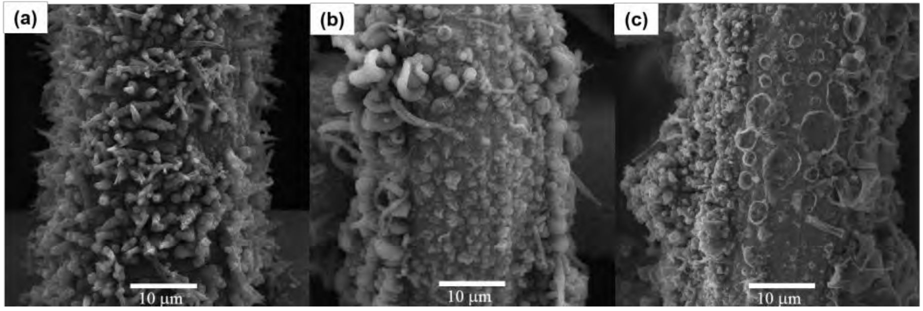

Fig. 1. SEM images of PEDOT synthesized in the presence of MO at (a) pH 2, (b) pH 4 and (c) pH 7

In this work, we report the study of the multifunctionality of PEDOT-NTs synthesized at pH 2 in energy storage and electrocatalytic degradation of nitrophenol isomers. The United States Environmental Protection Agency listed NPhs as priority pollutants, and *ortho* and *para* are classified as hazardous substances [2]. Moreover, nitroaromatics compounds are stable and recalcitrance to degradation [3]. The NPh reactions (Fig. 2(a)) provided an enhanced pseudocapacitance performance, reaching a specific capacitance 50% higher than PEDOT-NTs in the absence of NPhs (Fig. 2(b)). The presence of NPhs during the charge and discharge curves also increased the stability of the material (Fig. 2(c)) by forming poly(aminophenols) during the electrocatalytical processes. The extension of NPh degradation was evaluated by UV-Vis spectroscopy and the electrodes were characterized by electrochemical, vibrational spectroscopic and scanning electron microscopy techniques. By this way, this contribution presents an interesting perspective gathering the degradation of micropollutants and the energy storage devices which are certainly two of the biggest concerns of the scientific community nowadays [4].

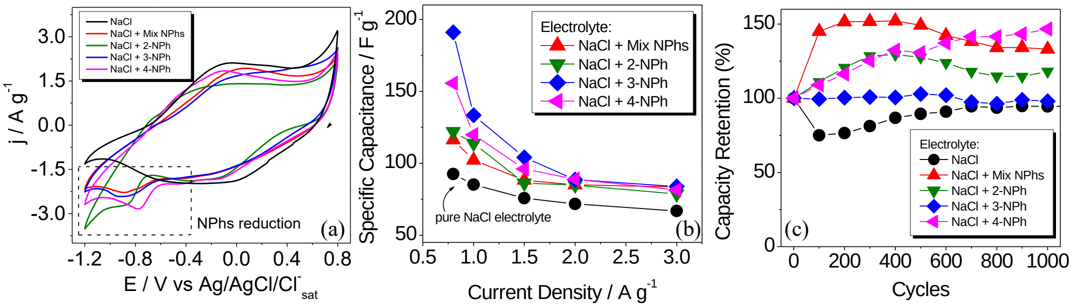

Fig. 2. (a) CVs of PEDOT-NTs at 20 mV s^{-1}, (b) specific capacitances calculated from GCD cycles at different current densities and (c) stability of the modified electrode during 1000 GCD cycles at 3 A g^{-1} in 1 mol L^{-1} NaCl in the absence and in the presence of NPhs.

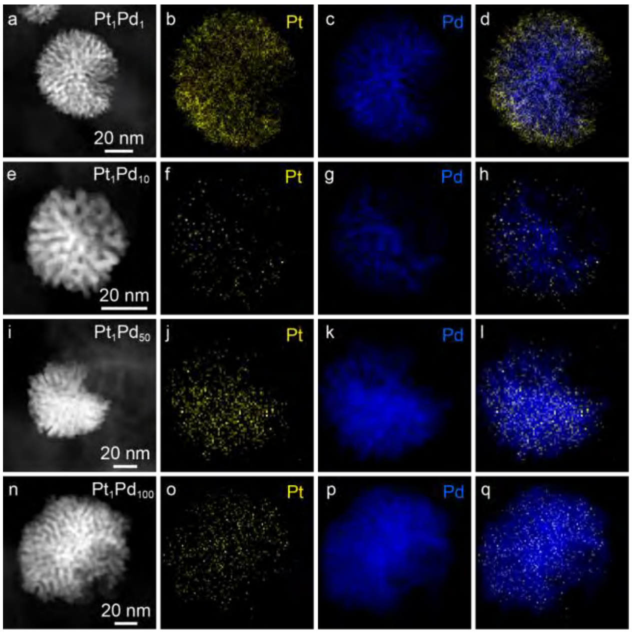
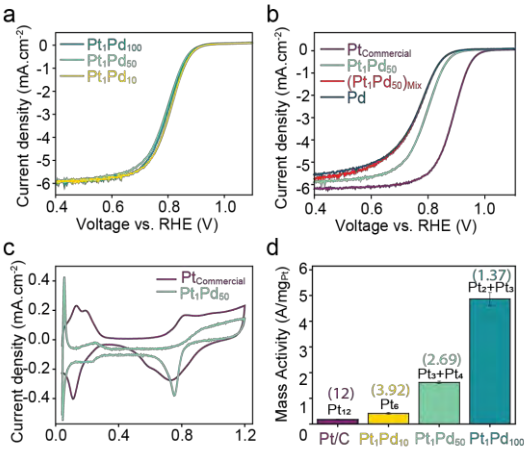
Pt Dimers in a Pd Lattice for the Oxygen Reduction Reaction

Sushila Marlow, Ruoyu Xu, Liqun Kang, Hao Gu, Hiroyuki Asakura, Feng Ryan Wang
Department of Chemical Engineering, University College London
Roberts Building, Torrington Place, London WC1E 7JE, UK
s.marlow.16@ucl.ac.uk

The oxygen reduction reaction (ORR) is widely studied in energy materials as it occurs at the cathode of a hydrogen fuel cell. Materials used currently face two major challenges – the high cost of Pt (reducing or replacing Pt) and the sluggish reaction kinetics (Pt is still the most active material known).

We propose the economical use of Pt in cathode systems by the precise design of atom efficient catalyst materials. Dimers are some of the smallest active centers that dissociate double and even triple bonds (e.g. O_2, NO, CO_2). This is particularly important in the electrochemical ORR where the O=O dissociation and subsequent desorption of oxygen species are crucial in achieving high mass activity. Here we report the design of Pt dimers within a Pd nanoparticle (NP) framework to reach a mass activity of 4.867 $A.mg_{Pt}^{-1}$, 23 times that of commercial Pt/C.





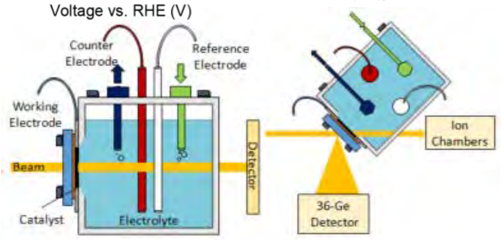


Figure 1(left): 20nm scale transmission electron microscopy (TEM) images of nanoparticles (first column) and energy dispersive spectroscopy (EDS) mapping showing the Pt (yellow), Pd (blue) and combined signal (last column) distribution. Figure 2(top right): (a) Electrochemical results of prepared nanoparticles, (b)comparison of mixture and alloy alongside reference materials, (c)cyclic voltammetry results and (d) exponential relationship observed between mass activity and Pt cluster size.Figure 3(bottom right): In situ electrochemical cell designed to monitor changes in oxidation state.

Pt-Pd NPs were synthesized through co-reduction with Pt:Pd ratios of 1:10, 1:50 and 1:100. Electron microscopy and elemental mapping in **Fig. 1** confirmed the even distribution of Pt on highly porous, flower-like Pd NP frameworks. The catalytic performance of NPs in **Fig. 2** was comparable with commercial Pt/C (**Fig. 2a,b,c**). The alloying effect achieved with colloidal growth increased activity, proven by comparison of an alloy and a physical mixture with the same ratio (Pt1:Pd50), plotted in **Fig. 2b**. It is believed that the Pt dimer absorbs and dissociates O_2, while the neighbouring Pd atoms activate H^+. The Pt cluster size in **Fig. 2d** was extrapolated from extended X-ray absorption fine structure (XAFS) fitting of Pt coordination. Increase in Pt cluster size led to a 60% decrease in the mass activity.

In situ XAFS monitoring found that a bulk sample (Pt1:Pd1) was oxidized during ORR while in extreme ratios (Pt1:Pd50) oxidation state was constant, attributed to Pt stabilization at the surface. The high mass activity achieved and in situ characterization of catalysts during ORR makes this research particularly relevant. We conclude that the precise molecular engineering of well-defined dimers is the key to activating chemically stable compounds, particularly in the utilization of renewable energy.

Design of low potential viologen-modified redox polymers for bioelectrochemical applications

Anna Lielpetere, Julian Szczesny, Felipe Conzuelo, Adrian Ruff, Wolfgang Schuhmann,

Analytical Chemistry – Center for Electrochemical Sciences (CES), Faculty of Chemistry and Biochemistry, Ruhr-University Bochum, Universitätsstr. 150, D-44780 Bochum, Germany
anna.lielpetere@rub.de

Bioelectrocatalysis is a promising research field for the development of sustainable energy conversion devices [1] and biosensors. The two main challenges for the development of new devices are the typically low current output due to inefficient wiring of enzymes or slow electron transfer in the matrix, and short lifetimes that can be attributed to the fragility of enzymes or instability of components forming the electrode archi-tecture [2,3].

A widely used strategy to ensure high electron transfer rates is to use redox polymers that electrically connect the redox centres of enzymes to electrodes through redox functions attached to the polymer backbone [4,5]. Possible limitations can be addressed by wiring enzymes in specifically designed redox polymers that are stable, provide a more efficient electron transfer and have an adapted potential to maximize the e.g. the open-circuit voltage of a biofuel cell or a self-powered sensor or to circumvent side reactions due to the co-oxidation/-reduction of interferences.

This work explores the design of tailored viologen-modified redox polymers for efficient wiring of low potential redox proteins, such as e.g. hydrogenases for the use in bioelectrodes. Firstly, the redox potential, determined by the potential of the redox mediator, the stabilizing effect of the polymer matrix [4, 6] and charged functional groups that can change the potential by electrostatic interaction [7], is adjusted with respect to the properties of the enzyme. Secondly, anchoring of viologen units to the polymer backbone needs to ensure both stability of the connection and mobility of polymer segments [5]. Thirdly, the stability and solubility of the polymer is determined by the ratio of hydrophobic and hydrophilic groups and the degree of crosslinking.

Considering these prerequisites, we have synthesized various viologen-modified redox polymers, changing the nature and the ratio between functionalities. Newly synthesized redox polymers have been evaluated for the use in bioelectrodes e.g. by integrating hydrogenases for possible application as bioanodes in biofuel cells [6, 8].

Stable metallo-isoporphyrin copolymer: electrochemical mechanism and photovoltaic properties

Y. Liang,[a] Y. Lv,[a] C. Boudon,[a] V. Badet,[a] A. Bonnefont,[a] L. Ruhlmann[a]
Laboratoire d'Electrochimie et de Chimie-Physique du Corps Solide
Institut de Chimie (UMR 7177), Université de Strasbourg, 67000 Strasbourg, France
yiming.liang@etu.unistra.fr

Isoporphyrin are mainly described in the literature as an intermediate of the reaction (biosynthesis of chlorophyll molecules as well as heme oxidation). The formation of isoporphyrins can be obtained upon nucleophilic attack on oxidized porphyrin. Optical spectrum of isoporphyrin present a typical strong absorption at the near-IR region but also remarkable redox behavior [1]. Most of the isoporphyrin reported show a high tendency to decompose either by ring opening or by rearomatization to give the starting porphyrin [2]. But, different procedures have developed to synthesize stable isoporphyrins [3].

In this presentation, new strategy to obtain stable isoporphyrin integrated in the polymers will be presented and will be compared with "classical" porphyrin copolymer with viologen spacers developed in our group [4]. Electrogenerated radical cation as well as dication porphyrin using porphyrin such as zinc 5,15-ditolyl-porphyrin (**ZnT$_2$P**) are powerful electrophiles which can rapidly react with nucleophiles such as dipyridyl ligand (py-R-py) to form copolymers containing stable isoporphyrins (**poly-ZnT$_2$isoP$^{\bullet}$**) or porphyrin (**poly-ZnT$_2$P**) depending of the applied potential chosen. Mechanisms of electrochemical routes to these electroactive copolymers will be presented as well as the optical and amazing redox properties of poly-**ZnT$_2$P** and **poly-ZnT$_2$isoP$^{\bullet}$** (Fig. 1). Formation of these two copolymers has been monitored by EQCM. The impedance properties (EIS) as well as the photovoltaic performances have been investigated where p**oly-ZnT$_2$isoP$^{\bullet}$** present considerably better performance in comparison of **poly-ZnT$_2$P**. Excitation of this new NIR band for the isoporphyrin radical copolymer lead, in the aerated media (presence of O_2), to the formation of the singlet state of the dioxygen $^1O_2$ which is the first step for the use of such materials for the photodynamic therapy for cancer.

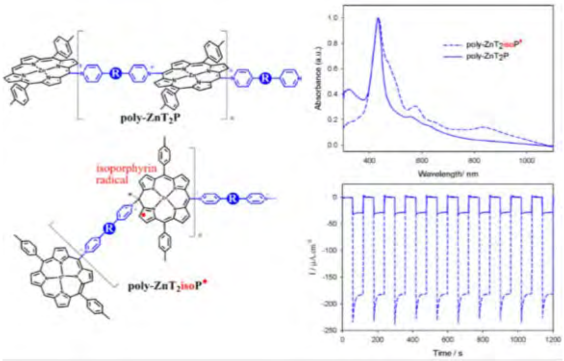

Figure 1. Left: structures of copolymers **poly-ZnT$_2$P** and **poly-ZnT$_2$isoP $^{\bullet}$**. Right: optical and photocurrent characteristics of **poly-ZnT$_2$P** and **poly-ZnT$_2$isoP $^{\bullet}$** copolymers.

Understanding of the Electrochemical Degradation of Nitrogen-doped Pt/C Electrocatalysts for PEMFC

B. Mahrt[1], P. Weber[1], C. Dosche[2], M. Oezaslan[1]
[1]*TU Braunschweig, Institute for Technical Chemistry, Franz-Liszt-Straße 35a, D-38106 Braunschweig*
b.mahrt@tu-braunschweig.de
[2]*Carl-von-Ossietzky-Universität Oldenburg, Carl-von-Ossietzky-Straße 9-11, D-26111 Oldenburg(Oldb)*

Currently, carbon black as support material has been widely used for PEM fuel cells. Degradation of state-of-the-art Pt nanoparticles (NPs) supported on carbon black is based on Ostwald ripening, particle agglomeration, Pt dissolution and/or Pt NP detachment associated with carbon corrosion.[1] The use of functional groups such as nitrogen incorporated in the carbon structure improves the (electro-)chemical stability of the Pt NPs by anchoring sites [2] and corrosion resistance of the support material.[3] However, the (electro-)chemical degradation of different N species during the ORR is still unclear.

In this work, we have combined a synthetic approach to tune the N content incorporated into the carbon material by using pyrolysis of 1,10-phenanthroline and iron(II)-acetate[4] with a deposition of platinum NPs (20 wt.-%) *via* wet-impregnation technique. Based on comprehensive XPS analysis, the N-doped carbon contains pyridinic (48%), pyrrolic (41%) and graphitic (11%) N surface species giving a total N content of 2 at.-%. The as-prepared N-doped Pt/C shows similar mass activity ($i_{mass}=0.23 \pm 0.07$ A mg^{-1}_{Pt}) and electrochemically active Pt surface area (ECSA= 65 ± 10 m^2 g^{-1}) towards ORR compared to commercial Pt/C electrocatalysts (Tanaka TEC10E30E) by using RDE technique. Thus, an effect of the N-doped support material on the initial ORR activity is not observed if the particles are well dispersed on the support material. In the second step, we performed various accelerated stress test (AST) studies to investigate the (electro)chemical degradation of N-doped Pt/C in 0.1 M $HClO_4$. We observed that the N-doped Pt/C shows comparable stability behaviour to the commercial Pt/C catalyst in relation to the changes in ECSA and particle growth. However, the XPS analysis signifies that the $N_{pyridinic}$ degrades much stronger than the other N surface species as a function of potential range and cycle number. For instance, after 4,000 cycles between 0.5 — 1.5 V vs. RHE the $N_{pyridinic}$ content decreases by up to 60% (from 44% to 27% of the N_{total}) and simultaneously an increase of the $N_{pyrrolic}$ content of 15% (from 44% to 53% of N_{total}) and of the $N_{graphitic}$ by up to 100% (from 10% to 20% of N_{total}) is observed. Obviously, the dynamic (cyclic voltammetry) AST protocols accelerate the degradation of $N_{pyridinic}$ compared to OCP experiments over 24 hours in 0.1 M $HClO_4$. After 24 h OCP, the $N_{pyridinic}$ decreases only from 48% to 44% of N_{total}, while $N_{pyrrolic}$ content increases by the same amount.
The combination of different AST protocols with XPS analysis reveals an advanced degradation model of different N surface groups ranging from pyridinic to graphitized N species for N-doped Pt/C catalysts under fuel cell conditions.

Influence of the Axial, Peripheral and Non-peripheral Substituents on the Redox Properties of Subphthalocyanines: an Electrochemical and DFT Study

Jeanet Conradie, Pieter J. Swarts
University of the Free State
Nelson Mandela Drive, Bloemfontein, 9300, South Africa
conradj@ufs.ac.za

A subphthalocyanine (SubPc) with a hydroxy group in the axial position and alkyl ligands ($C_{12}H_{25}$) on the non-peripheral positions, namely $(HO)BSubPc(C_{12}H_{25})_6(H)_6$, was synthesized in our lab. It contains an electron-rich macrocycle, with the lowest macrocycle-based oxidation potential of all reported SubPc molecules till date, namely 0.398 V *vs* Fc^+/Fc in DCM [1]. The ring oxidation process for molecule $(HO)BSubPc(C_{12}H_{25})_6(H)_6$ shows electrochemical quasi-reversibility, with $\Delta E = 0.084$ V (at 0.100 Vs^{-1}). A density functional theory study was conducted of $(HO)BSubPc(C_{12}H_{25})_6(H)_6$ and a series of related SubPc molecules (with peripheral and non-peripheral substituents = H, F or alkyl group; and with the axial substituent = Cl, alkoxy or phenoxy group), of which the ring-based oxidation and reduction potentials in DCM *vs* Fc^+/Fc were known [2–7]. This DFT study provided linear relationships between the first oxidation potential and HOMO energies (E_{ox} *vs* E_{HOMO}), as well as between the first reduction potential and LUMO energies (E_{red} *vs* E_{LUMO}), which can be used in future to determine the first oxidation and first reduction potential from HOMO and LUMO energies of further related SubPc molecules (and *vice versa*).

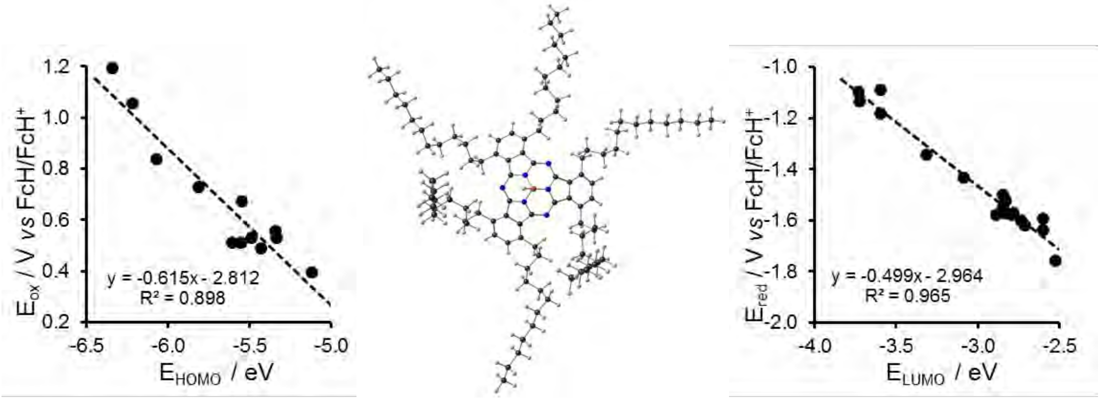

Figure: Optimized $(HO)BSubPc(C_{12}H_{25})_6(H)_6$ and relationship between the DFT energies and redox potentials.

Because of its low cost and high safety zinc-ion batteries (ZIBs) are regarded as promising alternative to lithium-ion batteries (LIBs). [1] Inorganic materials such as MnO_2, Prussian blue analogues (PBAs) have been intensively studied as cathode materials for ZIBs. [2-4] However, these inorganic materials dissolve during the charge/discharge process, which causes loss in specific capacity during cycling. Therefore, organic materials such as polypyrrole (PPy), polyaniline (PANI) are considered as potential candidates as cathode materials. [5]

Here we present in situ Raman studies of different zinc intercalation/deintercalation mechanism in rechargeable Zn/PPy battery in aqueous and bio-ionic liquid-water mixture electrolytes. Zn/PPy battery in the bio-ionic liquid-water mixture electrolyte showed a higher specific capacity than in the aqueous electrolyte. However, a significant capacity loss was observed during cycling which was related to polymer phase transformation and zinc ion trapped into the polymer matrix. Nevertheless, the existence of bio-ionic liquid in the electrolyte helps to reduce the stain in the polymer matrix during the cycling and improve the capacity. [6]

The discovery of antibiotics became a turning point in the struggle against infectious diseases and contributed to a significant improvement in the quality and length of human life. However, the widespread abuse of antibiotics caused that numerous bacteria have developed a resistance to their action [1]. Therefore, it is necessary to look for new, natural or synthetic active substances with a broad spectrum of antimicrobial activity and at the same time with low cytotoxicity on the eukaryotic cells. Lipopeptides appear to be one of the promising alternatives to the current antibiotics due to a completely different mode of action on bacteria cells [2]. Most antibiotics block the physiological processes of bacteria, such as the synthesis of the cell wall or DNA multiplication. In contrast, lipopeptides interact directly with the bacterial cell membrane, causing its destruction and, as a consequence, lead to cell death [3].

The interactions of two, novel synthetic lipopeptides with model lipid films mimicking bacterial cell membranes were examined. We verified whether branching in the fatty acid chain influences the mode of lipopeptide action on model bacterial cell membranes. For these purposes, three techniques were employed: Electrochemical Quartz Crystal Microbalance with Dissipation monitoring, Langmuir monolayer technique and Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy. Two model bacterial membranes were used reflecting the lipid composition of gram-negative bacteria: *Escherichia coli* and *Pseudomonas aeruginosa*. For *E. coli* lipid membrane the mixture of POPE, DPPG and POPG was used, whereas *P. aeruginosa* model membrane was prepared using POPE, DPPG, POPG and cardiolipin.

EQCM-D measurements showed that both lipopeptides influence the model lipid membranes. Lipopeptides incorporate into the membranes and lead to the disordering of the lipid bilayer. Moreover, the extent of the interaction of lipopeptides depends on the branching in the fatty acid chain. Langmuir monolayer and ATR-FTIR studies confirmed that lipopeptides influence the fluidity of the lipid membranes, but the extent of this action depends on both lipid membrane composition and branching in the fatty acid chain. The combination of these techniques enabled the detailed characterization of lipopeptide-membrane interactions and *in situ* monitoring of structural changes occurring within biomimetic assembly upon exposure to the active agent.

This study was financially supported by Polish National Science Centre, Project No. 2013/10/E/ST4/00343.

Electrochemical characterisation of α-hemolysin reconstituted into DMPC/CHAPSO bicelles

D.Dziubak, S.Sęk
Biological and Chemical Research Centre, Faculty of Chemistry,
University of Warsaw
Zwirki i Wigury 101, 02-089 Warsaw
ddziubak@chem.uw.edu.pl

Bicelles belong to the class of model membranes, which were originally developed for NMR studies. The morphology of these structures resembles the intermediate form between liposomes and micelles[1]. Additionally, the process of incorporation of protein into the bicelles is relatively simple. Therefore, we have attempted to reconstitute α-hemolysin in DMPC:CHAPSO bicelles and investigate the effect of protein on a model eukaryotic cell membrane. α-hemolysin is a toxic transmembrane protein, which creates ion channels in the membrane. In nature, the monomers of α-hemolysin bind to the cell membrane and pore assembly occurs upon collision during lateral diffusion in the bilayer[2]. Consequently, the presence of the pores leads to leakage of cellular fluid and cell death.

The process of incorporation of α-hemolysin requires a lot of space between the membrane and solid substrate. Therefore, for electrochemical measurements, we used stBLM (sparsely tethered bilayer lipid membranes) system. In the first step, we incorporated the α-hemolysin into the bicelles. Then bicelles were adsorbed on gold substrate modified with tethering molecules diluted by backfiller (1-thio-β-D-glucose). Every step was characterized by surface-enhanced infrared absorption spectroscopy (SEIRAS). Further electrochemical experiments enabled monitoring the effect of α-hemolysin on membrane hydration. The results obtained by alternating current voltammetry and electrochemical impedance spectroscopy confirmed that the presence of ion channels significantly facilitates water diffusion through the membrane. Moreover, protein incorporated in the membrane changes the potential of zero charge (pzc). The shift of pzc is around 200mV to more negative values, which may be directly related to the cell lysis.

Realizing Highly Stable Sodium Metal Batteries with Tactically Designed Graphene Structures

Huan Wang
College of Chemistry, Nankai University
No.94 Weijin Road, Nankai District, Tianjin, P.R.China 300071
Huan.wang0520@nankai.edu.cn

Sodium (Na) metal is a promising anode for grid-scale energy storage systems owing to its high theoretical capacity, low cost, and high earth abundance. However, the implementation of Na metal anode has been primarily hindered by Na dendrite growth and severe volume expansion that leads to low Coulombic efficiency, short lifespan and even safety issues. Therefore, it is critical to engineer the electrode-electrolyte interface and direct uniform Na deposition. Graphene, a representative of two-dimensional materials, has many unique features including chemical inertness, strong mechanical strength and tunable surface chemistry, which make it an ideal interfacial candidate to regulate Na deposition and thus suppress dendritic Na growth. By adjusting the kinetic parameters for chemical vapor deposition (CVD), graphene films can be readily tuned from single layer to multilayers, which can directly serve as coating layers to stabilize Na metal anodes. Our findings reveal that the rate capability of Na anode is critically dependent on the thickness of graphene films. Through rational design of precursor, a series of graphene films with different heteroatom dopants are synthesized to serve as substrates for Na plating and stripping. By probing the Na nucleation and growth behaviors, we revealed a binding-energy-dominated Na nucleation-growth pattern, and discovered that the strong binding affinity can decrease Na nucleation barriers and enables dendrite-free Na metal anodes. Furthermore, three-dimensional N-doped graphene microcubes can be achieved by employing sodium chloride salt as growth template. The as-grown N-doped microcubes can be directly blended into bulk Na metal to serve as solid additives, which can offer well-distributed nucleation sites to promote uniform Na deposition and minimize volume change over repeated cycles. As a result, highly stable Na metal anodes can be realized with ultrahigh capacity and rate capability over long-term cycles in carbonate electrolyte. Our works provides effective solutions to stabilize Na metal anodes from the perspective of designing CVD-grown graphene structures, paving the way towards the realization of high-energy Na battery systems.

**philipp.roese@kit.edu*

Polyaniline (PANI), a member of the class of intrinsically conductive polymers, possesses a great potential for energy storage applications, due to its tunable pseudocapacitive performance. [1,2] Yet, the understanding of its structure-property relationship is far from complete while the potential practical applications are also not fully exploited. [3]

In our efforts to close this gap, we developed a cost effective, advanced and optimized chemical oxidative route for the synthesis of three dimensional PANI nanofibers with large surface area and pore volume.

Electrodes for supercapacitors were manufactured by depositing the PANI on high surface area carbon fiber electrodes and were assembled to symmetric supercapacitors in two- and three electrode setups and in-depth electrochemical analysis including cyclic voltammetry, galvanostatic charge-discharge and electrochemical impedance spectroscopy was performed.

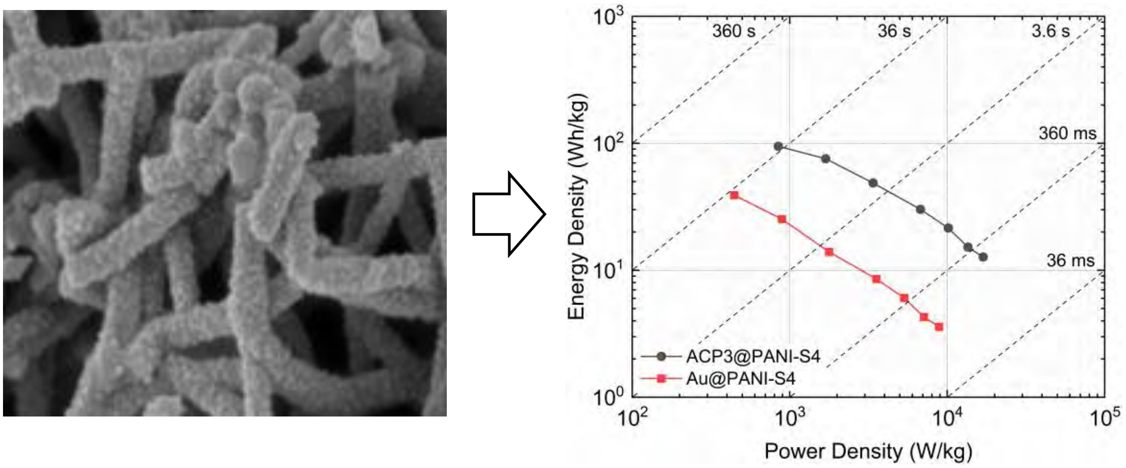

Figure: SEM image of PANI nanofibers (left); corresponding Ragone plot (right).

The overall results showed, that the various supercapacitors exhibited very good performance, rate capability and cycle stability. It is particularly interesting that the combination of the PANI nanofibers and the carbon fiber electrodes with its microporous graphene surface morphology showed a synergetic effect which resulted in a superior specific capacitance (up to 1107 F/g at 0.5 A/g), high capacitance retention (70-96%) and excellent coulombic efficiencies (92-98%).

With respect to practical applications, we believe that the presented study provides an efficient and promising way to produce electrode material with low cost, easy processability and excellent energy-storage performance.

Visible Laser Scribing Fabrication of Porous Graphitic Carbon Electrodes: Electrochemical Properties and Applications as a Disposable Sensor Platform

Eoghan Vaughan, Daniela Iacopino
Tyndall National Institute
University College Cork, Dyke Parade, Cork, Ireland
Eoghan.vaughan@tyndall.ie

Porous graphitic carbon electrodes were fabricated by laser scribing of commercial polyimide sheets. The process was performed by a simple one-step procedure using visible wavelength laser irradiation from a low-cost hobbyist laser engraver. The obtained electrodes displayed a highly porous morphology, rich in three-dimensional interconnected networks and edge planes, suitable for electrochemical sensing applications. Spectral characterization by Raman and XPS spectroscopies revealed a crystalline graphitic carbon structure with high percentage of sp^2 carbon bonds.

Extensive electrochemical characterization performed with outer-sphere $[Ru(NH_3)_6]^{3+}$ and inner-sphere $[Fe(CN)_6]^{4-}$, $Fe^{2+/3+}$ and dopamine (DA) redox mediators showed quasi-reversible electron transfer at the graphitic carbon surface dominated by mass diffusion process. Fast heterogeneous electron-transfer rates, higher than similar carbon-based materials and comparable to other graphitic carbon electrodes obtained by infrared laser irradiation, were obtained for these electrodes.

Thin-layer transport mechanisms occurring in parallel to the main linear diffusion-limited mechanism were taken in consideration. Overall the observed enhanced electron-transfer rates effects were ascribed to the large specific surface area of the extended 3D porous network which rich in edge-planes and electrocatalytic sites. The as-fabricated electrodes were capable of differentiating the three biomarkers ascorbic acid, dopamine and uric acid in solution and selective detection of dopamine. Moreover, the compatibility with light-weight, portable and handheld instrumentation makes such electrodes highly promising for the realization of low-cost disposable sensing platforms for point-of-care applications.

Electrophoretically Deposited Bioceramic Composite Coatings on Ti Substrate Intended for Medical Use

Bone implant materials are increasingly attracting attention in the biomaterials field. Among them, hydroxyapatite (HAP) has stood out as a prospective biomaterial due to excellent osseointegration ability, owing to its similarity with natural bone. However, due to the lack of adhesive and antibacterial properties, it is usually combined with polymers and antibacterial agents. Natural polymer chitosan (CS) was proven as an effective component of HAP-based composites, improving the adhesion and serving as a drug carrier.[1] Inclusion of antibiotics into composite biomaterials has gained a lot of attention, as it is thus possible to achieve the desirable antibacterial activity. Gentamicin (Gent) was shown to be one of the most effective antibiotics in treating bone infections. In this work, bioceramic composite HAP/CS and HAP/CS/Gent coatings were successfully assembled on Ti plates by electrophoretic deposition technique (EPD).[2] Deposition was carried out at a constant voltage of 5 V and for 12 min in a single step process from three-component aqueous suspension (Figure 1). Bioactive properties of deposited coatings were investigated *in vitro*, by immersion in simulated body fluid solution (SBF). After 7-day immersion in SBF, field emission scanning electron microscopy (FE-SEM) and Fourier transform infrared spectroscopy (FTIR) were employed to investigate the coatings' bioactivity, whereas electrochemical impedance spectroscopy (EIS) and polarization measurements were carried out during 28-day immersion in SBF in order to obtain valuable information about osseopromotive coatings' nature. Biological testing included monitoring of alkaline phosphatase activity (ALP) that is associated with the coatings' ability to promote new bone growth. The high increase in ALP activity (50 %) relative to the control pointed to the strong coatings' aptitude for the osseointegration process and new bone growth. FTIR and FE-SEM analysis gave evidence of carbonate-substituted HAP, whose presence is desirable in bone implant applications. The formation of the new apatite layer was also confirmed by electrochemical measurements pointing to the high biomineralization potential of the coatings. Antibacterial activity kinetics in suspension against *Staphylococcus aureus* and *Escherichia coli* was also monitored to examine the potential coatings' application. As expected, the gentamicin addition strongly improved the antibacterial activity of HAP/CS/Gent coating, and the effect was more pronounced against *S. aureus.*

All the obtained results potentially indicated a strong osseointegration ability of the HAP/CS/Gent coating classifying it as a promising material for bone tissue engineering.

Liquid biopsy is the most desirable but also the most challenging approach to diagnose cancer. This method relies on the presence of specific biomarkers in the accessible body fluids of cancer patients. However, many of these biomarkers are glycoproteins found in low concentration levels in a high protein content medium, the serum, thus hindering their detection. For this reason, biomarker detection requires strategies to boost sensitivity. Nucleic acid-based receptors such as aptamers are especially appropriate for this task because they can be easily manipulated with molecular biology tools such as polymerases and ligases, so they can be integrated in analytical schemes forbidden to other receptors like antibodies [1-2].

Affinity characterization is an essential step to develop reliable aptamers for tumor biomarker detection. For alpha-fetoprotein (AFP), a biomarker of hepatocellular carcinoma (HCC), two DNA aptamers were described with very different affinity. In this work, we estimate the dissociation constant of both of them by means of a direct assay on magnetic beads modified with AFP and electrochemical detection on screen-printed carbon electrodes (SPCE). Unlike previous works, both aptamers showed similar dissociation constants (Kd) values, in the subμM range. In order to improve the performance of these aptamers, we proposed the isothermal amplification of the aptamers by both terminal deoxynucleotidyl transferase (TdT) and rolling circle amplification (RCA). Both DNA amplifications improved the sensitivity and also the apparent binding constants of the aptamers. Nevertheless, this improvement depends on the true affinity of the binding pair, which ultimately limits the analytical usefulness [3].

Over the last couple of decades, microbial fuel cells (MFCs) have been attracting considerable attention as a promising technology that exploits microbial electrochemical activity for energy production from organic wastes and renewable biomass. This technology deals with several major issues of the modern society at once: production of sustainable energy, purification of water and/or utilization of waste.

In a MFC, electricity-generating bacteria – exoelectrogens – transfer electrons from oxidised organic compounds to an anode as the electron acceptor, and these electrons then pass through an electrical circuit and combine with a terminal electron acceptor at the cathode [1].
However, it is of crucial importance to improve the performance of MFCs before they can be scaled up, since, to date, their practical implementation is limited. The power output of MFCs is limited by the processes on the surface of electrodes, their rate and stability. Surface modification of graphite based anode materials could enhance bacterial cell adhesion, cell viability and facilitate extracellular electron transfer [2]. C-, N-, O-, and S-containing functional groups have been frequently investigated in anode surface modification for the purpose of enhancing bacterial attachment [3].

In this study, graphite felt (GF) was electrochemically oxidised and subsequent reactions with organic diamines were carried out with the aim to introduce amine group on the surface of GF. Modified GF electrodes were investigated by Fourier-Transform Infrared Spectroscopy (FT-IR) and Energy Dispersive X-Ray Analysis (EDX) techniques. Two-chamber MFCs were assembled with cathodes made of bare GF and PBS (pH 7.2) aerated with air as a catholyte. *Shewanella putriefaciens* was used as exoelectrogenic bacteria. The minimal medium was prepared as described in [4]. Sodium lactate was an electron donor. The MFCs operated at room temperature (21±1 °C).

At the end of the first 24 h period after bacterial inoculation, the MFCs reached the maximal stable values of generated voltage. Over the period of 2–7 days (25–168 h), the MFC with the anode from GF modified with *m*-xylilenediamine provided up to 45% higher voltage and current than the control MFC with bare GF, whereas the voltage and current generated by the MFC with the anode from GF modified with 2,4-diaminotoluene were 36% higher than those of the control, when electric circuits of the investigated MFCs were loaded with resistors of 659 Ω. Volume power density of the MFC with the anode from GF modified with *m*-xylilenediamine and the one with the anode from GF modified with 2,4-diaminotoluene, was approx. 2.3 and 2.0 times, respectively, higher than that of the control MFC.

It can be assumed, that bacterial adhesion of *Shewanella putrefaciens* bacteria is more favoured on the GF filaments, surface of which has been modified with *m*-xylilenediamine and 2,4-diaminotoluene.

The constantly evolving biomaterials fields is more and more shifting towards finding new solutions to the problem of multidrug resistant bacteria, and one of major aspects in this regard is deep and chronic wound care. Wound dressings for such a purpose have to be designed for long-term usage, and therefore must have significantly improved properties over the traditional cotton-based materials. One of the most promising directions are moisture-retentive hydrogel wound dressings, which can be tailored to meet many specific requirements of wound management and care, such as biocompatibility, debridement, gas exchange, low adherence, ease of maintenance, moisture and thermoregulation and mechanical stability.[1] Moreover, hydrogels represent ideal carrier vehicles for incorporation of antibacterial agents that are frequently loaded directly into the dressing material as this provides for quick delivery directly to the wound site and more efficient prevention of infections by skin-inhabiting bacteria, such as *Staphylococcus aureus*. Silver nanoparticles (AgNPs) are more and more used as a replacement for systemic antibiotics administration, due to the advantages such as the possibility for topical application over longer time periods without the issues of bacterial resistance. AgNPs are difficult to control and stabilize due to their high surface reactivity, but polymer-based hydrogels can be an excellent choice for their immobilization and controlled release.

In this work, we present the method to obtain physically cross linked poly(vinyl alcohol)/chitosan (PVA/CHI) hydrogels and an *in situ* electrochemical constant-voltage route to synthesize AgNPs directly inside their polymer matrix. The new electrochemical method consists of swelling the PVA/CHI hydrogel in $AgNO_3$ solution, followed by constant-voltage (90 V)-mediated reduction of Ag^+ ions in the hydrogel disc, which is placed between two platinum electrodes in a sandwich-type electrochemical cell setup (Figure 1).[2,3] The obtained AgNP-loaded hydrogels were evaluated by X-ray photoelectron spectroscopy and scanning electron microscopy in order to analyze their structure and morphology, whereas the successful incorporation of AgNPs smaller than 10 nm was confirmed using UV-visible spectroscopy, dynamic light scattering and transmission electron microscopy. Swelling and silver release behaviors were tested in phosphate buffer at 37 °C that simulated physiological conditions. Finally, *in vitro* biological validation confirmed their antibacterial activity against *Staphylococcus aureus* and *Escherichia coli* bacterial strains, and biocompatibility towards model fibroblast cell lines (MRC-5 and L929), unquestionably indicating the strong potential of these hydrogels for wound dressing applications.

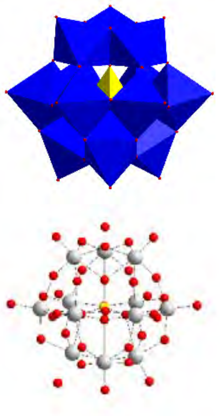
Differential Electrochemical Mass Spectrometry studies of nitrite reduction catalyzed by Keggin polyoxometalates

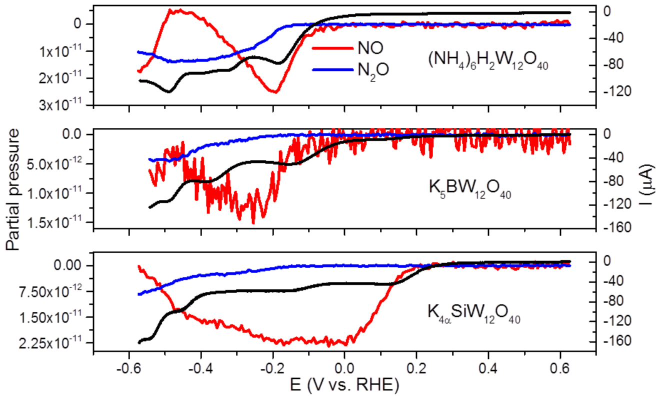
Yulin Zhou, Antoine Bonnefont, Laurent Ruhlmann, Vasilica Badets
Université de Strasbourg, Institut de Chimie, UMR CNRS 7177, Laboratoire d'Electrochimie et de Chimie Physique du Corps Solide
4 Rue Blaise Pascal, CS 90032, 67081, Strasbourg Cedex, France
badets@unistra.fr

Nitrite electrochemical reduction is catalyzed, among others, by polyoxometalates (POMs), a class of inorganic metal-oxides clusters. Since early 19xx different POMs have been tested, ranging from small compounds from Keggin and Dawson families [1,2] to more complex structures (such as Wells-Dawson-derived tetramers [3], crown-type structures), and even organic-inorganic hybrids. One important issue in the electrochemical reduction of nitrite is to identify the products. Nitrite is the first product obtained from the reduction of nitrate, and both compounds are known as environmental pollutants, despite their use as food preservatives. Thus, research is conducted to convert these two species into harmless compounds. Form this point of view, disposing of an analytical technique able to rapidly identify in a single test as many products as possible becomes an important tool in the research of those catalysts that able to convert nitrite (and/or nitrate) into nitrogen. Differential electrochemical mass spectrometry (DEMS) is the analytical technique able to identify the gaseous products during one single run.

In this presentation the reduction of nitrite catalyzed by a series of polyoxometalates (POMs) belonging to the Keggin family will be discussed. The POMs were selected due to the increase in their global charge and decrease of the redox potential, from $K_4SiW_{12}O_{40}$, $K_5BW_{12}O_{40}$ and $(NH_4)_6H_2W_{12}O_{40}$ respectively. DEMS analysis was performed for these compounds for the first time in order to identify the gaseous products. An isotopically marked source of nitrite was used for the first time, i.e. the nitrogen contains 98% of isotope ^{15}N. This allowed the specific attribution to the m/z signals to products of reaction thus eliminating the possible interference from atmospheric nitrogen and carbon dioxide. Experiments were conducted at both pH 2 and 5 in order to compare the differences on the products as a function of the source compound that is either nitrous acid or nitrite. The main found gaseous products were only ^{15}NO and $^{15}N_2O$ both at pH 2 and 5. A clear relation between the formation of NO and its consumption for the production of N_2O was observed suggesting that all POMs are able to bind NO. At pH 2 the less negative potential correlated with the formation of NO is recorded for $SiW_{12}O_{40}^{4-}$ (followed by $BW_{12}O_{40}^{5-}$ and $H_2W_{12}O_{40}^{6-}$), while at pH 5, the N_2O appears at the less negative potential for $H_2W_{12}O_{40}^{6-}$ (followed by $BW_{12}O_{40}^{5-}$ and $SiW_{12}O_{40}^{4-}$).



3D view (upper) and ball-and-stick view (lower) of $SiW_{12}O_{40}^{4-}$ (Si: yellow; W: grey; O: red)



DEMS analysis of nitrite reduction catalyzed by studied POMs

The Immobilisation and Reactivity of $Fe(CN)_6^{3-/4-}$ in an Intrinsically Microporous Polyamine (PIM-EA-TB)

Lina Wang,[1] Neil B. Mckeown,[2] Mariolino Carta,[3] Frank Marken[1]
[1] Department of Chemistry, University of Bath, Bath, BA2 7AY, UK
[2] School of Chemistry, University of Edinburgh, Edinburgh, Scotland EH9 3JJ, UK
[3] Department of Chemistry, Swansea University, Swansea SA2 8PP, UK
lw2165@bath.ac.uk

Heterogenization of homogeneous electrocatalysts is possible into polymers of intrinsic microporosity (PIMs).[1] Here, it is shown that protonation of the molecularly rigid polymer of intrinsic microporosity PIM-EA-TB can be coupled to immobilisation of $Fe(CN)_6^{3-/4-}$ (as well as immobilisation of Prussian blue) into 1-2 nm diameter channels. The resulting films provide redox active coatings on glassy carbon electrodes. Uptake, transport, and retention of $Fe(CN)_6^{3-/4-}$ in the microporous polymer are strongly pH dependent requiring protonation of the PIM-EA-TB ($pK_A \approx 4$).[2] Both $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ can be immobilised, but $Fe(CN)_6^{4-}$ appears to bind tighter to the polymer backbone presumably via bridging protons. Loss of $Fe(CN)_6^{3-/4-}$ by leaching into the aqueous solution phase becomes significant only at pH > 9 and is likely to be associated with hydroxide anions directly entering the microporous structure to combine with protons. This and the interaction of $Fe(CN)_6^{3-/4-}$ and protons within the molecularly rigid PIM-EA-TB host are suggested to be responsible for retention and relatively slow leaching processes. Electrocatalysis with immobilised $Fe(CN)_6^{3-/4-}$ is demonstrated for the oxidation of ascorbic acid.

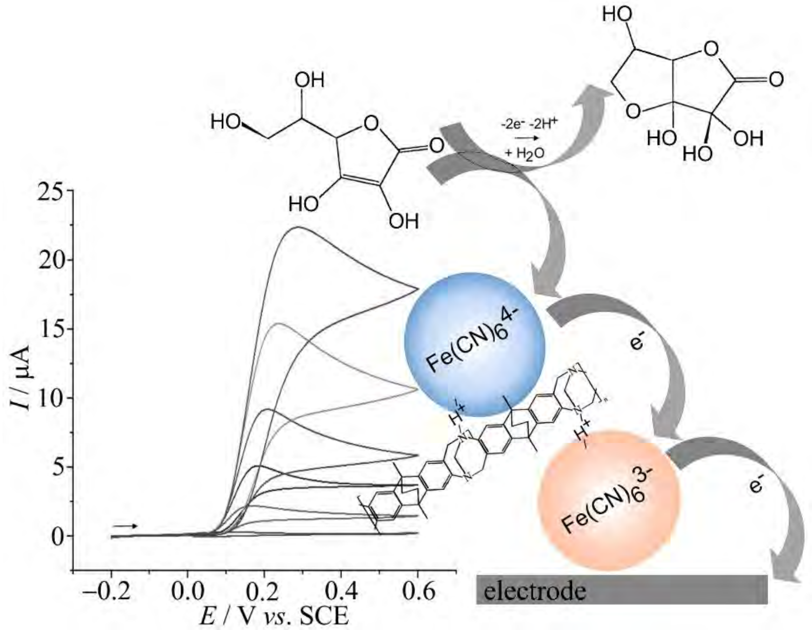

Figure 1. Schematic illustration of electron pathway of PIM-EA-TB/$Fe(CN)_6^{3-/4-}$ electrode during electron hopping and electrocatalysis application for ascorbic acid oxidation.

Fundamental Insight into Metal Adsorption, Migration, and Electrolyte Interaction at the Alkali Metal Ion Battery Anode Surface and Interface

Emilia Olsson, Qiong Cai
Department of Chemical and Process Engineering, University of Surrey
GU2 7XH, Guildford, United Kingdom
k.olsson@surrey.ac.uk

Energy storage battery technologies are receiving increasing attention due to the need for a transition to a more sustainable energy economy. Alkali metal ion batteries including lithium (Li) ion batteries (LIBs), sodium (Na) ion batteries (NIBs), and potassium (K) ion batteries (KIBs), are currently being investigated, with a lot of efforts on discovering and optimizing electrode materials. Carbon materials such as hard carbons have gained considerable scientific interest as anode materials in these batteries, due to their low cost, natural abundance, and suitability for the intercalation/storage of alkali metal ions. Hard carbons are complex disordered carbon structures with randomly orientated, defective, and curved graphene nanosheets, and turbostratically stacked graphitic layers. This complex structure leads to a plethora of carbon structural motifs being present in the anode, resulting in a large number of potential morphologies. These disparate morphologies need explicit consideration when investigating the metal adsorption and migration at the anode surface, and when modelling the anode electrolyte interface. In this work we aim to shed light on these mechanisms through systematic computational modelling studies. [1–4]

Density functional theory (DFT) simulations of Li, Na, and K on different carbon motifs (defective graphene basal planes, planar graphitic layers, and curved pores) found in hard carbon anode materials were conducted to investigate their effect on the metal adsorption.[1,2,5] Our calculations show that oxygen-, and nitrogen-containing defects are energetically favorable to form on single layer carbon fragment surfaces,[5] and on curved morphologies. These defects were found to be highly beneficial for the initial metal storage, with Li, Na, and K adsorption energies greatly improved as compared to the non-defective carbon surface. Hence, it was deduced, as also suggested by experiment, that the presence of surface defects could indeed lead to a higher degree of metal storage. The effect of these defects on metal migration, which would influence the cycling properties of anode materials, was investigated through nudged elastic band calculations, and showed that metal adsorption on surface defects can lead to capacity loss and irreversible metal storage. [5]

The anode-electrolyte interface is known to have a direct impact on the battery performance. One consequence of electrolyte molecule breakdown is the presence of functional groups at the anode surface. From DFT simulations of functional groups O, OH, NH_2, and COOH at different carbon motifs (planar basal plane, H-terminated edges, and curved morphologies), we show that O-functional groups from an energetical perspective are highly probable to form on these surfaces, and can act as favorable metal storage sites. The hydroxyl group on the other hand are found to form inorganic compounds, which could contribute to irreversible capacity.

Finally, we use *ab initio* molecular dynamics (AIMD) to investigate the effect of surface roughness, disorder, defects, and termination on the electrolyte anode interactions in the ethylene carbonate (electrolyte solvent) | hard carbon (anode) system. These simulations show that solvent intercalation and breakdown is directly influenced by the anode surface termination and roughness. Furthermore, defects are found to be more probable to form in terms of defect formation energies at strained and curved carbon morphologies, and to have a direct impact on the metal binding to the anode. The effects of different structural motifs on metal adsorption, intercalation, and diffusion are investigated, to form an understanding of the anode electrolyte interfacial reactions.

maximilian.kutter@uni-bayreuth.de

Due to the dependence on fossil fuels and therefore an increase of greenhouse gas emissions and the resulting accelerated global warming, environmentally-oriented energy supplies, such as hydrogen, offer an attractive option for the deep decarbonization of our global energy systems.[1]

Fuel cells, as a local, emission-free and versatile system, have been a major research activity throughout the years. Polymer electrolyte membrane fuel cells (PEMFCs) are considered one of the most promising technologies among the various kinds of existing fuel cells. Especially high temperature polymer electrolyte membrane fuel cells (HT-PEMFCs) can offer an improved performance due to their higher operating temperatures between 100-200 °C and therefore lead to better reaction kinetics, higher tolerance to fuel impurities and to an improved heat and power management of the system. However, some issues regarding durability and performance, such as poisoning of the platinum catalyst by phosphoric acid adsorbents, long-time stability and low oxygen solubility, are still unsolved.[2]

To overcome these difficulties we introduced planar polycyclic aromatic hydrocarbons (PAHs) to the electrode, which have a positive influence on the fuel cell system.[3] In our approach, fluorinated polycyclic aromatic hydrocarbons with specific functional groups were synthesized and integrated as additives into the electrode. Here, the specific structural features of the fluoranthene derivatives were designed to interact via π-π interactions with the porous carbon catalyst support and by their *N*-donor functionalization with the Pt-catalyst nanoparticles, to protect the active site from poisoning with phosphoric acids.
Rotating disc electrode (RDE) measurements have shown that the additives reduce poisoning of the platinum catalyst and can improve oxygen-solubility at the electrode/electrolyte interface. We have also shown that the additives can replace an additional binder, such as PTFE, for optimizing the membrane/electrode assembly. Even without PTFE, fuel cell tests have shown that the PAH additives, implemented to the electrode, increase the full cell performance significantly. The modified electrode showed double the power density compared to the untreated electrode.

A cathode which is one part of a battery has a large impact on the capacity of the battery. For this reason, Ni-rich layered oxides, $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NCM811) is a promising high-capacity cathode active material for high-energy density lithium-ion batteries for electric vehicles and energy storage systems. Generally, cathode is fabricated by coating the slurry of mixed active material, conductive agent and conventional polyvinylidenfluoride (PVDF) binder on aluminum current collector. NCM811 cathode coated with PVDF binder has however shown unstable cathode-electrolyte interface and structural degradation, especially, particularly under high charge voltages and elevated temperatures by fading capacity and reducing the life span of a battery. This problem originates from the physical binding mechanism of PVDF binder, which weaken the binding ability to active materials and current collector and insufficient thermal stability under harsh condition. In order to resolve those problems, we were motivated to develop a new highly functional binder as an alternative to PVDF. In this study, we present the effects of our new designed binder in improving the stability of NCM811 cathode and its performance in commercial electrolyte.

Anodic oxidation of Ti is a promising method to produce nano-porous oxides as photocatalysts for water splitting. Modification of the nano-porous structures via adsorption doping, pore-filling and/or deposition of material in the pores to produce effective optically absorbing and catalytic coatings is a strategic direction in contemporary photo catalysis material science.

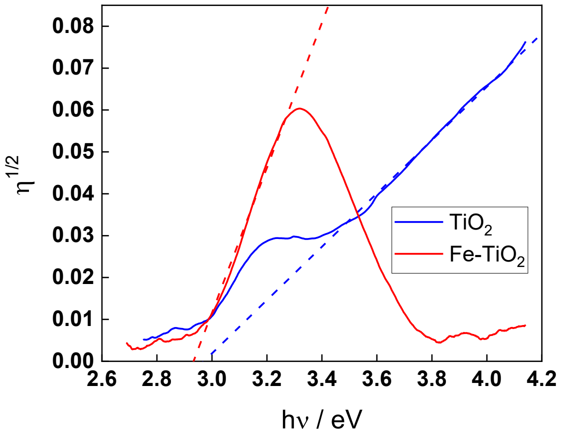

Fig. 1 Photocurrent spectra of undoped TiO_2 (blue) and Fe-doped TiO_2 (red) measured at potential of 0.3V in 0.1 M KOH

The present research reports an investigation of TiO_2 modified with Fe as prospective photocatalyst for water splitting.

Nanoporous anodic titanium oxides are synthesized in electrolytes based on ethylene glycol solvent with water and ammonium fluoride additions by anodic oxidation in a galvanostatic/tensiostatic regime (Agilent N5752A) using 99.6% Ti (Goodfellow) as working electrode and Pt mesh as counter electrode. The porosity of the oxides is estimated by re-anodization in a suitable non-dissolving electrolyte, their optical properties are assessed using diffuse reflectance spectroscopy.

Modification of the titanium oxides is achieved via anodization in electrolytes containing $K_3Fe(CN)_6$. Surface composition of oxides is studied by X-ray photoelectron spectroscopy. The conduction mechanism in such doped titanium oxides is assessed by electrochemical impedance spectroscopy. Photocurrent measurements indicate improved absorption of visible light in comparison with pristine nano-porous TiO_2 which points to prospective photocatalytic abilities of the modified oxides as photoanodes. Further optimization of the experimental conditions is needed to achieve better photo-catalytical performance.

Molecular Understanding of Ionic-liquid-based Supercapacitors

Guang Feng
School of Energy and Power Engineering, Huazhong University of Science and Technology,
Wuhan 430074, China
gfeng@hust.edu.cn

Electrical double layer capacitors (EDLCs), also called supercapacitors, store electrical energy via ion electrosorption directly at the electrolyte-electrode interface during the charging process, suggesting that the liquid-solid interfaces and the charging kinetics play a dominant role in the underlying energy storage mechanism and the resulting device performance. Among electrolytes used in supercapacitors, room-temperature ionic liquids (RTILs) have emerged as promising electrolytes, because of their exceptionally wide electrochemical window, excellent thermal stability, nonvolatility, and relatively inert nature. Despite considerable work on RTIL-based supercapacitors, the details of what would happen at RTIL-electrode interfaces still require in-depth exploration.

Adopting molecular dynamics simulation, we studied RTIL electrolytes with different electrodes, in comparison with the corresponding experimental measurements, to understand the energy storage mechanism underlying supercapacitors and thus to promote the design of supercapacitors. The contents of this talk would include:

1) Understanding the structural and dynamic nature of bulk RTILs at a molecular level, which would reveal the nano-aggregate, dynamics and ionic mobility, as well as the ion size impact on liquids without confinement.[1]
2) Investigating RTILs-based EDLs at open surfaces (e.g., planar, cylindrical, spherical, with defects, etc.), by integration of molecular modeling and the nano-/microscale experimental techniques (e.g., atomic force microscopy, in situ X-ray reflectivity, and neutron scattering), which would focus on the EDL structure and capacitance as well as the influence from ion size, ion type, applied potential, electrode curvature, etc.[2-4]
3) Exploring the influence of water impurity on RTIL EDLs, which would show for the first work on the adsorption of water on electrode surfaces in contact with humid RTILs and the possible strategy to reduce the water electrosorption at polarized electrodes.[5, 6]
4) Studying the capacitance and charging dynamics of RTILs in porous electrodes, which would show how conductive MOF as electrode could achieve promising capacitive performance[7] and how to tune pore size to obtain higher power density[8].

PHOTOELECTROCHEMICAL SYSTEM WITH p- $CuBi_2O_4$

Dergacheva M.B., Puzikova D.S., Khussurova G.M.

D.V.Sokolsky Institute of Fuel, Catalysis and Electrochemistry, Almaty,050010, 142 Kunaev str, Kazakhstan E-mail: ***m_dergacheva@mail.ru***

$CuBi_2O_4$ is a p-semiconductor and has many promising physico-chemical properties including magnetic susceptibility, dielectric constant, high-temperature heat capacity, electrochemical capacitance, photoelectrochemical ability and catalytic properties In this work the spin coating method was used, which is carried out under standard laboratory conditions from aqueous salt solutions, uses the advantages of centrifugation to uniformly distribute the coating on the surface, is characterized by low material consumption, allows the formation of thin nanocrystalline layers with a given thickness. The polyethylene glycol (PEG) was used to the uniform distribution of solution droplets over the entire surface of the deposited films. A solution for depositing $CuBi_2O_4$ films was prepared by mixing copper nitrate trihydrate and bismuth nitrate pentahydrate (at 0.05M and 0.1M, respectively) with acidification with concentrated (65%) nitric acid. Subsequently, the resulting mixture was evaporated without boiling to an amount of 1/5 of the original volume and cooled to room temperature. The preparation of solutions containing polyethylene glycol - 2000 (PEG) additives was performed after cooling the initial solution, adding PEG in the amount of 0.25 grams to each 5 ml of the solution. After that, the solution was subjected to treatment in an ultrasonic bath. The centrifugation procedure with rotation during 90 s. at a frequency of 500 rpm.on support glass/FTO wascarried out. After application, the films were annealed in a muffle furnace for 2 hours at a temperature of 600°C. Photoelectrochemical studies were performed in real time in a solution of 0.2 M Na_2SO_4 + 0.1 M phosphate buffer + 10 mM H_2O_2 under modulated illumination with a wavelength of 465 nm in a GillAC (ACM Instruments) apparatus using a quartz cuvette and a silver chloride reference electrode.

Surface micrographs showing the ordering of the growth of $CuBi_2O_4$ particles (size ≈200 nm) with the addition of polyethylene glycol to the solution were obtained by SEM. The results of AFM indicate 1.5 times decrease in the roughness of the relief and the formation of equidimensional rounded crystallites. For all films, the XRD method confirmed the presence of the crystalline Kusachiite phase corresponding to the $CuBi_2O_4$ compound. Comparative analysis of the XRD diagram of samples obtained from solutions containing PEG and "pure" (without PEG) shows an increase in the number of peaks and their intensity in the first case. Based on photoelectric measurements, it is established that $CuBi_2O_4$ films precipitated from solutions containing polyethylene glycol show a photoactivity of 2 times higher. Thus, the developed method of deposition of a complex copper-bismuth $CuBi_2O_4$ system makes it possible to obtain polycrystalline films with high photosensitivity, p-type conductivity, which are promising for use in photoelectrochemical converters as photocathodes.

Electrochemical Synthesis of (Hydro)oxides for Oxygen Evolution

Zhenhua Yan, Xiang Chen, Fangyi Cheng, Jun Chen

Key Laboratory of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy
Conversion and Storage Center, College of Chemistry, Nankai University
No 94, Weijin Road, Nankai District, Tianjin 300071, China.
E-mail: yzh@nankai.edu.cn

Electrochemical water splitting is a promising technology for hydrogen production and sustainable energy conversion, but the currently available electrolyzers still require highly active and robust anodic electrodes for the oxygen evolution reaction (OER). In this talk, we focus on two electrochemical synthesis strategies for (hydro)oxide design and water oxidation applications. On the one hand, we developed a universal electrodeposition method for synthesizing of metal hydroxides/oxides on varied substrates via reduction of oxyacid anions. On graphitic substrates, we find that the insertion of nitrate ion in graphene layers significantly enhances the electrodeposit–support interface, resulting in high mass loading and low interface resistance. For the electrocatalytic OER, the nanocrystalline cerium dioxide and amorphous nickel hydroxide co-electrodeposited on graphite sustains long-term robust durability (over 300 h) at a large current density of 1000 mA cm^{-2}. On the other hand, an electrochemical reduction etching method has been developed for controllable tailoring of the cationic defects in iron-based oxides under mild conditions. The optimized defective spinel-type iron nickel oxide exhibits an overpotential as low as 270 mV at 10 mA cm^{-2} and a Tafel slope of only 33.8 mV dec^{-1} for the OER, outperforming the benchmark RuO_2 and pristine oxide. Experimental investigations and theoretical calculations further demonstrate that the presence of iron defects increases the Ni–O covalency that promotes the adsorption and activation of H_2O, modulates surface electronic structure that endow moderate oxygen intermediate species adsorption, promote electron transfer, and enrich active sites, thus boosting the OER activity. These results provide new and effective electrochemical methods for synthesis and construction of efficient OER eletrocatalysts.

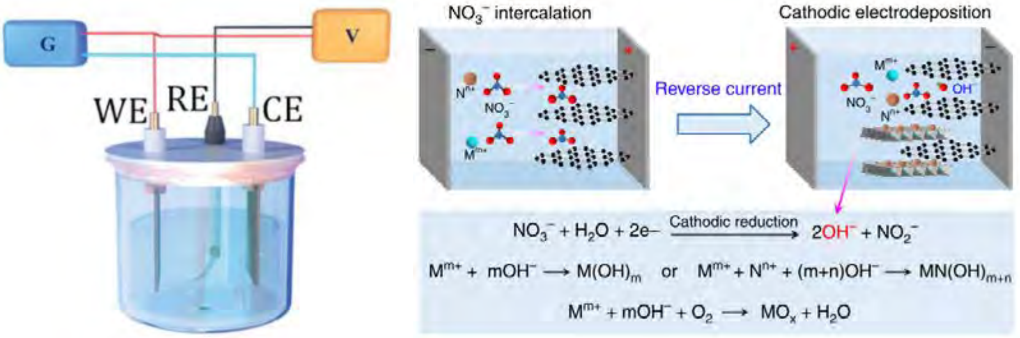

Fig.1 Electrodeposition strategy and principles.

Dimensionally stable anodes (DSAs), most often based on IrO_2 as a core component, have been widely utilized for industrial chlorine production (chlor-alkali) and high-salinity wastewater treatment via generation of reactive chlorine species (RCS). For an effective electrochemical water treatment, a competition between oxygen and chlorine evolution reactions for the surface coordinated reactive oxygen species would be an important consideration. This study reports variable strategies on heterojunction architecture over the conventional DSA configuration to enhance reactive chlorine species (RCS) generation in dilute aqueous solution in terms of current and energy efficiency. Firstly, we investigated the effects of TiO_2 over-layers with variable loadings on $Ir_{0.7}Ta_{0.3}O_x$ anodes. The $IrTaO_x$ layer was found to serve as ohmic contact with the Ti substrate by redox cycle of Ir(IV)/Ir(VI) couple, while the outer TiO_2 layer could shift the heterogeneous reaction selectivity. In particular, an elevated concentration of adsorbed hydroxyl radical could enhance the rate of RCS generation. Secondly, we demonstrated that bismuth titanate outer layer on the $IrTaO_x$ layer could significantly enhance the current and energy efficiency of reactive chlorine generation, while allowing •OH mediated oxidation in the absence of the chloride ion. In particular, formation of $Bi_2Ti_4O_{11}$ was noted at Ti:Bi ratios of 5:5 and 3:7 in precursor. Considering relatively low electrical conductivity of TiO_2 and Bi_2O_3 as well as the instability of Bi_2O_3 in circum-neutral pH, our findings would boost the efficacy of IrO_2 based DSA with minimal losses in current generation and operation lifetime.

Pd- and Pt-Polypyrrole coated Nitrogen-doped Reduced Graphene Oxide for Voltammetric Sensing of Formaldehyde

Pei Meng Woi
Chemistry Department, Faculty of Science, University of Malaya
50603, Kuala Lumpur, MALAYSIA
pmwoi@um.edu.my

The study presents the synthesis of polypyrrole-coated palladium platinum/nitrogen-doped reduced graphene oxide nanocomposites (PdPt-PPy/N-rGO NC) via direct the reduction of Pd(II) and Pt(II) in the presence of pyrrole monomer, N-rGO and L-cysteine as the reducing agent. X-ray diffraction confirmed the presence of metallic Pd and Pt from the reduction of Pd and Pt cations. Transmission electron microscopy images revealed the presence of Pd, Pt and PPy deposition on N-rGO. Impedance spectroscopy results gave a decreased charge transfer resistance due to the presence of N-rGO. The nanocomposites were synthesized with different Pd/Pt ratios (2:1, 1:1 and 1:2). A glassy carbon electrode (GCE) modified with the nanocomposite showed enhanced electrochemical sensing capability for formaldehyde in 0.1 M sulfuric acid solution. Cyclic voltammetry showed an increase in the formaldehyde oxidation peak current at the GCE modified with Pd2Pt1 PPy N-rGO. At a typical potential of 0.45 V (vs. SCE), the sensitivity in the linear segment was 345.8 μA.mM $^{-1}$. cm^{-2}. The voltammetric response was linear between 0.01 and 0.9 mM formaldehyde concentration range, with a 27 μM detection limit (at S/N = 3).

Towards Personalization of Electropolishing Post-Treatments

Zahra Chaghazardi[a], Rolf Wüthrich[a,b]
[a] *Department of Mechanical, Industrial, and Aerospace Engineering, Concordia University, Montreal, Quebec, H3G 1M8, Canada*
[a,b] *Department of Chemical and Materials Engineering, Concordia University, Montreal, Quebec, H3G 1M8, Canada*
zahra.chaghazardi@concordia.ca
Rolf.wuthrich@concordia.ca

The present study investigates the possibility of introducing the concept of mass personalization to electropolishing treatments. The goal of product personalization is to cater to the unique preferences of the customers by close integration of them in the design process (1-2).

Electropolishing is among the flexible industries that are suited to the concept of personalization because it presents a relatively small machining overhead. It enhances the aesthetics and durability of metal parts by smoothening and brightening of their surface (3-4). The flexible yet effective nature of electropolishing makes it highly appealing to many applications, especially industries such as watchmaking that can benefit from the aesthetically pleasing metal surfaces as well as the possibility of demanding different surface appearances. Such industries need to adopt strategies to increase their level of product customization to maintain their competitiveness in today's market. Electropolishing services offered nowadays do not offer diverse options at least in terms of the appearance of the final surface, much less the possibility of providing the customer's specific selection of surface gloss. There seems to be a huge potential in customization of the electropolishing services, where the process can be tuned in order to achieve the specific surface finish demanded by the customer.

In this study, various surface finishes are obtained for stainless steel 316L and grade 5 Titanium samples, which are two of the most used alloys by the watchmaking industry. In order to achieve different surface roughness and brightness, some electropolishing parameters (time and electric potential) are modified.

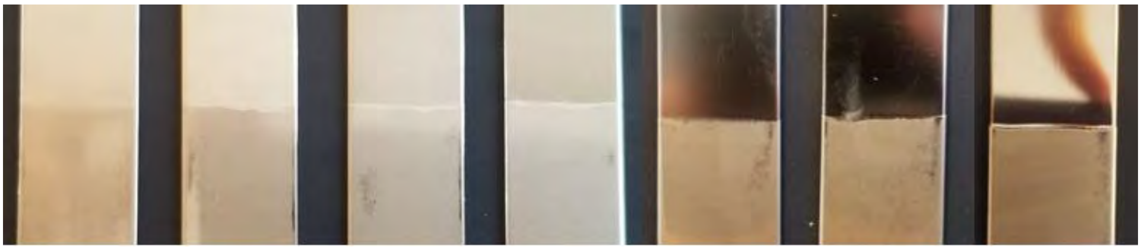

Figure 1. Various surface finishes achievable for Stainless Steel 316 L samples, by electropolishing at different times and applied potentials

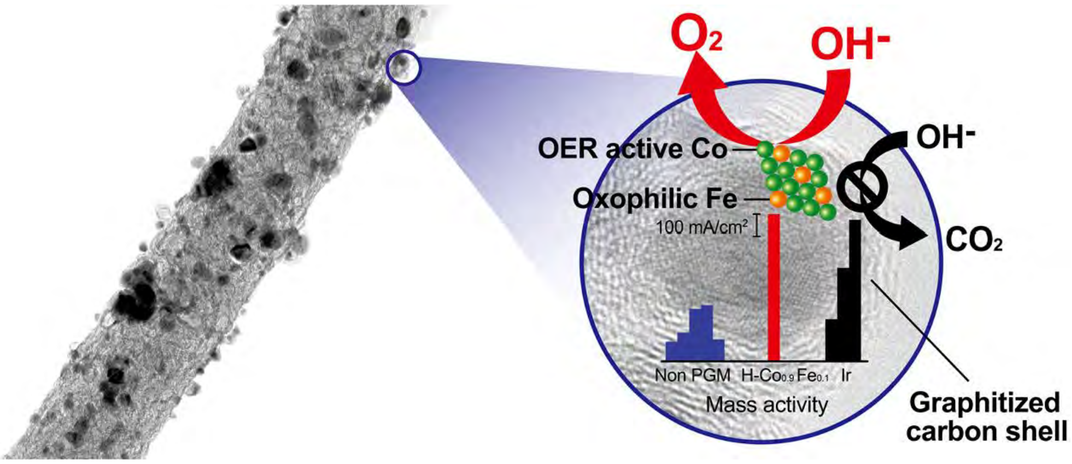
**Corresponding author e-mail address: jaeyoung@gist.ac.kr*

We propose corrosion-resistant carbon-coated $Co_{0.9}Fe_{0.1}$ alloy nanoparticles as highly active and durable electrocatalysts for the oxygen evolution reaction (OER) in anion exchange membrane water electrolysis (AEMWE). In the presence of 10% Fe atoms, the oxophilicity of Co metal is modulated in a direction to facilitate OH^- adsorption on Co^{3+}; thus, $Co_{0.9}Fe_{0.1}$-carbon nanofiber (CNF) can exhibit smaller overpotentials than other metal ratios in $Co_{1-x}Fe_x$-CNF. Additionally, we confirm catalytic degradation from the oxidation of the carbon layer, which is triggered by defects in the carbon originating from Fe during the pyrolysis step. The $Co_{0.9}Fe_{0.1}$ metal is further optimized by increasing graphitization to simultaneously achieve superior activity and durability for application on AEMWE. This work not only demonstrates the role of Fe in Co metal for controlling the proper oxophilicity but also shows the importance of graphitized carbon as a catalyst support for stable water oxidation.



The Influence of O_2 and Local Changes of pH on Pt Oxide Formation

Oliver Rodriguez, Guy Denuault
Chemistry, University of Southampton
Southampton, SO17 1BJ U.K.
G.Denuault@soton.ac.uk

The effect of oxide coverage on the oxygen reduction reaction has been widely studied and it has been reported that a partially oxidised surface is less electroactive towards the ORR than a fully reduced metallic surface. In contrast, the effect of molecular oxygen on oxide formation and reduction has not received much attention, probably due to the difficulty to separate the contribution from both processes that occur at similar potentials and time scales. Some groups have studied this by forming oxide in the presence of molecular oxygen and reducing it in its absence; this requires precise control to change the solution or to fully degas it before the reduction takes place. Furthermore, these experiments do not take into account the different states of the surface due to the availability of molecular oxygen. Recently, our group reported the presence of oxygenated species that are pre-adsorbed on metallic electrodes after being exposed to oxygen (1, 2). Recent results in neutral media suggest that these species are related to oxide formation that could be influenced by the presence of molecular oxygen in solution and by local changes of pH. To study this, we exploit the negative feedback mode of SECM and control the tip/substrate distance to minimise the influence of dissolved oxygen on the reduction response; this procedure also ensures that the state of the surface is the same since it is always exposed to oxygen. The results in acidic conditions show a good correlation between the oxide coverages obtained under hindered diffusion and the coverage obtained in a fully degassed solution, suggesting that the oxide formation is not influenced by the presence of dissolved oxygen at low pH. In neutral and unbuffered media the oxide formation shows a dependence on the tip/substrate distance. Furthermore, under hindered diffusion we observe a diffusion controlled wave that we ascribe to OH^- oxidation; this suggests that the differences seen in the oxide formation region in the presence and absence of oxygen are due to local changes of pH. Overall, we show that Pt electrochemistry is not influenced by the presence of O_2 in solution as previously reported, but by the local changes of pH that occur during reactions under neutral and unbuffered media.

Consecutive Ag^{I} Ion Incorporation into Oligonucleotides containing Cytosine-Cytosine Mispairs

M. Nur Hossain[a], Syed Ahmad[a,b], Heinz-Bernhard Kraatz[a,b]

[a]*Department of Physical and Environmental Sciences, University of Toronto, 1065 Military Trail, Scarborough, ON M1C 1A4, Canada; Email: mnur.hossain@utoronto.ca*
[b]*Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, M5S 3H6, Canada.*

Metal ions interact with DNA at various sites and play an essential role in stabilizing the diverse possible confirmations. In particular, Ag^{I} binds to bridges the nucleobases, effectively putting it within the double helix, instead of phosphate backbone, and it is selectively captured by cytosine-cytosine mispairs in the DNA duplex. Herein, we have demonstrated the consecutive incorporation of Ag^{I} ion into the dsDNA containing adjacent C-C mispairs and the corresponding conformational effects on the overall duplex conformation. Our ultraviolet (UV) and circular dichroism (CD) spectroscopy studies have shown that a stable bridging of C-Ag^{I}-C upon the incorporation of the stoichiometric amount and significant structural changes in the presence of an excess amount of Ag^{I}. Subsequently, the Ag^{I}-mediated DNA strands are immobilized on Au surfaces, and their electrochemical properties are monitored using CV, EIS and SECM showing increased overpotentials and charge-transfer resistances and decreased the rate constant in the presence of an excess of Ag^{I}, respectively, which are linked to dramatic structural changes. These results are further supported by the XPS and sulfide-Au reductive desorption measurements. Our findings demonstrate that metal ion mediation of nucleobase mispairs plays an important role in the conformational stabilization of DNA duplexes and to change their electrochemical properties, two facts indispensable to the study of DNA and DNA based sensors.

Combustion synthesis of La-perovskites for fuel cell reactions

Anand Kumar
Department of Chemical Engineering
Qatar University, P O Box 2713, Doha, Qatar
akumar@qu.edu.qa

High energy density technologies of fuel cell and metal air batteries are considered as the energy conversion and storage systems to meet the future energy requirements. These technologies are greatly dependent on a pair of sluggish electrochemical reactions such as oxygen reduction reaction (ORR) and oxygen evolution reaction (OER). Both reactions require high cost metals to enhance the activity and stability, but their availability and cost limits the worldwide application in electrochemical technologies. Recently, a new class of materials, perovskites, have shown great potential for energy conversion and other relevant applications. In this paper, I plan to discuss the synthesis and electrocatalytic property evaluation of lanthanum based perovskites. Combustion based techniques were used to synthesize $LaMO_3$ (M=Cr, Mn, Fe, Co, Ni) perovskites by using metal nitrate precursors in presence of glycine fuel [1]. The structural and morphological properties of the catalysts were studied using XRD, SEM, and TEM. The synthesis conditions are found to have a significant effect on the nature of the nanoparticles and it can be tuned to synthesize amorphous or crystalline materials. The perovskites showed exceptional performance for oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) in alkaline medium. $LaMnO_3$ is found to be most active for ORR, whereas $LaCoO_3$ for OER. The onset potential of $LaMnO_3$ is -0.12 V, and for other La-transition metals is nearly -0.2 V. The Koutechy-Levich plot obtained from rotating disk electrode shows a higher number of electron transfer for $LaMnO_3$ catalyst and the least for $LaCrO_3$, whereas the stability results indicate the $LaCoO_3$ to be more stable as compared to $LaMnO_3$. Based on the experimental results and literature survey, it is suggested that the improved activity of Mn and Co based lanthanum perovskite catalyst could be due to the optimum stabilization of reaction intermediates involved in the rate-determining step (RDS) of ORR/OER.

Another aspect of this paper is based on a novel approach to the synthesis of perovskites. Addition of a small quantity of leachable salts during combustion helps in creating a thin coating of salt around the nanoparticles, in addition to lowering the combustion temperature resulting in smaller crystallites. Post combustion leaching of the salts results in agglomeration controlled smaller nanoparticles with high surface area and oxygen deficient surface cites suitable for electrocatalytic applications. Initial results indicate approximately two-fold increase in the kinetic current density of $LaMnO_3$ after salt assisted synthesis [2].

y.zhao@bath.ac.uk

An “indirect” photo-electrochemical sensor is presented for measuring a mixture of analytes including reducing sugars (e.g. glucose, fructose) and non-reducing sugars (e.g. sucrose, trehalose). The novelty is in the employment of a palladium film creating a two-compartment cell to separate the analytical compartment and electrochemical responsive compartment (see Figure 1). The photo-catalytic compartment relies on a well-known photocatalyst Pt@g-C_3N_4[1] immobilised into a polymer of intrinsic microporosity (PIM-1)[2]. The immobilised photocatalyst is deposited onto a thin palladium membrane, which allows rapid pure hydrogen diffusion. When applying blue LED light, hydrogen is generated driven by quenchers, captured by the polymer coating, and then driven across the palladium foil. Chronopotentiometry (zero current) responses from the localized photo-driven production are observed in the electrochemical compartment. This concept demonstrated potential to measure any types of hole-quenching analytes with no conductivity or buffer requirements. Potential for applications of “indirect sensing” is demonstrated with commercial soft drinks. This design is proposed to pave the way for sensing applications studying complex samples like colloids, foods, formulations, or drugs without any directly applied electrochemical process.[3]

Self-powered drug delivery systems based on conductive polymers (CPs) that eliminate the need for external power sources, are of significant interest for use in clinical applications. Osmium redox polymer mediated glucose/O_2 enzymatic biofuel cells (EBFCs) were prepared with an additional CP-drug layer on the cathode. On discharging the EBFCs in the presence of glucose and dioxygen, model drug compounds incorporated in the CP layer were rapidly released with negligible amounts released when the EBFCs were held at open circuit. Controlled and *ex situ* release of three model compounds, ibuprofen (IBU), fluorescein (FLU) and 4',6-diamidino-2-phenylindole (DAPI), was achieved with this self-powered drug release system. DAPI released *in situ* in cell culture media was incorporated into retinal pigment epithelium (RPE) cells. We present a proof-of-concept responsive drug release system that may be used in implantable devices.

Industry 4.0: Model Sized Smart Factory for Electropolishing

Gobinath Vellapalayam Manoharan [a] and Rolf Wuthrich [a, b]

[a] *Department of Mechanical, Industrial, and Aerospace Engineering, Concordia University, Montreal, Quebec, Canada*

[b] *Department of Chemical and Materials Engineering, Concordia University, Montreal, Quebec, Canada.*

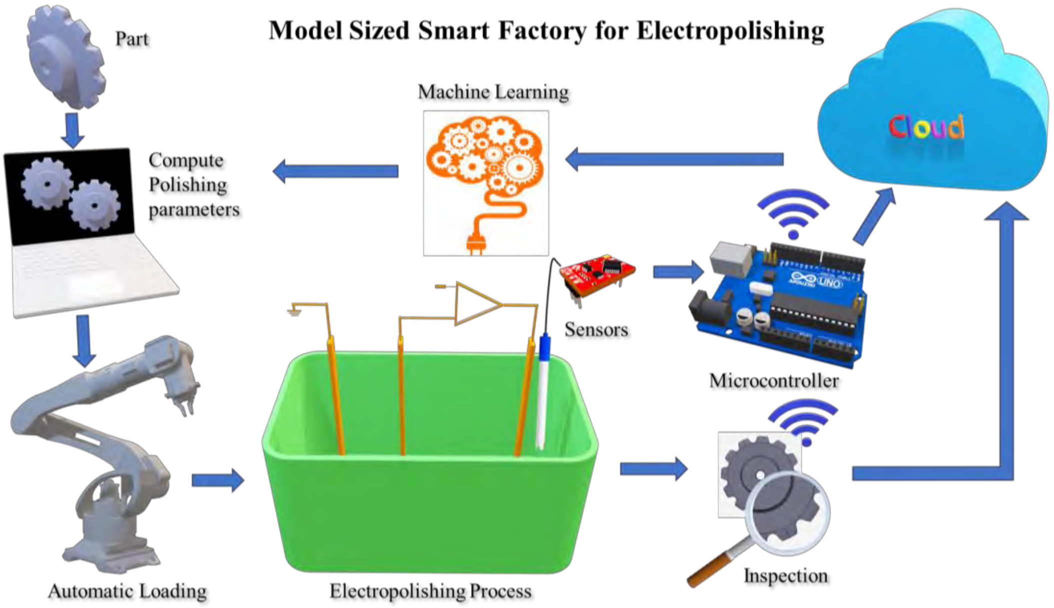
Abstract:

With the arrival of Industry 4.0, manufacturing industries are initiating the manufacturing process through the latest smart technologies, which allows them to make faster, smarter, more confident decisions. Notably, the small and medium-sized industries are moving their manufacturing facility to smart factories. However, most of the electropolishing industries do not have enough know-how and assets to build high technology like smart factories. In fact, automation and smart technologies are almost non-existent in industrial electropolishing. As a result, the industry is facing problems in terms of automation, long term quality control, and data collection. This paper proposes a model sized automated smart manufacturing setup for the electropolishing manufacturing process in the laboratory environment. The proposed model sized manufacturing setup has automated loading & unloading of workpieces, real-time monitoring of bath parameters (such as bath temperature, pH, electrical conductivity, density, and viscosity) and machine to machine communication without the need for human intervention. The process parameters information is stored and processed in a cloud. We employed a machine learning approach to adjust the process parameters of electropolishing to maintain consistent quality and repeatability of manufacturing products using the long-term history of data. Finally, the performance of the model sized smart factory is analysed from the viewpoint of real-time monitoring of bath parameters, machine to machine communication, and consistent quality of the product. The results show that the system is effective in the monitoring of bath parameters and delivers consistent quality.



3D printed electrodes for fuel electroanalysis: Simultaneous determination of lead (II) and copper (II) in ethanol

In this work, we report a simple and sensitive protocol for the simultaneous sensing of lead and copper at low levels in liquid fuel samples (bioethanol) by square-wave anodic stripping voltammetry (SWASV) at a carbon black/polylactic acid (CB/PLA) 3D-printed working electrode. A 3D printing pen was used to fabricate the working electrode in a similar design to a conventional disc electrode. The CB/PLA electrode was treated by the application of a potential of +1.4 V per 200 s and then by -1.0 V for the same time in 0.5 mol L^{-1} NaOH. The CB/PLA surface treatment dramatically improved the electrochemical response of copper and lead as shown in Figure 1, probably exposing the CB conducting sites of the 3D printed surface. The parameters that affect the SWASV technique for the determination of metals in the hydroethanolic samples were carefully optimized using univariate and multivariate designs. Under the optimized conditions, wide linear ranges were observed up to 200 µg L^{-1} ($R^2 = 0.991$) for lead and up to 400 µg L^{-1} ($R^2 = 0.995$) for copper. The limits of detection (LOD) were estimated as 1.0 and 1.7 µg L^{-1} with sensitivities of 0.0054 and 0.0047 µA µg L^{-1} for lead and copper, respectively. The inter-day (n=3) and interelectrode (n=2) studies provided RSD results lower than 2.8%, showing good stability of the proposed CB/PLA 3D-printed sensor in hydroethanolic medium with 30% (v/v) ethanol. The proposed protocol was applied to determine lead and copper in fuel ethanol samples, which were just diluted in the supporting electrolyte (HCl). Recovery values for two fortified samples in three different levels of lead and copper ranged from 82% to 107%. The developed method is feasible to be applied for the quality control of automotive (bio)fuels in gas stations (in-loco analyses) and the use of the CB/PLA 3D-printed working electrode makes this protocol very attractive in terms of cost-effectiveness and sustainability as low volumes were used and the 3D-printed electrodes are biodegradable. Figure 1 shows

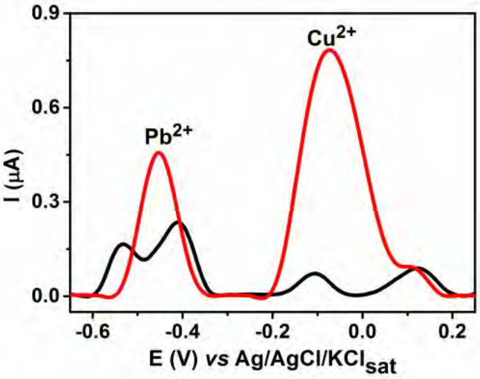

Figure 1. Baseline-corrected SWASV recordings for Pb^{2+} and Cu^{2+} (both 100 µg L^{-1}) before (black line) and after (red line) electrochemical treatment. SWASV conditions: deposition time: 180 s; deposition potential: -1.1 V; stirring rate: 1500 rpm; conditioning potential: +0.6 V; conditioning time: 30 s; step potential: 1 mV; modulation amplitude: 40 mV; frequency: 10 Hz. Supporting electrolyte: ethanol:water (30:70%; v v^{-1}) containing 0.1 mol L^{-1} HCl.

Assessing the Reactivity of Polyphenolic Antioxidants with Electrochemically Generated Superoxide Anion Radical by Cyclic Voltammetry

Tyra Lewis, Dr. Sanela Martic*
Department of Forensic Sciences, Environmental and Life Sciences, Trent University
Peterborough, ON Canada
**sanelamartic@trentu.ca*

Electrochemistry is a valuable tool that has been used to study the interaction between reactive oxygen species (ROS) and antioxidant compounds, such as phenols.[1-3] ROS, such as the superoxide anion radical, $O_2^{\cdot -}$ (SAR) is naturally produced within the biological environment *via* a single electron reduction of molecular oxygen (O_2).[2,4] Excess ROS can contribute to oxidative stress leading to cellular death and to the onset of health issues, such as cancers, diabetes and neurodegenerative diseases.[1,2,4] Flavonoids, such as quercetin (QCR), are polyphenolic compounds with antioxidant properties which react with SAR, further preventing cell damage.[3-5] Biologically relevant metal ions are also known to regulate ROS activity *via* Fenton reactions.[4] Interactions between flavonoids with metal ions, and the role of metallo-flavonoid complexes on the antioxidant capacity and activity remains poorly understood.[4,5] Using a three-electrode electrochemical cell, cyclic voltammetry (CV) was carried out to identify antioxidant activities of QCR and its metal ion complexes. A glassy carbon working electrode, a Pt wire counter electrode and an $Ag/AgNO_3$ reference electrode immersed in DMF were used to generate the $O_2^{\cdot -}/O_2$ redox couple electrochemically *in-situ*.[2] The current and potential associated with the $O_2^{\cdot -}/O_2$ redox couple were monitored to measure and quantify the scavenging ability of metal ions (Fe^{3+} or Cu^{2+}), QCR and their metallo-QCR complexes. In addition, *in-situ* or preformed metallo-QCR complexes were also tested and compared. CV data indicated that all additives played a role as free radical scavengers and decreased the concentration of SAR in solution. Overall, the copper-QCR complexes induced greater reduction of SAR concentration compared to the iron-QCR complexes.

Performance modelling and design of the electrode microstructure for batteries using a 3D pore-scale lattice Boltzmann model

Qiong Cai, Duo Zhang
Department of Chemical and Process Engineering, Faculty of Engineering and Physical Sciences,
University of Surrey, Guildford GU2 7XH, United Kingdom
q.cai@surrey.ac.uk

The 3D microstructure of porous electrodes plays an important role in the performance of electrochemical energy devices including fuel cells, batteries and electrolysers. Computational models are useful as they can provide a direct link between microstructure properties and the complex transport phenomenon and electrochemical performance [1]. A three-dimensional (3D) pore-scale lattice Boltzmann modelling (LBM) framework has been developed at University of Surrey to simulate the transport mechanisms of gases, liquid electrolyte flow, species and charge in the porous electrodes [2-4], coupled with electrochemical reactions.

In this paper, we will show the application of the 3D pore-scale LBM framework for modelling 3D porous fibrous electrode microstructures in redox flow batteries (RFBs), with electrochemical reactions implemented at the interfaces between the solid fibres and the liquid electrolyte. The model is able to capture the multiphase flow phenomenon and predict the local concentration for different species, over-potential and current density profiles under charge/discharge conditions [3]. It is found that the electrochemical performance is reduced with air bubbles trapped inside the electrode [3]. To validate the model, the simulated pressure-drop and electrochemical performance are compared against the experimental measurement based on the same electrode structures [4]. Three electrode structures (SGL paper, Freudenberg paper, Carbon Cloth) are reconstructed from X-ray computed tomography (CT). These electrodes are used in an organic aqueous RFB based on TEMPO. Excellent agreement is achieved between the simulated and experimentally measured electrochemical performance, indicating the validity of our model [4]. The effects of different porous structures on the performance are also investigated, to reveal the desirable electrode microstructural features for RFBs.

We will also report the application of 3D pore-scale LBM framework for simulating lithium-ion battery (LIB) electrodes [5]. The model is further developed to simulate the complex transport processes of ions, electrons, and multicomponent liquid species in real electrode geometries, and predict electrochemical performance. The simulated discharge curves of a realistic nickel-manganese-cobalt (NMC) battery electrode are in good agreement with the experimental measurement, demonstrating the validity of the model. The LBM framework is then applied to simulate a series of electrode structures generated using a discrete element method, to understand the effects of particle size and distribution, porosity, surface area, and tortuosity on the performance of the electrode. It is revealed that surface area and porosity are the determining factors for the performance, and structured patterns are beneficial for achieving uniform local distribution of lithium and current densities within the electrode. The current modelling work enhances our understanding of the impact of electrode microstructure on electrode performance, leading to design principles for electrodes with optimal microstructure for LIBs applications.

Finally, we will report our recent work on using the 3D pore-scale LBM framework to help design 3D porous carbon structures as lithium host, to suppress Li dendrite growth and enable long cycle life for lithium metal batteries (LMBs).

Model-Based System Design of Alkaline Water Electrolyzers Powered by Renewable Energy

Jörn Brauns, Thomas Turek
Institute of Chemical and Electrochemical Process Engineering, Clausthal University of Technology
Leibnizstr. 17, 38678 Clausthal-Zellerfeld, Germany
brauns@icvt.tu-clausthal.de

Alkaline water electrolysis is a key technology to utilize increasing amounts of fluctuating and intermittent renewable energy. Conventional alkaline water electrolyzers are designed for a stationary operation at fixed process conditions. Therefore, this technology needs to be enhanced to handle the required dynamic operation. The main problem of existing systems is the limited part-load range. Below 10 – 20 % of the nominal load, the gas purities decrease significantly. As hydrogen and oxygen can form explosive mixtures in a very broad range, this is a major safety issue. In consequence, electrolyzers perform a safety shutdown when reaching a gas impurity of 2 vol.% hydrogen in oxygen, which is 50 % of the lower explosion limit [1]. An additional problem is the electrode degradation due to an increased number of on/off cycles [2]. Furthermore, the system temperature needs to be in a fixed range for an efficient operation. Since most electrolyzers powered by renewable energy do not provide a heating unit, only the heat generation of the reaction is used to maintain a suitable temperature. Hence, the system inertia defined by the liquid electrolyte volume should be optimized for the local conditions [3]. As this parameter also influences the product gas purity, an optimal sizing without an adequate process model is difficult.

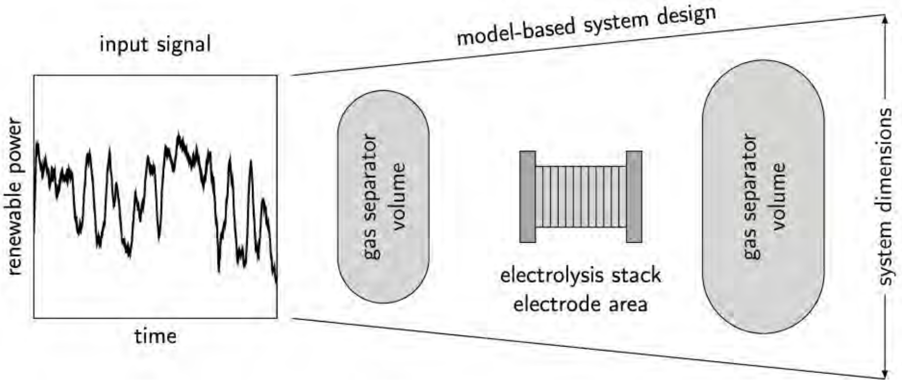

Figure 1: Scheme of model-based system design. Location depended availability of renewable power can be used to determine the optimal system dimensions.

This contribution shows how model-based system design can help to improve the overall system performance and production availability. Since every location offers different conditions, the electrolyzer must be adapted accordingly. A mathematical model is used, which extends an existing approach by implementing dynamic balance equations, pressure effects and concentration drifts [4]. Model validation is performed by stationary and dynamic experiments in a lab-scale electrolyzer. In Figure 1, a typical fluctuating wind power profile is provided, which can be utilized to optimize the system dimensions. The combination of suitable system designs and dynamic operation strategies enables longer production periods by enhancing the gas purity. As a result, more renewable energy can be used and the system components benefit from a longer lifetime. Whereas the local renewable energy production rate determines the nominal load, the fluctuation amplitude and frequency can be used to calculate the optimal system dimensions.

Calcium, being the fifth most abundant metal on earth, combines high abundance with competitive volumetric capacity. As newer studies show promising results concerning electrochemical Ca plating/stripping (1-5), a combination with an oxygen cathode promises impressive theoretical energy densities. In literature some pioneering work on the Ca $–O_2$ system exists (6-8) but deeper fundamental research is necessary to get insights into the reaction mechanism of oxygen reduction reaction (ORR) and oxygen evolution reaction (OER).

In this study we are investigating the ORR and OER in Ca^{2+} containing system with various electrochemical and analytical methods. The product distribution of ORR products is investigated with differential electrochemical mass spectrometry (DEMS) and rotating ring disc electrode (RRDE) using Pt and Au as electrocatalysts. The main products are Ca-peroxide and Ca- superoxide. Both products are soluble in DMSO. A complete blocking of the electrode surface, as it is known from $Li-O_2$ literature, was not observed. Still the formation of superoxide in presence of the deposited film on the electrode is observed. Characterization of the ORR products was done via ex situ XPS measurements. There we could confirm calcium peroxide and calcium superoxide as ORR products. Another oxygen containing product seems to be calcium oxide, which is located close to the electrode (shown by Ar^+ etching and XPS). In the electrochemical experiments the electrocatalysts can fully be regenerated by applying higher electrode potentials as XPS studies showed. In addition the deposition of products on the electrode was investigated with EC-AFM.

On basis of the new findings the reaction mechanism of the ORR in Ca^{2+} containing DMSO will be discussed.

Pillar[5]arenes: comparison of electrochemical behavior in different organic solvent

Magdalena Z. Wiloch, Grzegorz Sobczak, Volodymyr Sashuk, Martin Jönsson-Niedziółka
Institute of Physical ChemistryPolish Academy of Sciences
Kasprzaka 44/52 01-224 Warsaw, Poland
mwiloch@ichf.edu.pl

We have studied the electrochemical properties of dimethoxypillar[5]arene in two organic solvents, dichloromethane and acetonitrile.

Research based on host–guest chemistry has attracted considerable interest in supramolecular chemistry for many years. Over the last decade, not only in optical but also electrochemical sensing, macrocyclic hosts like cyclodextrins, calixarenes or crown ethers have been in the spotlight. However, recently, in 2008 Ogoshi[1][1] reported a new type of macrocyclic compounds called Pillar[n]arenes. Pillar[n]arenes consist of five or six hydroquinone units linked by methylene bridges in the para position. Their rigid, symmetrical and cylindrical structures as well as the ease of functionalization make them particularly attractive in comparison to many other host molecules. Host-guest complexation as well as structure properties of different pillar[n]arenes are mainly studied by spectroscopic techniques. Far less research has been carried out by voltammetric techniques. Since most of the pillar[n]arenes are dissolved in organic solvents, voltamerometric studies were performed mainly in dichloromethane[2][3] solution or with aqueous electrolytes[4] mixed with acetone.

The main goal of this work was to investigate the anodic voltammetric behavior of dimethoxypillar[5]arene using cyclic voltammetry and pulse techniques. The influence of different organic media - dichloromethane and acetonitrile in which we conducted our voltammetric experiments, on redox properties were studied. Discrepancy of redox reaction reversibility were compared using different scan rate and range of potentials. The proposed approach could provide better description of pillar[n]arenes voltammetric behavior and thus could be helpful in the understanding of the electron donor properties in supramolecular host–guest interactions.

Among the various energy sources, hydrogen is considered as an efficient energy source which stands out due to its high energy per mass content, easy transportability and clean electricity generation. Furthermore, hydrogen production not only obtained from water splitting with solar light irradiation but also zero CO_2 emission to earth. A most of promising photoanode material TiO_2 has more advantage because of easy synthesis method with various surface morphology for photoelectrochemical hydrogen production [1, 2]. Herein, we introduced that one-dimensional, versatile TiO_2 with rutile phase structure was synthesized via hydrothermal method on conductive glass substrate (FTO) and then modified with $BiVO_4$ by electrochemical deposition and drop casting method. Fig. 1 shows Nyquist(a), Bode(b) and Phase angle-frequency(c) plots of electrodes. EIS measurement was carry out under a bias potential of 0.6 V to examine oxygen evolution reaction (OER) on electrode surface. It indicates that Uncal_TiO_2/$BiVO_4$ electrode is the smallest semi-circle in order to utmost photocatalytic response under solar irradiation compare to applied calcination on TiO_2. LSV result of electrodes display in Fig. 1 d. Uncal_TiO_2/$BiVO_4$ electrode demonstrates a high photo-current density at 1.0 V (0.474 mA cm^{-2}) in contrast to calcinated TiO_2 electrodes for photocatalytic hydrogen production under solar light. It suggests hindering rate of electron-hole recombination and improved photoelectrode separation.

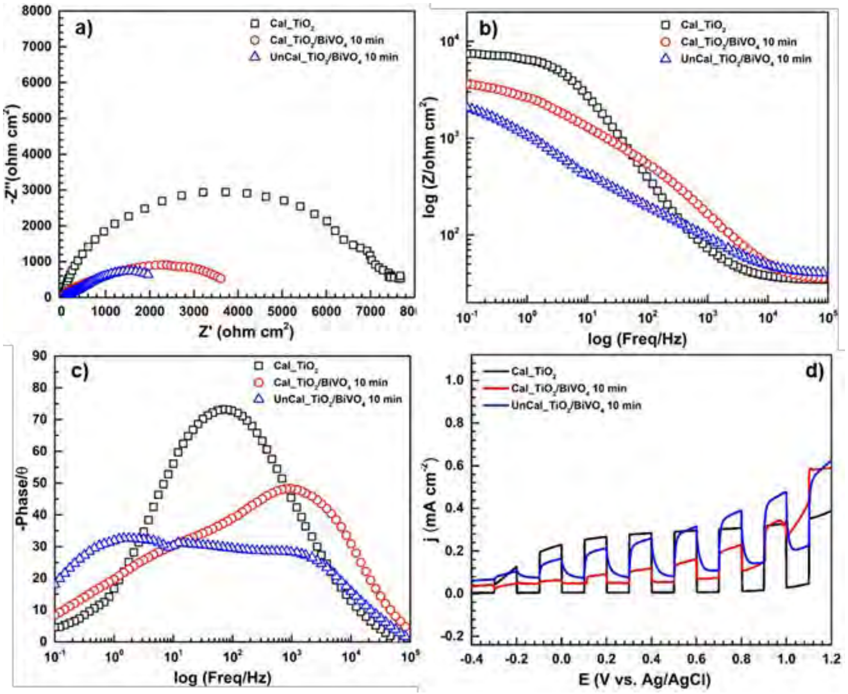

Fig. 1. Nyquist a), Bode b), phase angle-frequency c) and LSV d) graph of electrodes in 0.1 mM Na_2SO_3 electrolyte with 0.1 mM phosphate buffer.

Electrochemical Study of The Effect of Aluminum Ions on The Stability and Performance of Cu-Based Catalysts in Atom Transfer Radical Polymerization in Organic Media

Jie Luo, Abdirisak Ahmed Isse, Christian Durante and Armando Gennaro
Department of Chemical Sciences, University of Padova
Via Marzolo 1, 35131 Padova, Italy
jie.luo@studenti.unipd.it

Copper-based catalyst complexes played a critical role in the development of atom transfer radical polymerization (ATRP).[1] Among recently developed various advanced techniques, electrochemically mediated ATRP (*e*ATRP) proved to be a clean, robust and versatile method. The applied potential or current (E_{app} or I_{app}) determines the Cu^I/Cu^{II} ratio, allowing easy fine-tuning of reaction rate and polymerization control.

However, *e*ATRP is usually carried out in a divided cell with a separator that significantly increases the overall resistance. Also, Pt electrodes are often used. However, it has been shown that *e*ATRP can be successfully achieved on non-noble metals and also in undivided cells with Al anodes. In the latter cases, a significant challenge aroused due to the small amount of released metal cations. Indeed, it was observed that the presence of Al^{3+} in DMF strongly interferes with the catalytic system, drastically affecting the performance of *e*ATRP catalyzed by $[Cu^{II}Me_6TREN]^{2+}$.[2] However, the nature of the interference of Al^{3+} ions with Cu complexes was not investigated in depth. Here we report a detailed investigation on the effect of Al^{3+} on the performance of two of the most active and widely used ATRP catalysts, $[Cu^{II}Me_6TREN]^{2+}$ and $[Cu^{II}TPMA]^{2+}$, in DMF, DMSO, and MeCN.

These complexes have been previously used in *e*ATRP in both organic solvents and water.[2-5] In general, very stable Cu complexes with 1:1 Cu^{II} to ligand stoichiometry are formed.[6] Fig.- 1 illustrated the effect of Al^{3+} on the voltammetric behavior of $[Cu^{II}Me_6TREN]^{2+}$. When $C_{Al^{3+}}/C_L$=1.5 in DMF (Fig. 1a), two well-separated irreversible reduction peaks followed by an anodic stripping peak were observed in place of the reversible peak couple of $[Cu^{II}Me_6TREN]^{2+}$, which instead disappears. The presence of Al^{3+} caused dissociation of $[Cu^{II}L]^{2+}$ with release of Cu^{2+}, which is reduced to Cu^+ at less negative potential. Fast disproportionation of the latter to Cu^0 and Cu^{2+} and/or reduction at the electrode produced a deposit of metallic Cu on the GC electrode. Similar phenomena were observed also in DMSO and MeCN (Fig. 1b and c). Interestingly, the typical voltammetric pattern of $[Cu^{II}L]^{2+}$ could be restored by adding excess ligands. Conversely, the stability of $[Cu^{II}TPMA]^{2+}$ was affected by Al^{3+} only in MeCN.

The role of Al^{3+} was also investigated in *e*ATRP of butyl acrylate, providing results in agreement with the voltammetric analysis. In conclusion, this study, together with an ongoing work in water, provides useful guidelines for *e*ATRP in undivided cells with sacrificial Al anodes.

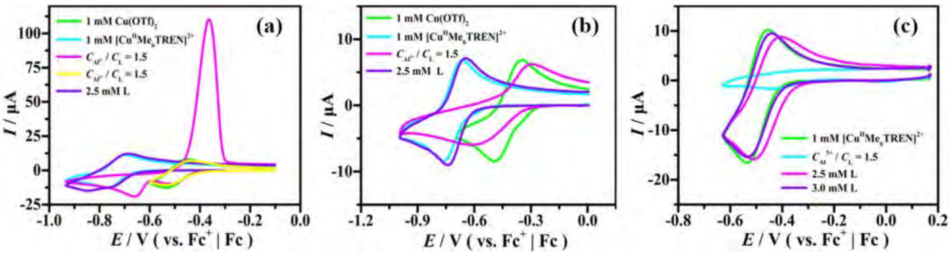

Fig. 1 CVs of 1 mM Cu $(OTf)_2$ in the presence of 1 mM Me_6TREN, 1.5 mM Al^{3+}, and excess Me_6TREN in (a) DMF, (b) DMSO, and (c) MeCN, recorded on a GC electrode at $\upsilon = 0.2\ V\cdot s^{-1}$.

tana.sebechlebska@uniba.sk

3D printing has been applied to every field of chemistry including electrochemistry. In recent years conductive composites containing different allotropes of carbon [1,2] or metals such as copper [3] have been used to manufacture 3D printed electrodes. For carbon nanotube-based composites it was recently demonstrated that after simple anodic activation procedure almost the whole surface of the electrode becomes electrochemically active (85 % relative area, further denoted as A_{EC}). On the other hand, current sensing atomic force microscopy imaging revealed that only 33% of the electrode surface is electrically conductive (A_{CON}). [1] To explore relationship between A_{EC} and A_{CON} we performed finite-element-method numerical simulations of cyclovoltammetric experiments with the electroactive probe in the electrolyte and composite electrodes. Simulations considered model 2D geometries and were performed in program COMSOL Multiphysics®. [4] In the electrolyte phase a continuity equation is formulated for both (oxidized and reduced) forms of the probe. The charge transfer at the electrode/electrolyte interface is formulated as Butler-Volmer kinetic expressions introduced as source/sink terms of the electrode boundary condition of continuity equations. Results (Figure 1) indicate that the non-linear diffusion is of great significance at the interface of electrolyte and composite electrodes. The simulated cyclovoltammetric response of the electroactive probe at the composite electrode with A_{CON} = 33 % (corresponding to the electrode surface shown Figure 1B) leads to A_{EC} = 98 %. This value is comparable to experimental value obtained at the electrode 3D printed from this composite (A_{EC} = 85 %).

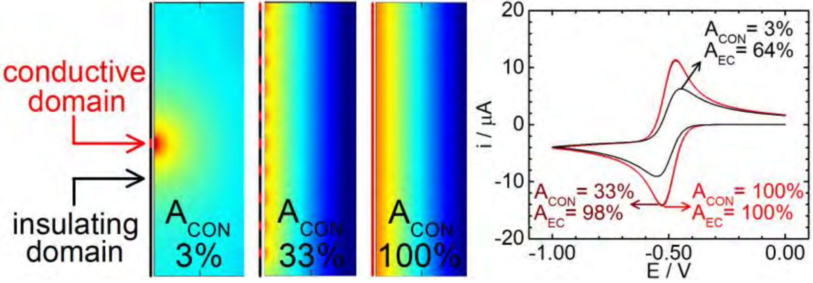

Fig. 1 COMSOL simulations. (A) Concentration profiles of the reaction product generated at composite electrodes with A_{CON} values of 3 to 100 %. (B) Corresponding simulated voltammograms.

Electrochemical reduction of CO_2 into carbon-based fuels has received great attention due its importance as source of renewable energy. Copper and copper oxide electrodes are well known to electrochemically convert CO_2 to a range of products. The selectivity is associated to the species adsorbed on the surface and/or its crystallographic orientation [1]. For example, methane is the dominant product on Cu(111), whilst ethylene is favoured on Cu(001) [2].

Surface x-ray diffraction (SXRD) can be used to study Cu electrodes in electrochemical environment and correlates the changes in the atomic structure with the redox reactions. In this work in-situ SXRD studies are presented on Cu(111) and Cu(001) electrodes in a neutral phosphate buffered electrolyte (pH 8). Strong dependence in the morphology and stability of the Cu(111) surface during the potential cycling arises from the preparation method and history of the electrode. The phosphate adsorption and deprotonation of the (di)-hydrogen phosphate can lead a fully reversible adsorption process of oxygenated species for a smooth and defect free surface.

However, in the presence of defects on the electrode surface, the formation of a mixed copper-oxygen layer is accompanied by irreversible changes on the surface morphology due to a 3D Cu growth mechanism [3]. Results for Cu(001) oriented electrodes in the same electrolyte suggest a potential dependent roughening and facet formation. In the presence of defects and for prolonged potential changes the formation of Cu(111) terminated islands is observed.

Acad. Semenov Ave., 1, Chernogolovka, Moscow Region, Russia
vpvasiliev@mail.ru

The mass production of high-quality graphene is important for its application in next-generation electronics, composite materials, energy storage devices, humidity sensors and development of platinum group metals free catalysts of oxygen reduction reaction (ORR). Therefore, determination of conductivity of films formed by graphene structures is of both fundamental and applied importance. In this study, we propose a simple and effective method to estimate the resistance of films formed by few-layer graphene structures obtained by plasma-assisted electrochemical exfoliation of graphite electrodes in 0.3–1 M Na_2SO_4 solutions [1]. The analysis of the influence of humidity and the nature of solvent on the conductivity of FLGS films was carried out.

Synthesized graphene-like structures are particles with a wide distribution of lateral size,which varies from 60 to 550 nm. The thickness of FLGS flakes was estimated at 2–4 nm; the thickness of FLGS films is 200–300 nm. According to X-ray photoelectron spectroscopy, the content of O and S is 18.8 and 1.3 at.% for c-FLGS and 23.8 and 4.1 at.% for a-FLGS.

In a dry atmosphere, a current observed for FLGS films is determined by their electronic conductivity. An increase in the relative humidity always leads to a sharp decrease in the current and a subsequent gradual decrease in its value. The observed decrease in conductivity of FLGS films in a humid atmosphere is associated with the shielding of FLGS flakes by a film of water. Returning a sample to a dry atmosphere leads to an abrupt growth and further slow recovery of the current values. Probably, the reverse process proceeds much slower, since the rate of water molecules removal and restoration of electrical contacts between FLGS flakes is less than the rate of formation of water film around FLGS particles. The electronic conductivity of films in a dry atmosphere could be a qualitative criterion for a small degree of functionalization of FLGS surface. However, in our case, the oxygen content in FLGS is sufficiently high and electronic conductivity should be explained by the fact that functional groups are mainly concentrated at the edges of graphene planes.

We observed a change in the conductivity of FLGS films in vapors of various solvents: heptane, CCl_4, ethanol and water. Despite high saturation vapor pressure, in the atmosphere of non-polar solvents (heptane, CCl_4), the conductivity of FLGS films is higher than that in the case of ethanol and water. Evidendly, high concentration of hydrophilic groups at the edges of graphene planes contributes to faster wetting of flakes and to more intensive diffusion of polar molecules into the film.

Thus, the conductivity of FLGS films can be controlled by external conditions, i.e. by increasing or decreasing the vapor pressure of various solvents. With the increase in vapor pressure, the molecules of polar solvents diffuse into FLGS film. It causes a lessening of the number of contacts between FLGS flakes and, consequently, the electric current decreases. Moreover, established influence of chemical nature of solvent on the electrical conductivity of FLGS films is due to the hydrophilic nature of synthesized FLGS particles.

The study was performed in accordance with the State Assignment (state registration No 0089-2019-0007). The work has been performed using the equipment of the Multi-User Analytical Center of IPCP RAS.

Proton Conductivity of Graphene Oxide and Nafion Films: Effect of Dry Charged Battery

V.P. Vasiliev
Institute of Problems of Chemical Physics, Russian Academy of Science
Acad. Semenov Ave., 1, Chernogolovka, Moscow Region, Russia
vpvasiliev@mail.ru

After separation of individual graphene sheets in 2004, the world's interest in graphene and graphene-like materials increased dramatically. Graphene oxides (GO) were initially considered as a source product for the production of graphene but are currently being actively studied to be used in various materials and devices. Materials with proton conductivity are used in various devices: fuel cells; electrolysis cells; electrochemical sensors; electrochemical reactors, electrochromic devices. Proton transport is observed in biological systems. In the dry state GO is an insulator, and in a humid atmosphere GO demonstrates proton conductivity. As a proton conductor the GO has various applications: humidity sensor, a separator in a supercapacitor, also in a field-effect transistor, and nanocomposite membranes. The proton conductive Nafion is widely used in fuel cells as membranes, it possesses high proton conductivity and the ability to control its swelling in water. In the present work the effect of charge accumulation in film was shown to be common to proton conductors. The effect of charge accumulation and conservation was studied using the example of proton conductors - Nafion and GO films

GO and Nafion films are typical proton conductors in water vapor and their conductivity depends on the humidity of the environment. The charging curve (curves 1 in Fig. 1) has a characteristic feature with a maximum in the initial period and a gradual decrease in current to a stationary value in the course of measurement. Such behavior of the current can be explained by vacancies filling with protons from the negative electrode and electrons from the positive electrode. The current decrease on curve 1 is comparable with the discharge current on curve 2 (Fig. 1). The amount of accumulated charge (discharge current) is proportional to the charging current. In this case, their difference (the sum of curves 1 and 2) corresponds to the stationary current in the cell, as can be seen from curve 3 in Fig. 1.

In the case of GO at a voltage of 400 mV and a film thickness of about 400 nm, the charge is about 10^{-6} C. The maximum charge value is limited by the concentration of traps in GO (OH groups) and can theoretically be ~ 10^{-2} C. In a dry atmosphere, the charge is maintained even when the voltage is applied to the electrodes - the current occurs only in a humid atmosphere. The observed behavior of the current in the films of GO and Nafion is similar to a charged capacitor, this process can be compared with the behavior of a dry-charged battery, unlike liquid batteries, where the charge is stored as a chemical compound accumulated during charging.

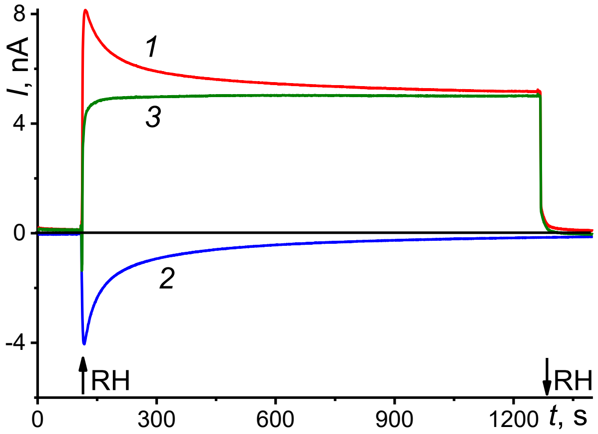

Fig. 1. *1* – The kinetics of charge accumulation in GO film at RH = 75%, U = 0.4 V. *2* – Process of GO film discharge at RH = 75%, U = 0 V.
3 – The sum of curves 1 and 2.

For the first time, the possibility of accumulation and storage of charge in films of typical proton conductors was shown experimentally using GO and Nafion films. The amount of charge accumulation depends on the humidity of the environment. In a dry atmosphere the accumulated charge can be stored for up to several days. Accumulation of charge occurs directly in GO or Nafion film, which significantly distinguishes proton conductors from electric capacitors and liquid batteries.

The study was performed in accordance with the State Assignment (state registration No 0089-2019-0012). The work has been performed using the equipment of the Multi-User Analytical Center of IPCP RAS.

Assessment of Antioxidant Activity of Some Chlorogenic Acids by an Electrochemical DNA-based Biosensor

**e-mail: ivana.tomac@ptfos.hr*

An electrochemical DNA-based biosensor, dsDNA/SWCNT-COOH/SPCE, was applied for the first time to assessment of antioxidant activity of six chlorogenic acids (CGAs) After the incubation of the electrochemical biosensor in the mixture of a DNA cleavage agent created by the Fenton type reaction, the degree of dsDNA degradation was determined using cyclic voltammetry (CV) of the redox indicator $[Fe(CN)_6]^{3-/4-}$. The normalized biosensor responses observed from CVs (ΔI_{rel} and $\Delta(\Delta E_{p,\ rel})$) were used to express the antioxidant activity of CGAs. The results showed that addition of CGAs in the cleavage agent significantly reduces the degree of DNA degradation and the antioxidative activity decreases in order caffeic acid, CFA, > caffeoylquinic acids, CQAs, > dicaffeoylquinic acids, diCQAs, exposure the relative portion of survived DNA of about 71 %, 70 % and 69%.

Electrochemical Imaging of Biomarkers for Oral Cancer Staging

Yen-Tzu Lin, Tzu-En Lin*

Institute of Biomedical Engineering

National Chiao Tung University, Hsinchu 300, Taiwan

Email: telin@nctu.edu.tw

Each year, approximately 450,000 new cases are reported with oral or oropharyngeal cancer worldwide. Despite their high incidence, oral cancers are often neglected at the first stage, resulting in cancer metastasis with high mortality rate, especially for men. Conventional methods for diagnosis of oral cancer rely on the visual inspection and biopsy. However, it may lead to misdiagnosis or delayed diagnosis because of insufficient information. Therefore, it is important to develop a novel tool for the detection of oral cancer at an initial stage itself.

Electrochemical screening methods have shown to be very promising for the rapid, sensitive, and cost-effective detection of oral cancer biomarkers.[1] To enhance the resolution of the electrochemical imaging, we employ the concept of image fusion, with the image obtained by scanning electrochemical microscopy (SECM) and optical microscopy. Through the prediction of the presence of biomarkers in tissue area, the fused image can provide a more accurate description of the biomarker distribution of the oral cancer slices. For the purpose of investigating the distribution of IL-6 protein, a biomarker of oral cancer, in different cancer stages, we use SECM to image tissue sections and fused it with H&E stain images obtained by optical microscope. SECM is a scanning probe technique that is composed of three electrode system and soft probe can scan closely over a sample surface. The primary antibody and secondary antibody labeled with horse radish peroxidase (HRP) were applied to reveal the locations of IL-6 on the samples. Then, the cancer sections were immersed in electrolytes containing FcMeOH and H_2O_2. The $FcMeOH^+$ ions were generated from the catalytic reaction of HRP, and hence, the Faradaic current signals from the reduction of $FcMeOH^+$ can be recorded through the scanning of SECM probe. Due to the fusion of SECM with H&E stain, IL-6 distribution patterns in cancers with different stages can be analyzed precisely. We discovered that in stage III of oral cancer, the IL-6 expression level is the highest as compared to the normal tissue and cancer tissue at earlier stages.

e-mail: sanchezraquel@uniovi.es

The early diagnosis of cancer is decisive for the survival of patients. However, traditional protein tumor markers do not always exhibit the sensitivity and selectivity required in clinical diagnostics applications. For this reason, current trends search for specific biomarkers with clinical validity and highly sensitive detection methods. Recent progress in modern biology has revealed that the proportion of DNA that encodes proteins represents only 2% of the human genome, so the vast majority is transcribed into the form of non-coding RNAs. Among the latter, long non-coding RNAs (lncRNAs) i.e. transcripts with length above 200 nucleotides, make up a large group that has aroused special interest due to their participation in a wide range of biological processes, thus freeing themselves of their initial name of "junk RNA". Altered expression levels of certain lncRNAs in human body fluids have been recently related to different diseases including cancer, turning them into potential non-invasive biomarkers (liquid biopsy).[1][2] Among them, prostate cancer antigen-3 or PCA3 is the only one so far approved by the US-FDA as a urinary marker for prostate cancer diagnosis. In fact, PCA3 is a good alternative to traditional serum PSA able to distinguish between aggressive and indolent tumours.[3][4] However, to exclude any nonspecific variation, levels of PCA3 should be normalized with an internal RNA control of stable expression, which demands the development of multiplex tests.

In this work we report a sandwich-type hybridization assay for the detection of the urinary biomarker PCA3. To overcome the challenge of the long size and internal secondary structure of this transcript, as well as its low abundance, we have proposed the use of multiple fluorescein-tagged hybridization assistant probes to favour the selective capture onto the sensing platform, while incorporating multiple redox enzymes per target molecule, via fluorescein-antifluorescein interaction. This strategy enabled on-surface quantification with an enhanced sensitivity and a wider range of linear response. An equivalent approach was also designed and developed for the detection of PSA mRNA, selected as endogenous control for normalization, because it is not up-regulated in cancer. Both optimized genosensors were successfully integrated into the same sensing platform for simultaneous assessment of PCA3 and PSA RNA levels. The usefulness of this multiplex platform was demonstrated by analysing total RNA extracts from the prostate cancer cell line LNCaP.

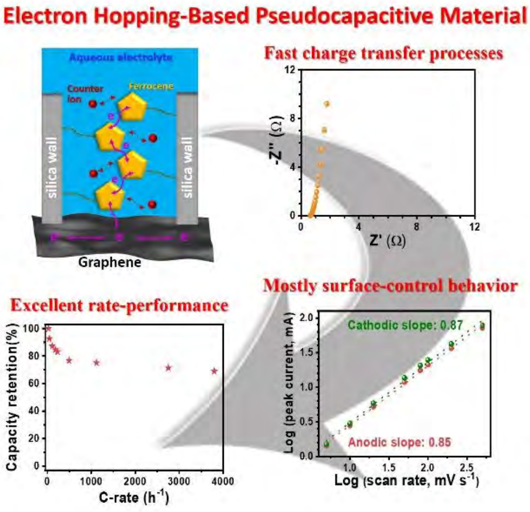
Electroactive Organically Modified Mesoporous Silicates on Graphene-Graphite 3D Architectures Operating with Electron-Hopping for High Rate Energy Storage

Jianren Wang, Neus Vilà, Alain Walcarius
Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l'Environnement (LCPME), UMR 7564 CNRS – Université de Lorraine, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France.
jianren.wang@univ-lorraine.fr

The ever-growing energy demand calls for energy storage devices with both high energy and power density. In contrast to electrical double-layer capacitors, the faradic pseudocapacitors can gain much higher energy density by involving faradic reactions, but the slow reaction rate severely restricts their power outputs. Here, a pseudo-capacitive material operating with electron-hopping as the charge transfer mechanism is generated onto a high surface area graphene current collector to study its interest in delivering fast redox reactions over a large-scale (contrary to monolayer-based electroactive systems). The extensive assembly of fixed redox molecules is achieved by anchoring ferrocene moieties onto the surface of graphene-supported mesoporous silica film and various physico-chemical techniques are used to characterize the resulting composite material. The obtained EG@Fc-MS electrode (ferrocene functionalized silica film coated onto electro-exfoliated graphene) can deliver a specific capacity of 196 mC cm^{-2} (326 mF cm^{-2}) at a current density of 2 mA cm^{-2} and a 69% capacity retention even at 3800 C, which is much better than the traditional faradic materials. The electrochemical analyses reveal the energy storage behavior of EG@Fc-MS is a fast surface-controlled redox process with the time constants τ_0 of 0.78 s due to the low resistance of charge transfer (no obvious semi-circle in Nyquist plot) and fast counter-ions compensation rate (diffusion coefficient ~1.9×10^{-5} cm^2/s). The electrode can be assembled into an asymmetric device which exhibits excellent cycling stability (no noticeable fading after 10 000 cycles) and competitive energy densities (respectively 17.7 or 9.2 µWh cm^{-2} at power densities of 0.53 or 13.7 mW cm^{-2}). These results open up new opportunities for pseudocapacitive materials based on electroactive inorganic frameworks bearing surface-tethered molecular redox sites with high energy storage capability.



Redox Properties of Electrophilic Fatty Acids

Martina Zatloukalova, Jan Vacek
Department of Medical Chemistry and Biochemistry, Faculty of Medicine and Dentistry,
Palacky University, Hnevotinska 3, Olomouc 775 15, Czech Republic
Martina.Zatloukalova@seznam.cz

A new class of lipidic signaling molecules known as nitro-fatty acids (NO_2-FAs) has been recently identified. NO_2-FAs possess unique electrophilic properties affecting enzyme activity regulation, the modulation of inflammation and various cellular responses in a broad spectrum of pathologies[1]. Because of their tissue-protective and anti-inflammatory properties, synthetic analogs of these species are involved in clinical evaluations as new drug candidates for the treatment of renal and pulmonary diseases etc.

In this study, we focused on an evaluation of the redox properties of nitro-oleic acid (NO_2-OA), conjugated nitro-linoleic acid (NO_2-cLA) and nitro-linoleic acid (LNO_2) using cyclic voltammetry and constant-current chronopotentiometric stripping (CPS) analysis. Nitroalkenes are stable in free and/or esterified form in hydrophobic micellar, lipoprotein, or membrane environments. Based on the reduction signal of the nitro group at a potential of around -0.8 V (vs. Ag/AgCl) at pH 7.4, the reactivity and stability of NO_2-FAs and NO_2-oleoyl-glycerol were studied[2]. EPR and fluorescence probe DAF-2 were used to evaluate its ability to release NO·.

The key mechanism of NO_2-FAs signaling actions is based on the post-translational modification of proteins. Electrophilic compounds mainly react with the -SH groups (Cys residues) of a variety of biological nucleophiles through Michael's addition reaction (Fig. 1). In our study we also focused on the interaction of NO_2-FAs with basic amino acid residues by CPS analysis. In a single CPS scan we can observe the reduction peak of NO_2-FAs at a potential of around -0.8 V and the peak H related to electrocatalytic process in which proton-donating amino acid residues (Cys, His, Lys and Arg) are involved. Depending on the decrease in both reduction peaks, the interactions of NO_2-FAs with the protein were monitored. Mass spectrometry (peptide mapping) and spectrophotometric (Ellman's and ninhydrin) methods were utilized to evaluate the formation of Michael's adducts.

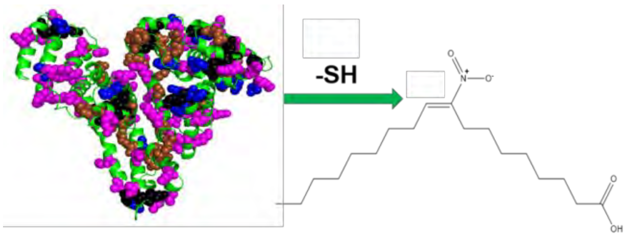


Fig. 1. Schematic representation of interaction of 9-nitro-oleic acid with human serum albumin. In the model of human serum albumin, electroactive amino acid residues (His-blue, Arg-brown, Cys-black and Lys-purple) are highlighted.

The data presented here are the first mechanistic view of the redox properties, reactivity and stability of NO_2-FAs, and could be used in further molecular studies focusing on other electrophiles with high biological relevance.

The authors wish to thank the Czech Science Foundation (GACR 19-21237Y), prof. B. Freeman (University of Pittsburgh, USA) for his cooperation and the preparation of nitro fatty acids and prof. M. Mojovic for EPR analysis.

The nickel-rich NMC ($LiNi_xMn_yCo_zO_2$, x+y+z=1; where, x≥0.6) is regarded as promising cathode active material for future Li-ion batteries due to their ability to deliver high specific capacities. However, their capabilities are limited by the unwanted side reactions with the electrolyte leading to decomposition on the surface of the particles at high voltage (> 4.2 V vs. Li^+/Li). This also leads to surface degradation and limited cycling performance [1]. Surface coating is a predominant strategy to minimize side reactions that occur on the surface preventing material degradation [2].Due to high electronic conductivity and stability of carbon against electrolytes at higher voltages, this study presents for the first time a carbon-coated $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$(NMC622/C) material using the approach of polymerising furfuryl alcohol monomers on the surface of NMC particles followed by a carbonization step. This simple mixing approach for the coating process opens up the possibility of an easy implementation in industrial processes. Numerous analytical techniques were performed to characterize the coated materials, i.e. Thermogravimetric Analysis (TGA) to understand the kinetics during carbonisation, in-situ High-Temperature X-Ray Diffraction (HT-XRD) to monitor the phase changes, Scanning and Transmission Electron Microscopy (SEM & TEM) were used to observe the morphology of the particle. Fourier-Transform Infrared (FT-IR) spectroscopy to observe the presence of polymerisation and the carbon in the sample, CHNS(O) analysis to quantify the amount of carbon in the sample after the heat treatment step. Furthermore, electrochemical; analysis such as cyclic voltammetry, charge-discharge and rate capability tests were carried out to investigate the impact of the carbon coating on the electrochemical performance and structure stability of the material. The results from the XRD show no phase change in the sample after the calcination, SEM and TEM show the homogenous coating of the carbon on top of the NMC and FT-IR shows the presence of the carbon bonds on the calcined samples, TGA results show the decomposition of the polymer ~230°C and formation of carbon. Further, the rate capability test shows ~15% improvement in the capacity of the coated samples.

The electro-valorization of carbon dioxide has been investigated for decades,[1] with fairly recent renewed interest and investments sparked by its detrimental environmental effects. Disregarding current catalyst performance and economic viability, the study of the formation of liquid carbonic species and carbon-containing platform molecules is an important and interesting scientific endeavor due to the industrialized world's widespread employment and reliance on such molecules. Its importance is further substantiated by the fact that the current source of these chemicals (i.e. oil) is an exhaustible commodity that is distributed unequally globally, as opposed to CO_2, H_2O and electricity, which are readily available.

Regarding the electro-reduction of CO_2, copper catalysts have long enjoyed the limelight due to their capability of forming C-C coupled products such as ethanol and ethylene with somewhat reasonable faradaic efficiencies.[2,3] However, notwithstanding the enormous amounts of effort invested in studying this system,[4] selectivity and activity for the production of C_{2+} species still remain an obstruction to industrial viability. In part, the non-selectivity of the reaction can be explained mechanistically: the proposed pathways for different carbon-coupled products share many intermediates before eventually bifurcating at the later stages.[4-6]

As the pathway depends predominantly on the catalyst's attributes and local surface structure, the selectivity issues of copper catalysts are rather an inherent property of the system. On this account, we decided to step away from copper catalysis and investigate a different catalytic system capable of forming C_{2+} species: Ag.[7] Silver is part of a small group of catalysts known to date that are capable of producing carbon-coupled products,[7-10] and was chosen on the basis of a theoretical study wherein it was calculated that (thermodynamically speaking) silver surfaces should be superior to copper in producing ethanol.[11] Thus, this study concerns itself with investigating the mechanism of C-C bond formation on silver.

Because of the unfavorable adsorption energy of carbon monoxide on silver surfaces,[12] the CO reduction reaction (CORR) was studied at a series of elevated CO pressures so as to increase the fractional coverage of CO_{ads}. This enhances the likelihood of the reaction between two adsorbed carbon (e.g., monoxide) species, which is important for the C-C coupling step(s) that is (are) fundamental in producing C_{2+} species. The reaction was carried out on a GDE to maximize surface area and thereby product formation, and conducted in alkaline electrolyte to negate any local pH effects.

It was observed that at pressures between 10-60 barg, CO can be further reduced on metallic silver to yield methane (gaseous) and methanol, ethanol, n-propanol, acetate and ethylene glycol (liquid). Notably, ethylene was not observed as a product. By increasing the pressure, faradaic efficiency towards CO reduction (vs. HER) at the same applied potentials was found to increase, with the sum of C_{2+} product faradaic efficiency reaching ~6% at 60 barg of CO at an applied potential of -2 V_{RHE} (non-IR corrected). As is evident from the product distribution, the silver surface is capable of breaking C-O bonds. But, the absence of ethylene formation indicates that the final C-O bond breaking step appears to be suppressed on silver, which is in agreement with computational predictions.[11]

Abstract:

Lithium-sulfur batteries possess tremendous prospect in the future energy evolution, despite facing some tough challenges on the road. Carbon coated low-valence state polar metal oxide Mn_2O rarely reported, which owning a hierarchical porous nanosheet in figure 1a benefit to alleviate the shuttle effect of lithium-sulfur batteries and immobilize the soluble polysulfide in the process of galvanostatic charge/discharge to improve the electrochemical property by chemisorption and physical limitation. And the composite synthesized by simple hydrothermal and pyrolysis methods in the scheme 1. The mode of Mn_2O-PC/S-800 established reveals 1384 mAh g^{-1} at 0.2 C in the initial discharge which closes to the theoretical specific capacity 1675 mAh g^{-1} and high-retention capacity of 593 mAh g^{-1} after 200 cycles in figure 1b.

Keywords: lithium-sulfur batteries, chemisorption, carbon coated, Mn_2O, low -valence state

Ever growing demand of portable electronic devices and EV, which requires Li based storage devices leads to the depletion of Li reserves in the earth. With practically inexhaustible and less cost, Sodium could replace the Li as charge carriers in electrochemical storage devices. Na-ion capacitor is one type of hybrid storage device which delivers high energy density, high power density and long-life span. In present work, MoS_2-TiO_2-rGO (MTG) was synthesized composite using hydrothermal route. MoS_2 possesses layered structure where Mo atoms are sandwiched between two planes of S atoms and it leads to higher charge diffusion at layer interfaces. Large charge accumulation is possible due to higher surface area of MoS_2. Further, MoS_2 was composited with TiO_2 and reduced graphene oxide (rGO) for following reasons: (a) TiO_2 has large ion diffusion length and improved electron mobility due to presence of Ti^{3+} and Ti^{4+} at the surface, which confirmed by XPS. (b) Graphene oxide has excellent electrical, mechanical properties and power handling capability. The device was fabricated using coin cell with non-aqueous electrolyte, $NaClO_4$ in DEC/PC (diethylene carbonate/propylene carbonate). Both anode and cathode electrodes were coated with MTG by Doctors blade method. Cyclic voltammetry was performed for the device at different scan rates, which shown in the figure 1a. The CV results shows the rectangular shape and symmetrical pattern discloses better suitability of composite material for electrochemical storage devices. The charge-discharge profile of the MTG device is shown in the figure 1b at different current densities such as 1 Ag^{-1}, 1.25 Ag^{-1}, 1.5 Ag^{-1}, 1.75 Ag^{-1} and 2 Ag^{-1}. Symmetric charge and discharge curves show good capacitive storage behavior of the device. Energy density of the device is about 17 $KW\text{-}hkg^{-1}$ and power density stands at 1300 $W\text{-}hkg^{-1}$. Excellent cycle stability was exhibited by the device for 10000 cycles at the current density of $2Ag^{-1}$ without any degradation in efficiency, which is shown in the figure 1c. The remarkable cyclic stability is attributed from positive synergetic effect from MoS_2, rGO and TiO_2. The presence of rGO is not only ensured the stability electrode but also improved the electrical conductivity of MoS_2 and prevented the agglomeration. The interfacial charge transfer between individual elements in the composite improved the intercalation and ion transfer. This work gives more insights about the synergetic effect of MTG composites in cycle stability which is very crucial for practical applications. In best of our knowledge, it is the first time in reporting MTG for Na-ion capacitor

Low-Overpotential Li-O_2 Battery with Ru nanoparticles in-situ Formed on Binder-free Carbon Paper

Dejian Tang, Jiehua Liu*
Future Energy Laboratory, College of Materials Science and Engineering, Hefei University of Technology, Tunxi Road No.193 Hefei, Anhui, 230009, China
**Corresponding: liujh@hfut.edu.cn*

Today, for numerous next-generation energy storage devices[1], non-aqueous Li-O_2 battery has triggered worldwide attention due to its ultrahigh energy density (about 3500Wh/kg)[2]. But one of the problems is the sluggish redox kinetics caused by insoluble and insulating Li_2O_2[3], thus developing high-efficiency electrochemical catalysts is necessary for Li-O_2 battery. Hence, we achieve Ru nanoparticles catalyst that in-situ generate on carbon paper without binder by electrochemical method. Firstly, we prepare electrolyte containing Ru^{3+} to assemble coin-type cell with carbon paper, the constant-current discharging of cell exhibits a steady platform corresponding to "$Ru^{3+} \rightarrow Ru$", Ru nanoparticles uniformly coat on 3D space network skeletons of carbon paper. We find that the binder-free carbon paper with Ru nanoparticles in Li-O_2 cell shows remarkable ORR and OER low-overpotential (0.15 V and 0.2 V, respectively). The work presents a new design of a binder-free O_2 electrode for Li-O_2 battery, which gives an insight into the improvement about the preparation of in-situ catalysts.

Exploring dynamic interactions of single nanoparticles at interfaces for surface-confined electrochemical behavior and size measurement

Wei Ma
Department of Chemistry, East China University of Science and Technology,
130 Meilong Road, Shanghai, China
weima@ecust.edu.cn

Single-entity electrochemistry has attracted increasing attention not only for its extremely high sensitivity but also for the insight that it offers with respect to individual direct electron transfer that is masked in ensemble-averaged measurements.[1] Over the past several decades, electrochemical measurements of individual entities, including nanoparticles (NPs), cells, molecules, and atoms, have been achieved conveniently with the use of stochastic collision measurement at a ultramicroelectrode (UME) or nanoelectrode. Significant advances have been made in the analysis of the dynamic electrochemical behaviors of individual entities.[2–4] Although the combination of stochastic collision electrochemistry with scanned nanoprobe microscopies or optical-based techniques was introduced as a new tool for real-time analysis of the electrochemical reaction mechanism/kinetics of individual NPs with high spatial and temporal resolution, it remains an open and challenging issue to elucidate how nanoscale particles interact with an electrode interface to clearly understand the dynamic electrochemical processes of such particles. Here, using first-principle density functional theory (DFT) calculations, we study the adsorption-energy scaling relations by examining NPs on two different UME surfaces. This allows us to semi-quantitatively predict the adsorptive interaction effect of NPs on UME interfaces and helped helps in identifying the dynamic electrochemical nature of single NPs during the stochastic collision process. Based on the theoretical predictions, we explored the interaction-modulated electrochemical oxidation behavior of individual AgNPs, producing significantly distinguished current traces (Fig. 1).[5] By attempting to suppress the stochastic path of AgNPs and control their motion in an alkaline media, we observed the complete oxidation of the AgNPs with different diameters of 10, 18, 34, 55, 65 and 75 nm, and successfully realized the in-situ size discrimination of AgNP mixtures with multi-parameter analysis using the stochastic collision electrochemistry.

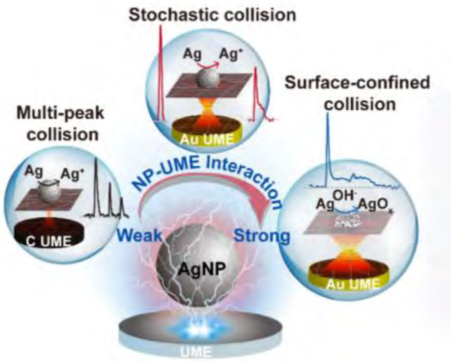

Figure 1. Interaction-modulated dynamic electrochemical behaviors of single NPs.

Introduction

Alkaline water electrolysis (AWE) has attracted much attention for hydrogen production from renewable energy. One of the most important issues in water electrolysis is to prevent degradation of electrodes under fluctuation of power from renewable energy. Nickel is well known as a good AWE anode; however, frequent start/stop simultaneously causes its corrosion due to oxidation and reduction.1) It has been reported that the coating of nickel with conductive metal oxides improves durability, whereas activity was somewhat lowered.2) Manganese-based mixed metal oxides (MMMO) have high oxygen evolution reaction (OER) activity and are used as secondary battery electrodes with high cycle stability; thus, MMMO is expect to have both high activity and durability. Here, the activity and durability of MMMO-coated nickel electrode were investigated under potential cycling test.

Experimental

Catalyst deposition: a nickel plate was etched 10 min in 20 wt. % HCl solution at 90 °C. The plate was then vertically immersed into 0.2 mM $KMnO_4$ aq. (50 mL) and hydrothermally reacted at 180℃ for 20 h. This coated electrode was again immersed into 0.2 mM $CoCl_2$ aq. (50 mL) and hydrothermally reacted at 130℃ for 3 h, followed by calcinated at 500 ℃ for 1 h. The obtained nickel plate covered with Co-Mn mixed metal oxide is denoted CMN130.

Electrochemical measurement : the working, counter, and reference electrodes were CMN130, Ni coil, and reversible hydrogen electrode (RHE), respectively. 1.0 M KOH was used as an electrolyte. Cyclic voltammetry (CV) was performed at 50 mV s^{-1} between 0.5 and 1.8 V vs. RHE for 100 cycles as pretreatment. The durability test was performed by repeating the following processes for 20 times. CV at 5 mV s^{-1} between 0.5 and 1.8 V vs. RHE for 2 cycles, CV at 500 mV s–1 in the same range for 1000 cycles, and AC impedance at 1.6 V vs. RHE to correct *iR*.

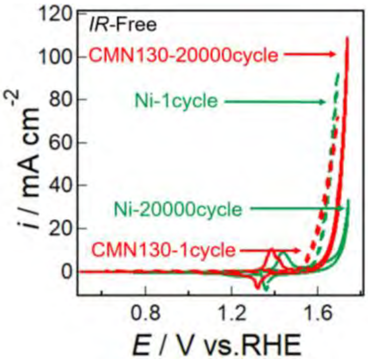

Fig.1 CV curves of Ni and CMN-coated Ni at 1st and 20000th cycles.

Results and discussion

The formation of δ-MnO_2 and Co-Mn-O spinel oxide at the first and second hydrothermal reactions, respectively, was confirmed by XRD. The δ-MnO_2 consisted of platy particles, and the spinel layer consisted of nanoparticles. The polarization curves of CMN130 and nickel presented the overpotential (η) 276 and 24 mV, respectively, at 10 mAcm^{-2}, showing that CMN130 is more active for OER than the nickel (Fig. 1).

In the durability test (Fig. 2), nickel was activated at 1000th–2000th cycles, whereas η significantly increased after the 3000th cycle. On the other hand, CMN130 showed lower overpotential compared to Ni in every cycle. Almost no degradation was observed up to the 6000th cycle. η increased after the cycle, though η is always lower than those of nickel at the same cycle. At the 20000th cycle, the redox peaks due to Co(II/III) t 1.38 V vs. RHE and Ni(II/III) at 1.41 V vs. RHE were observed for CMN130, implying that the nickel surface is exposed by partial detachment of the MMMO layer. In conclusion MMMO made by hydrothermal reaction showed good stability and durability under potential fluctuations.

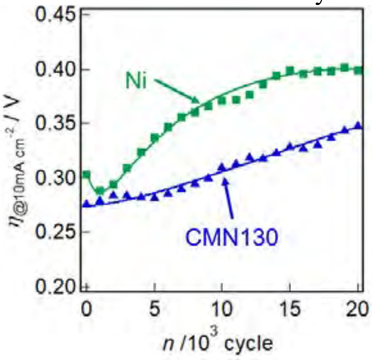

Fig.2 OER overpotential as a function of durability test cycles.

Oxygen transport ohmic resistivity R_{ox} in a low--Pt PEM fuel cell has been determined using two methods. The first one is fitting of our recent physics--based impedance model [1] to the experimental impedance spectra. The second method is calculation of distribution of relaxation times (DRT) using the same experimental spectra. Comparison of the two methods shows that the DRT peak with the characteristic frequency on the order of 500 to 1000 Hz describes oxygen transport in the open pore and in Nafion film covering Pt/C agglomerates in the catalyst layer. The resistivities R_{ox} calculated by the two methods agree well. This result makes it possible using experimental impedance spectroscopy and DRT for routine measurements of R_{ox} in low-Pt PEMFCs.

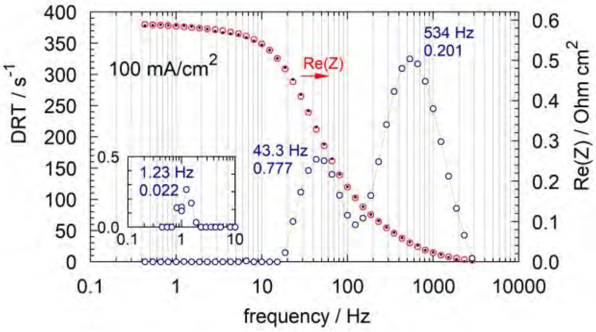

Figure 1. DRT of a low-Pt PEMFC (blue open circles) and the real part of cell impedance: measured (solid points) and reconstructed from DRT (red open circles).

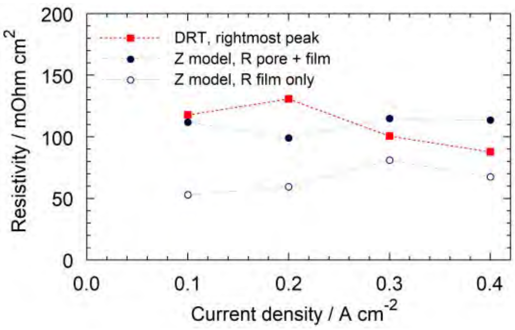

Figure 2. Oxygen transport resistivities determined from DRT (red squares) and from impedance model fitted to the spectra.

The solid-solid interfacial contact is a critical issue during the studies of solid-state batteries (SSBs), which greatly affects the electrochemical performance of SSBs, such as the Coulombic efficiency, and cycle life. For flexible polymer/garnet electrolytes (PGEs), the interfacial issue mainly comes from the interactions between the inorganic fillers and the polymer matrix. The slow Li^+ transport through the polymer/garnet interface can lead to the low ionic conductivity of PGEs. While for garnet ceramic electrolytes (GCEs), the ceramic bulk with a relative density over 99% shows no obvious grain boundary, leading to the ionic conductivity over 10^{-3} S cm^{-1} at room temperature. Under this circumstance, the interfacial issue could be attributed to the poor interfacial contact between the GCEs and Li metal anodes. It can induce the large interfacial resistance as well as the lithium dendrite growth. In this presentation, I'll focus on the aforementioned interfacial issues, various targeted strategies will be introduced to construct the excellent interfacial structure, thus significantly improving the performance of SSBs [1-3].

ABSTRACT

Supercapacitors are a promising energy storage system owing to their high power density and long cycling life [1]. One of the limitations, however, is their low energy density as compared to the batteries which hinders their wide applications [2]. This problem can be effectively solved by designing the hybrid electrodes: combining capacitor and battery materials to result in synergistically high electrochemical performance by incorporating two distinct energy storage mechanisms in a single device [3].

We report two hybrid electrodes designed by using graphene-based conductive matrix and compositing them with high capacity bimorph akaganeite and manganese dioxide nanoparticles [4,5] *via* a simple hydrothermal self-assembly method. The resultant nanocomposites have a high surface area and a large number of mesopores which facilitate channels for ion transport [4]. When used as the electrodes in symmetric and asymmetric supercapacitors in an aqueous electrolyte system, excellent energy-power profile, high specific capacitance and remarkable cyclic stability of up to 99.8% after 20,000 galvanostatic charge-discharge cycles have been obtained. This performance is attributed to a dominant capacitive charge storage mechanism by the synergistic combination of the components of the nanocomposites, well-structured hybrid electrodes, and chemically bonded components. This approach can be useful in designing high-performance electrodes for long life supercapacitors with both high energy and power densities.

Rational Material Design for Ultrafast Rechargeable Organic Lithium Ion Batteries

Kamran Amin, Zhixiang Wei
National Center for Nanoscience and Technology, School of Nanoscience and Technology, University of Chinese Academy of Sciences, Beijing China
No.11.Beiyitiao Zhongguancun 100190 Beijing, P. R. China.
kamran@nanoctr.cn

It is very important to design the devices capable of fast charging and long life for commercial application. But fabrication of lithium ion batteries with high power and energy density is quite challenging. In recent years, a lot of work has been done to improve the rate performance and life of LIBs.[1] We believe that better understanding of the kinetics limitations for faster batteries can guide us to design materials for ultrafast long-life batteries.[2] To prove this, we started exploring redox active conjugated microporous polymers as an electrode for LIBs. In these systems interconnected microporous network can facilitate faster diffusion of ions. Large surface area can make the deep buried active sites accessible on or near to surface and conductivity can be improved by making composite with suitable conductive media. Combining all these effects together we were able to develop a lithium ion cell that can be charged as fast as 66C with significant capacity retention. Also, we found that cell can be charge and discharge for 3000 cycles without any capacity loss. Through carefully investigation we revealed that high surface area, porosity, and conductivity lead to energy storage process through surface or near surface pseudo capacitive energy storage mechanism which is usually found in supercapacitor and is faster than batteries. This study shows how we can transfer kinetically slow, diffusion controlled faradic reactions in batteries to faster pseudo capacitive reactions by rationally designing the materials.[3] We expect that this will pave the way for high power batteries with high energy density.

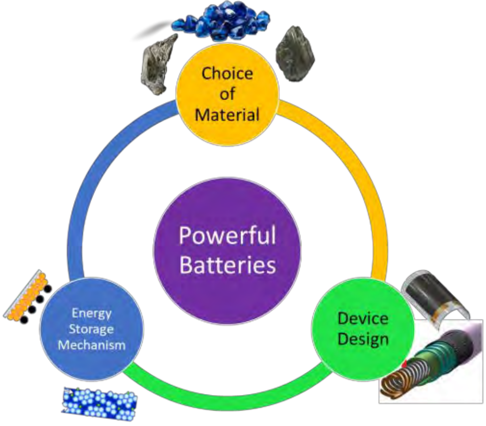

Figure 1: Important factors need to consider for high-power high-energy density batteries

Electrocatalytic reduction reactions (i.e., the hydrogen evolution reaction (HER) and oxygen reduction reaction) at individual, faceted Au nanocubes (NCs) and nano-octahedra (ODs) expressing predominantly {100} and {111} crystal planes on the surface, respectively, were studied by nanoscale voltammetric mapping. Cyclic voltammograms were collected at individual nanoparticles (NPs) with scanning electrochemical cell microscopy (SECCM) and correlated with particle morphology imaged by electron microscopy. Nanoscale measurements from a statistically informative set of individual NPs revealed that Au NCs have superior HER electrocatalytic activity compared to that of Au ODs, in good agreement with macroscale cyclic voltammetry measurements. Au NCs exhibited more particle-to-particle variation in catalytic activity compared to that with Au ODs. The approach of single-particle SECCM imaging coupled with macroscale CV on well-defined NPs provides a powerful toolset for the design and activity assessment of nanoscale electrocatalysts.

Voltammetric characterization of hesperidin with electroactivated pencil graphite electrode

Flavonoids represent a large group of polyphenolic compounds which are widely distributed in plants and show beneficial effects on human health. Their biological activity can be connected with structural diversity and a wide range of their derivatives. Hesperidin is a phytochemical classified as bioflavonoid and can be primarily found in citrus fruits as well as in some other fruits and vegetables. Due to the suppression of pro-inflammatory cytokine production and its antioxidant defense mechanism, hesperidin shows different pharmacological activities such as cardio protective, antihypertensive, antidiabetic, anti-inflammatory, and antihyperlipidemic activity [1]. Graphite can be used as an electrode material since it has nonmetallic and metallic properties. The pencil graphite leads are composite materials which contain approximately 65% of graphite, approximately 30 % of clay, and around 5 % is a binder (wax, resins, or high polymer) [2]. The use of a disposable pencil graphite electrode (PGE) is proven to be a simple, cheap, and fast alternative with superior sensitivity and performance compared to more expensive electrodes [3].

In this study, PGE and electroactivated pencil graphite electrode (ePGE) were used for voltammetric characterization of hesperidin in model system with cyclic and differential pulse voltammetry. Both electrodes were characterized with electrochemical impedance spectroscopy (EIS) and scanning electrochemical microscopy (SECM) and the enhancement of electron transfer kinetics was observed after electroactivation. The effect of scan rate, pH, and hesperidin concentration on oxidation peak current were also studied. It was determined that oxidation peak current increases with the increase of scan rate and hesperidin concentration. The hesperidin oxidation was the most pronounced at pH = 5. The peak current and the hesperidin concentration showed linear dependence in the concentration range from 5×10^{-7} mol dm^{-3} to 1×10^{-5} mol dm^{-3}. Estimated limit of detection (LOD) was 5×10^{-7} mol dm^{-3}.

TiO_xN_y powders were synthesized by sol-gel using titanium (IV) isopropoxide. Interconnected porosity was incorporated through phase separation of hydrophilic and hydrophobic blocks, and elimination of organic components with a thermal treatment. Partial substitution of oxygen by nitrogen was accomplished using thermal treatment in NH_3 atmosphere and incorporation of urea during the synthesis procedure. Powder characterization includes surface area (BET), scanning electron microscopy (SEM), X-ray diffraction (XRD) and cyclic voltammetry (CV). The results show a high surface area around 200 m^2/g and a combination of titanium oxides, nitrides and oxinitrides.
These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated.

Self-assembly of Mesoporous Nanostructured Catalysts for Enhancing the Electrochemical Energy Reactions

Mohamed A. Ghanem,* Abdullah M. Al-Mayouf, Prabhakarn Arunachalam, Mabrook S. Amer, Maged N. Shaddad
Chemistry Department, King Saud University, Riyadh 11451, Saudi Arabia

Abstract

Nanostructured mesoporous materials are of interest for a variety of applications for developing renewable and clean energy sources. This work presents the synthesis of entirely new classes of nanostructured mesoporous transition metal oxides, hydroxides and phosphate nanocatalysts with improved electrocatalytic properties for hydrocarbon oxidation, water splitting, and fuel-cell reactions [1-5]. Mesoporous nanocatalysts of nickel, cobalt, tungsten and titanium oxides, hydroxides and phosphates with high surface areas, mesoporosity, and different nano-architectures are prepared via the surfactant template chemical deposition and hydrothermal approaches. The compositions, periodicities, surface areas, pore diameters, and architectures of the nanocatalysts can be varied in a controllable way through changes in the template compositions and deposition conditions. The electrochemical and catalytic activity of the resulting mesoporous nanocatalysts investigated and screened for electrochemical energy reactions of hydrocarbon (urea, methanol) oxidation and water splitting reactions of hydrogen, oxygen evolution and oxygen reduction reactions.

Keywords: *Mesoporous; Oxides; Phosphates; Energy Reactions.*

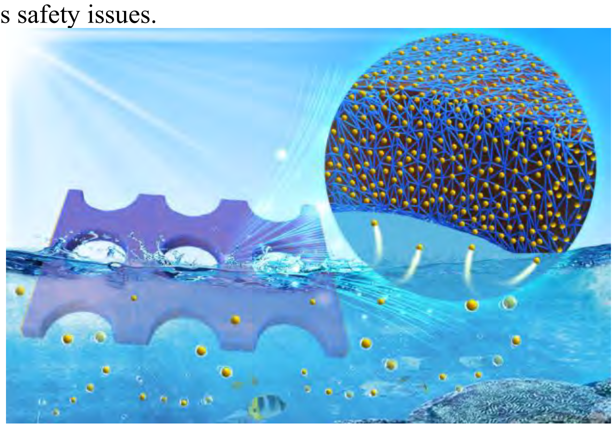
High energy density, long cycle lifespan, sufficient safety along with low manufacturing cost are among the ultimate goals for both the widely used lithium-ion batteries (LIBs) and other battery types. Owing to the high theoretical specific capacity (3860 mAh g^{-1}), lowest reduction potential (-3.04 V) and ultra-small theoretical density (0.534 g cm^{-3}), metallic lithium is regarded as the “Holy Grail” among various anode materials for the next-generation rechargeable batteries. Unfortunately, the inhomogeneous Li deposition and uncontrolled dendrite growth during repeated cycling lead to low Coulombic efficiency, poor performance, and serious safety issues.



Herein, a novel two-pronged strategy is proposed to effectively guide Li nucleation and suppress the unwanted Li dendrites growth, by a synergized approach of combining the laser-machined 3D holey Cu matrix (3D Cu) and lithiophilic polydopamine (PDA) surface coating layer. The PDA@3D Cu scaffold is shown to exhibit the wanted dendrite-free Li plating/stripping behavior. It delivers a remarkable Coulombic efficiency of 96.4% after 150 cycles (2.0 mA cm^{-2} at 1.0 mAh cm^{-2}), and achieves an excellent lifespan of over 1000 h operation tested in Li/Li symmetric cells, together with good stability for Li//$FePO_4$ full batteries. Our molecular dynamics (MD) simulations, density functional theory (DFT) calculations, and *in-situ* real-time monitoring using optical microscopy together have established the direct correlation between reversible Li electrodeposition and lithiophilic 3D holey structure scaffold. Significantly, the new findings suggest that a synergistic combination of 3D Cu with lithiophilic PDA coating layer represents an effective pathway to regulate metallic Li anodes towards practical applications.

The term Organic Electronics is used to indicate the vast field of science regarding the use of organic materials (either "small" molecules, oligomers or polymers) in electronic devices. Thiophene derivatives are among the most studied and used organic semiconductor materials due their excellent charge transport properties and well-established synthetic procedures. These requisites are fulfilled by oligothiophene derivatives: in many cases they possess better characteristics (physical, optical, electronic and self-assembly properties, possibility to work in solution, ease of purification, low-cost synthetic procedures, and so on) over their polymeric counterparts. Electrochemical studies on a series of new conjugated oligothiophene derivatives are carried out. The molecular architectures (D-π-A and A-π-D-π-A, Figure 1) of these compounds present different donor cores (thiophene, bithiophene) with different numbers of 3-octylthiophene units (that act as π-bridge and solubilizing components). The acceptor end groups adopted were, in all the cases, ethyl cyanoacrylate units. The obtained results from electrochemical studies gave us the possibility to develop a new synthetic strategy including electrosynthesis (Figure 2) with an approach more environmentally friendly than classical synthetic procedures.

For orthopedic prosthesis, titanium alloys, chromium alloys or stainless steel are suitable materials since mechanical properties are more similar to human bones. However, metal ions or nanoparticles release could produce Adverse Local Tissue Reactions (ALTRs) around periprosthetic tissues of the patients during post-surgery period [1], causing pain and rejection effects. In addition, corrosion phenomena could be occurred since after surgery, the local pH could be decreased around 5. Covering the metal substrate with biocoatings could be a solution in order to overcome these issues. In the last decades, many works were focused on composite coatings not only to improve the corrosion resistance but also to increase biocompatibility with human environment. In fact, in composite coatings the different components are able to act synergistically to give properties superior to those provided by component alone. Among the different composite coatings, those ones based on calcium phosphate compounds are the most interesting. In particular, hydroxyapatite is largely studied, since bones are constituted by hydroxyapatite crystals interspersed in the collagen fibers. Considering the bone structure, it is clear that a composite coating of hydroxyapatite and collagen could improve the performance of an orthopedic prosthesis. Another interesting material is chitosan, that is increasingly used in biocoating technologies thanks to its bioactive and biocompatible features.

In this work Hydroxyapatite/Chitosan/Collagen composite biocoating on AISI304 Stainless Steel was investigated. Biocoatings were realized through the deposition method of galvanic coupling. This process occurs without external power supply, because starting just from the coupling between two materials with different standard electrochemical potential [2-5]. In particular, the corrosion of the material with the low redox potential (sacrificial anode) produces the electrons necessary for the deposition. Electrons flow towards the cathode, where are used to produce hydroxyl ions thanks to electrogeneration of base reactions of nitrate ions and water molecules. The increasing of local pH at electrode/electrolyte interface leads to the deprotonation of amine groups of chitosan (pKa=6.4) while positively charged collagen fibrils start to self-assemble into fibers. Simultaneously, several equilibria reaction cause the precipitation of calcium phosphate (brushite/hydroxyapatite). The global process is the co-deposition of three components with the hydroxyapatite crystals that are incorporated in polymeric composite chitosan/collagen.

Physical-chemical characterizations of the samples were executed in order to evaluate morphology and chemical composition. In addition, potenziodynamic polarization and electrochemical impedance spectroscopy were carried out in a simulated body fluid to scrutinize the corrosion resistance. Furthermore, the metal ions release due to corrosion phenomena were quantified through Inductively Coupled Plasma Optical Emission Spectrometry. Also, cytotoxicity tests using MC3CT cells line was carried out in order to verify coatings' biocompatibility.

Abstract

Surface engineering on the electrocatalyts is one of the most popular strategies to tune the electrocatalytic activities. Here, we will present our recent progress on the Co-based electrocatalyst for oxygen evolution reaction (OER), which is the key process for metal-air batteries, and water splitting. Currently, the typical electrocatalyst for OER is RuO2 and IrO2-based precious metal compounds. However, these noble metal-based electrocatalysts are of high cost and poor stability. Therefore, various strategies have been developed to enhance the electrocatalyst performance through the surface control. Recently, we have developed the plasma technology to tune the electrocatalytic performance of carbon-based metal-free electrocatalyst, Co-based compound and 2D layered nanomaterials for OER. In this talk, we will focus on the recent development of plasma treated electrocatalysts in the aspects of defect chemistry.

IrO_2/Ir/Ti and IrO_2/Ir(Ni)/Ti Oxygen Evolution Anodes prepared by Galvanic Deposition and Galvanic Replacement

IrO_2-modified Ti electrodes have been prepared by either a simple galvanic deposition process or a Ni-mediated galvanic replacement method. In the former case a freshly etched Ti substrate has been treated with an Ir(IV) solution, resulting in the spontaneous deposition of metallic Ir on the surface of the Ti substrate with the simultaneous oxidation of nearby freshly etched Ti sites [1]. In the latter case, a smooth Ni film has been electrodeposited on the Ti substrate from a Watts bath and its surface layers spontaneously exchanged with metallic Ir upon treatment with an Ir(IV) solution [2-3]. Anodization of the resulting Ir/Ti and Ir(Ni)/Ti electrodes by means of continuous potential cycling in acid solutions resulted in the formation of IrO_2 porous surface layers (or IrO_x, depending on the positive potential limit), showing typical Ir oxide surface electrochemistry (*Figure 1*). SEM pictures revealed that the thus prepared IrO_2/Ir/Ti electrode is made of sparse IrO_2/Ir micrometer-sized islands and nanoparticles, while the IrO_2/Ir(Ni)/Ti electrode consisted of a continuous film with a nodular morphology (as confirmed by AFM). The composition of the coatings was estimated by EDS and XPS spectroscopy while Ir mass loading was determined by ICP-MS following etching in acid. These electrodes have been tested as oxygen evolution reaction (OER) anodes by slow potential sweep voltammetry *(Figure 2)*. IrO_2/Ir/Ti electrodes exhibited mass specific activities for OER (ca 200 mA mg_{Ir}^{-1} at η=300 mV) better or comparable to traditional Ir DSAs [4] or state-of-the-art thin thermal films [5], whereas the IrO_2/Ir(Ni)/Ti electrodes were proven comparable or better than both state-of-the art thin thermal films [6] and nanoparticle $IrNiO_x$ catalysts [7] (ca 2 A mg_{Ir}^{-1} at η=300 mV). The recently established enhancement of IrO_2 OER activity by Ni, combined with the widespread use of Ti as a stable electrode substrate, make IrO_2/Ir(Ni)/Ti attractive DSA electrodes.

Abstract. In the malaria disease, the released haem group into erythrocytes is oxidized to haematin and inert dimeric haemozoin bio-crystals form, which provides the parasite a unique way to avoid the toxicity associated with the haem group. Due that, antimalarial drugs to inhibit dimer formation; however, recent electrochemical studies indicate that an inert dimer also promotes a toxic oxidizing environment. This work explores drug reactivity with monomers and dimers and their contribution to maintain redox balance. Materials and methods. Through cyclic voltammetry three medicines mixed with haemozoin or β-haemozoin were tested. Results and discussion. The data indicated again that the drugs "*per se*" (Figure 1) and in combination (Figures 2 & 3), modify the natural redox state of haemozoin and β-haemozoin. The natural oxidation potential of the drugs alone was evident. It was found that the oxidation potential decreased through quinine, lumefantrine and artemether with the same tendency in the haemozoin presence but with less current density. Finally, the oxidation response between the monomer haemozoin and antimalarial drugs is carried out at more negative potentials.

The results indicate that antimalarials *per se* can contribute to oxidation processes and that in combination with monomeric or dimeric haemozoin can increase or decrease the oxidizing power of the haemozoin forms. The various oxidizing environments suggest that the cell membranes can also be damaged by the unique presence of the antimalarial. To maintain the intracellular redox balance is very important, so indicate treatments that could potentially alter it, (artemether) or (benflumetol,) should consider that maybe there will be an imbalance.

claudio@uvigo.es

The pesticides Thiamethoxam (THI), Acetamiprid (ACT), Imidacloprid (IMI) and Thiacloprid (TCP) are four examples of common chemicals used in the control of plagues in agriculture. The manufacturing, formulation, storing, manipulation and use of pesticides generate effluents difficult to treat due to the high toxicity of those compounds. This work tests the use of photochemical and electrochemical oxidation as an effective method to eliminate pesticides from aqueous effluents. Both, the photochemical and the electrochemical oxidation were able to oxidize the pesticides molecules, but the efficiency largely depended on the chemical nature of the compounds. THI was easily degraded with UV-C light photochemical oxidation, whereas TCP was removed by electrochemical oxidation. ACT was the compound that showed the highest resistance to be degraded by both, photochemical and electrochemical oxidation. The combination of the photochemical and the electrochemical oxidation in a dual reactor (a reactor with two separate chambers for the photochemical and electrochemical reactions) enhanced the degradation of the THI, IMI and TCP reaching a complete removal in 1 h. ACT was only removed by 50% in 2 h. the removal of ACT was enhanced up to 70% in 2 h by electro-Fenton oxidation, using ferrous iron in the effluent treated in the electro-photochemical reactor.

Combination of Electrochemical and Photochemical Methods for TOC/COD Removal in Industrial Effluents

Rua Maxwell s/n. Building Fundicion. 36310 Vigo. Spain.
claudio@uvigo.es

Activated carbon is a common adsorbent material for the retention of organic and inorganic contaminants. Various industrial sectors use activated carbon in purification of liquid and gaseous streams and in the retention of valuable materials. These industrial sectors include Au mining, water purification, pharmaceutical and chemical industry, etc. The reactivation and reuse of the spent activated carbon is a more sustainable practice than "one-use" and dumping. However, the classical thermal regeneration of activated carbon shows a large impact due to the emission of CO_2 and the partial loss of carbon and activity. The electrochemical regeneration of saturated activated carbon has been proposed as an efficient and sustainable alternative to the classical reactivation methods. The electrochemical treatment consumes less energy and produces less CO_2 than the traditional thermal activation. The electrochemical regeneration of activated carbon is based on the application of a DC electric current directly to the carbon specimen using a solution of sulfuric acid as electrolyte. The electric current desorbs and mobilizes the contaminants retained in the activated carbon. The contaminants include organic compounds and inorganic ions. At the end of the regeneration process, the contaminants released from the carbon remains in the electrode solutions (anolyte and catholyte). Such end-waste effluents require treatment before their final disposal. This work has analyzed the chemical composition of the end-waste effluents and have proposed and tested various technologies for the separation/degradation of organic and inorganic contaminants. The chemical neutralization and precipitation of the contaminants is a practical method to remove all the toxic metals in the effluent that it can be discharged directly in the sewage system. The precipitation with NaOH, $NaCO_3$, $CaCO_3$ and CaO showed similar metal removal results, but the precipitation with $CaCO_3$ showed the additional benefit of TOC and nitrogen removal. Despite the good results of the neutralization/precipitation method, this treatment did not allow for the recycling of the effluent to the activated carbon regeneration process. Various advanced oxidation processes (electrochemical, photochemical and chemical oxidation) have been tested to identify an alternative method that allowed for the recycling of the effluent to the carbon regeneration system. A combination of electrochemical and photochemical oxidation with persulfate was identified as a practical treatment to remove the TOC and COD from the effluent. The electro-photochemical treatment was able to remove all the organic contaminants in the effluent, expressed as COD, in 8 h with 16 W UV-C lamp and an electric consumption of 5.7 Wh/L. The treated effluent can be recycled back to the electrochemical regeneration system.

Bioelectrochemistry of neuronal protein tau

Dr. Sanela Martic
Trent University
1600 West Bank Drive, Peterborough, ON, Canada, K9L0G2
sanelamartic@trentu.ca

Tau is a neuronal protein and one of the biomarkers of neurodegenerative diseases, such as Alzheimer's disease. Tau protein undergoes post-translational modifications, aggregation, and is a viable drug target. In addition, this protein is a vital biomarker in biological fluids towards early detection of neurodegenerative diseases. We reported on using electrochemical impedance spectroscopy and cyclic voltammetry for detection of protein-protein interactions (1), protein-ligand interactions (2), enzymatic catalysis and enzyme inhibition (3) while focusing on tau protein and its biochemistry. For example, tau-tau, tau-ferritin, tau-transferring protein interactions were monitored, and protein kinase-catalyzed phosphorylation of tau protein was detected. The phosphorylation inhibitors, such as antibodies, were screened for their efficacies. New research directions in neuroelectrochemistry of tau protein alongside other neuronal biomarkers, such as Amyloid beta and alpha synuclein, will also be described.

Lithium-air (Li-O_2) batteries promise a drastic increase in energy densities and a reduced ecological footprint compared to intercalation-type Lithium-ion batteries. Considering mass and volume of non-active materials, real performance improvements are only achieved if lithium peroxide (Li_2O_2) is packed as dense as possible in the nanoporous carbon cathode host. [Freunberger, S. A. , *Nature Energy* **2**, 17091 (2017)]. To understand how structural features of the formed Li_2O_2, dynamic phenomena during product growth and the underlying reaction mechanisms determine the discharge capacity, quantitative real-time in situ metrologies with structural information at the atomic to micron level are required.

Here we present *operando* small and wide angle X-ray scattering (SAXS/WAXS) as a novel method to study the morphological evolution of Li_2O_2 during charging and discharging a custom-built in situ Li-O_2 cell [*ChemRxiv* 2019, DOI 10.26434/chemrxiv.11447775.v1]. For data analysis a recently developed method was adapted [Prehal, C. *et al.*, *Nature Energy* **2**, 16215 (2017)] and synergistically combined with modelling of Li_2O_2 nucleation and growth in a realistic 3D carbon pore model. This allows visualizing the nanoscale product formation in real-time and distinguishing between Li_2O_2 formed via disproportionation (solution mechanism) or a second, consecutive electron reduction (surface mechanism). We show that Li_2O_2 is formed exclusively via solution mediated disproportionation of LiO_2 across the whole range of organic electrolytes and carbon electrodes. Deciding for particle morphology is the concentration distribution of associated LiO_2 in solution, governing nucleation and growth rates of Li_2O_2 formation. Discharge capacity and Li_2O_2 pore filling hence equally depends on electrolyte solvation energies, true areal current densities and species mobilities in solution. Given that species mobilities are high and current densities low, this allows for high discharge capacities even in low donor number electrolytes, previously thought to be prototypical for Li_2O_2 surface growth with poor discharge capacities. Next to rotating ring disc measurements, electron microscopy and numerical modelling, *operando* SAXS/WAXS was the essential tool for these insights. On a wider perspective *operando* SAXS/WAXS proofs as a powerful *in situ* metrology to study electrodeposition in all conversion-type batteries and more generally structural changes in complex electrochemical energy storage systems at length scales ranging from atomic to sub-micron resolution.

Exploiting glucose meters for early detection of prostate cancer

Cancer is a major global public health problem with enormous human and economic costs [1]. Liquid biopsy has emerged as a potential supplement of traditional biopsy for early cancer diagnosis. Specifically, appropriate bodily fluids are analysed to monitor the level of tumour biomarkers present in the medium. There is, therefore, a clear need to develop non-invasive, easy-to-use and inexpensive methods for the detection of biomarkers that allow improving diagnosis and minimizing the mortality of cancer, while reducing healthcare expenditure of cancer care. In this context, electrochemical platforms have demonstrated great potential due to their high sensitivity, low cost, fast response as well as compatibility with point-of-care (POC) testing, what contributes to decentralize the analyses and favours the implementation of screening studies. Among them, personal glucose meter (PGM) employed daily in the measurement of blood glucose is the most used analytical method worldwide. Taking advantage of this mature technology, PGM has been recently applied to quantitate a wide range of non-glucose analytes by establishing a relationship between their recognition and glucose generation [2]. This strategy is of particular interest for monitoring tumour biomarkers since PGMs are already approved by international agencies for application to clinical practice, thus paving the way for the launch of the new device to the market.

Thus motivated, we describe the development of a hybridization assay for the detection of prostate cancer antigen-3 o PCA3, a urinary RNA biomarker for prostate cancer diagnosis [3]. Specifically, a sandwich-type genoassay has been implemented onto magnetic microparticles functionalized with streptavidin in combination with a personal glucose meter and alkaline phosphatase (ALP) as a glucose-generating enzyme for signal transduction. Moreover, with the goal of detecting clinically relevant PCA3 levels, an isothermal DNA amplification strategy such as Rolling Circle Amplification (RCA) has been designed [4]. In this strategy, a circular DNA called padlock acts as a template for the phi29 polymerase, which is capable of generating thousands of padlock copies, resulting in multiple binding sites for a fluorescein-tagged reporting probe. Numerous antifluorescein-ALP conjugates are then incorporated per target analyte, for enzymatic conversion of glucose-1-phosphate into glucose, whose concentration is subsequently determined with a glucometer. This isothermal and portable approach allows the reliable detection of PCA3 at picomolar levels.

Electrochemiluminescence (ECL) is a leading technique in bioanalysis.[1] Since the excited species are produced with an electrochemical stimulus rather than with a light excitation source, ECL displays improved signal-to-noise ratio compared to photoluminescence, with minimized effects due to light scattering and luminescence background. The most challenging breakthrough in the development of analytical electrochemiluminescence (ECL) applications was reported from Bard and co workers that presented for the first time the generation of ECL with a coreactant.[1] This finding opened the application of ECL to large literature and transformed ECL from an academic curiosity to a real application and industrial success. In this context, the only real used materials for the ECL analytical and commercial application are tripropylamine (TPrA) as sacrificial "oxidative-reductant" coreactant and Ruthenium(II)-tris(2,2'-bipyridine) ($[Ru(bpy)_3]^{2+}$) as emitting species. In this case the mechanism for the ECL generation was proposed by Bard and still nowadays the only one accepted.[2],[3]

Here we show an additional, and very efficient, mechanism pathway for the generation of ECL by using TPrA as coreactant. Thanks to the combination between ECL and microscopy we experimentally prove the alternative mechanism with the standard $[Ru(bpy)_3]^{2+}$/TPrA system.[3],[4] These mechanistic findings allow us to propose alternative amines as coreactant enhancing the ECL signal of more than one order of magnitude.

The reported results, besides contributing to a better understanding of the mechanisms operating in the chemiluminescence generation, also pave the way for the development of very highly efficient ECL coreactants for ultrasensitive bioanalysis.[5]

Photoelectrochemical CO_2 Reduction in Aqueous and Room-Temperature Ionic Liquids-Based Media by Scanning Electrochemical Microscopy

Lin ZHANG, Carlos M. SANCHEZ-SANCHEZ, Vincent VIVIER
Sorbonne Université, CNRS, Laboratoire Interfaces et Systèmes Electrochimiques,
LISE, 75005 Paris, France
zhanglin_irene@163.com

The photoelectrochemical (PEC) carbon dioxide (CO_2) reduction reaction (CO_2RR) can convert CO_2 to various products such as carbon monoxide (CO), formic acid (HCOOH), methane (CH_4), methanol (CH_3OH), which can contribute to remit environmental and energy issues caused by increasing CO_2 concentration. The Scanning Electrochemical Microscopy (SECM)[1] employs an ultramicroelectrode (UME) as the tip to apply a suitable potential and collect the corresponding electrochemical signal response as a current, which allows to explore the electrocatalytic properties of different materials. The UME tip can be replaced by an optical fiber (OF), which is connected to a Xenon light source and provides UV-visible or visible light. This illumination can be locally driven on the candidate catalysts for PEC-CO_2RR activity evaluation by scanning photoelectrochemical microscopy (SPECM). Possessing many physicochemical properties, room-temperature ionic liquids (RTILs) can dissolve more CO_2 and inhibit competitive side reactions (ex: H_2 evolution) during CO_2RR. Furthermore, it is reported that the cation of imidazolium based RTILs ($C_n$mim$^+$) has a co-catalyst role for electrochemical CO_2RR on Ag electrode.[2]

In our work, we apply SPECM to locally illuminate p-type semiconductor materials such as $CuCo_2O_4$ immersed in different electrolytes solutions for evaluating the performance of PEC-CO_2RR. The PEC reduction currents obtained by SPECM in aqueous solution ($KHCO_3$), in binary mixture solution (25% [C_2mim][BF_4]/H_2O and 25% [C_4mim][BF_4]/H_2O) and in pure RTILs are compared in this work. We get a relevant increase in photocurrent in 25% [C_2mim][BF_4]/ H_2O mixture in comparison with all other media tested either under UV-Visible or Visible illumination, pointing out the co-catalyst role of imidazolium cation for the photoelectrochemical reduction of CO_2. In contrast, we find a decrease in photocurrent in 25% [C_4mim][BF_4]/H_2O mixture, probably due to the strong interaction of [C_4mim]$^+$ and CO_2. Meanwhile, as reported by Zigah et al,[3] we fabricated a dual tip which combined optical fiber and Pt UME (OF-UME) acting simultaneously as a light source and a sensor for detecting the PEC-CO_2RR products in SPECM.

Chemically Modified Electrodes with Clickable Thiosemicarbazones for Metal Ions Sensing

George-Octavian Buica, Matei D. Raicopol, Nicoleta Aurelia Chira
University Politehnica of Bucharest, Faculty of Applied Chemistry and Material Science, 1-7 Gheorghe Polizu, 011061, Sector 1, Bucharest, Romania
buica_george@yahoo.com

Originally designed as a tool in organic synthesis, the concept of "*click chemistry*" introduced by Sharpless and co. in 2001 [1] emerged very rapid as one of the most employed routes for designing the architecture and functions of different types of surfaces with important applications (e.g. nanomaterials) [2]. Moreover, due to the mild conditions, this method can be applied even in aqueous solvents in the presence of a catalyst and of many functional groups without protection. The process is fast, selective and resistant to side reactions. However, this approach has rarely been applied to modify electrodes with chelating groups for heavy metal ions sensing.

We report here, the synthesis of novel thiosemicarbazone ligands bearing azido groups, which were further immobilized on a phenylethynyl-functionalized glassy carbon surface, through a Cu(I)-catalyzed azide-alkyne cycloaddition reaction. In this manner, new modified electrodes were obtained, and their ability to coordinate metal ions, due to the intrinsic properties of the immobilized ligands, was studied.

jl.gomez@uco.es

The large development of renewable energy sources requires the parallel development of sustainable energy storage systems because of its non-continuous production. In this reality, the lithium–sulfur battery emerges as one of the most promising technologies to face this problem. Moreover, the use of biomass to produce cathodes for these batteries addresses not only the aforementioned problem, but also it reduces the carbon footprint and gives added value to something normally considered waste. In this work, we report the production, by simple and non-activating pyrolysis, of a carbon material using the abundant 'after-boiling waste' derived from beer brewing.[1]

In a typical fabrication, the after-boiling waste that come directly from the factory was dried overnight, then heated from to 900 °C for 60 min for carbonisation under a nitrogen atmosphere. No further activation or washing was needed. The material was named ABW-C.

Regarding the structural characterization, a carbon percentage of 88% was found by TG analysis on the ABW-C material in oxygen atmosphere. This is a value that confirms a material with a high carbon content, a strictly necessary condition for suitable carbon materials from biomass or industrial waste. The XRD pattern of the ABW-C shows the expected two broad peaks of low intensity, with the peaks centred at 25 and 44° coming from to the crystallographic planes of graphite (002) and (100), respectively. Pore size distribution calculated by DFT method revealed dual micro- and mesoporous structure of the ABW-C. From BET isotherm a total pore volume of 0.277 $cm^3\ g^{-1}$ with a micropore volume of 0.141 $cm^3\ g^{-1}$, can be calculated (approx. 50% microporosity).

After adding a high sulfur loading (70%) to this biowaste-derived carbon by the 'melt diffusion' method, the sulfur–carbon composite (ABW-C@S) was used as a cathode in Li–S batteries. The cathode exhibited excellent performance, reaching high capacity values and ultra-long cyclability at high current: 847 mAh g^{-1} (at 1C, Fig. 1), 586 mAh g^{-1} (at 2C) and even 498 mAh g^{-1} (at 5C) after 400 cycles, drastically reducing the loss of capacity per cycle to values close to 0.01% per cycle.

In conclusion, carbon derived from brewing waste, without any activation process, has demonstrated suitable textural properties for the preparation of high-sulfur-content composites to use as effective cathodes in Li–S cells. Its high surface area, combined with its interconnected micro- and mesoporous system, raises its performance, in both capacity values and cyclability, even at high current densities. Therefore, this work demonstrates the possibility of revaluing the brewing waste by transforming it into a porous carbon, using a simple process without activation stages, with promising performance in a sustainable cathode for ultra-high-cyclability Li–S batteries. In short, this work demonstrates the possibility of obtaining low-cost, highly sustainable cathodic materials for the design of advanced energy storage systems.

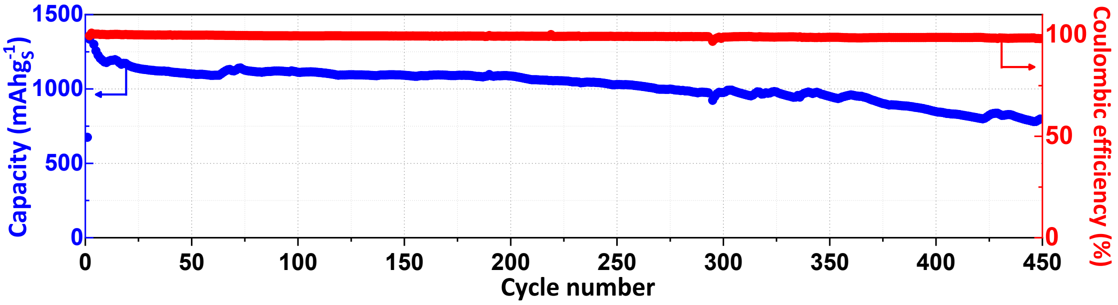

Figure 1. Long-term cycling performance of Li/LiTFSI-LiNO$_3$-DOL:DME/ABW-C@S at 1C (1675 mA g^{-1}).

Hybrid Capacitor with Anthraquinone-Grafted Carbon as Battery-Type Electrode Operating in Low pH Aqueous Salt Solution

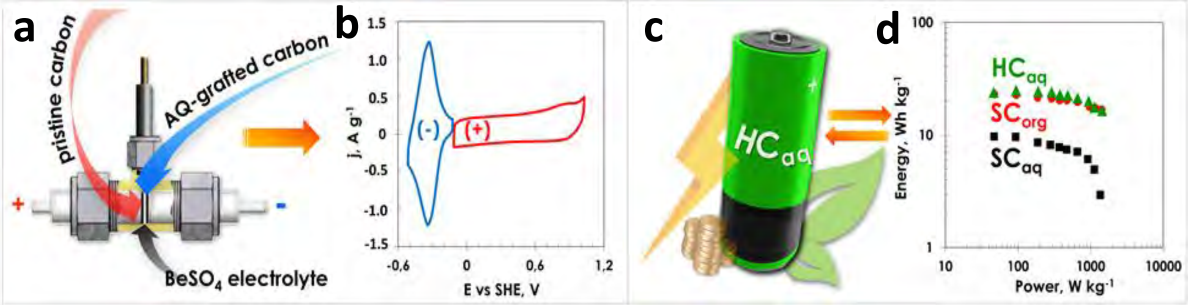
Emmanuel Pameté Yambou*, Barbara Górska, Paula Ratajczak and François Béguin

Poznan University of Technology, ul. Berdychowo 4, 60-965, Poznan, Poland

*emmanuel.yambou@doctorate.put.poznan.pl

Hybrid capacitors combine one electrical double-layer electrode - usually a high surface area carbonaceous material, together with a faradaic battery-type component [1]. Recent examples of high conductivity battery-like electrodes are realized by operating carbon electrodes in a redox-active electrolyte [2] or by modifying carbon with electroactive molecules [3]. Grafted carbons, e.g., with anthraquinone (AQ) moieties, are recognized to display highly reversible redox activity in acidic electrolytes such as sulfuric acid, unlike in basic electrolytes where quinone-dianions are formed causing AQ detachment from the surface [3]. However, in H_2SO_4 electrolyte, expensive gold current collectors are required to avoid corrosion issues, and the operational voltage of carbon-based capacitors is restricted (~ 1V).

In the present study, anthraquinone (AQ) moieties (0.1eq. vs. carbon) have been grafted using the corresponding diazonium salts on the surface of the SC2A carbon black (Cabot, S_{DFT} =1502 m^2 g^{-1}, total pore volume = 1.05 $cm^3 \cdot g^{-1}$). The AQ mass loading in SC2A@AQ was ~16 wt% as determined by CV and TG analysis. The DFT specific surface area of SC2A@AQ was reduced to 191 m^2 g^{-1}, and the total pore volume dropped to 0.46 $cm^3 \cdot g^{-1}$. Despite the large difference in S_{DFT} values of the materials, the EDL capacitance values of SC2A and SC2A@AQ electrodes in 1 mol L^{-1} $BeSO_4$ (pH = 2.1) were comparable, owing to the improved wettability of the latter material. The performance of a (-)SC2A@AQ//SC2A(+) hybrid capacitor (HC_{aq}) in 1 mol L^{-1} $BeSO_4$ was characterized by a quasi-linear GC/GD profile and twice higher capacitance compared to the symmetric (-)SC2A//SC2A(+) cell. The capacitance retention of the HC_{aq} reached 87 % after 10,000 galvanostatic cycles up to 1.6 V. Owing to the AQ grafting, the negative SC2A@AQ electrode of the HC_{aq} demonstrated a very low potential decay (so-called self-discharge) of 0.11 V after 4-hour voltage hold at 1.5 V, as opposed to 0.92 V for the SC2A negative electrode in the SC_{aq}. Overall, the HC_{aq} delivered energy and power performance comparable with a symmetric SC2A/SC2A capacitor operating up to 2.7 V in usual organic electrolyte (SC_{org}), whilst succeeded by being an economically viable energy storage device.



Scheme 1: (a) hybrid cell with reference electrode (to study the behavior of individual electrodes) made of as received SC2A carbon black as positive EDL electrode and its modified SC2A@AQ counterpart employed as battery-type negative electrode operating in 1 mol L^{-1} $BeSO_4$ aqueous electrolyte; (b) cyclic voltammograms of the electrodes at cell voltage of 1.6 V; (c) illustration of the (-)SC2A@AQ//SC2A(+) hybrid capacitor (HC_{aq}) which ensures a low production cost, high power and energy; (d) Ragone plot of HC_{aq} and (-)SC2A//SC2A(+) symmetric (SC_{aq}) cells in $BeSO_4$ (range of 1.5-0.75 V) at constant power; it shows that HC_{aq} advantageously competes with the (-)SC2A//SC2A(+) cell in $TEABF_4$/ACN organic electrolyte (SC_{org}; in the range 2.7-1.35 V).

Temperature Dependent Non-linear Electrochemical Impedance Spectroscopy Analysis to Elucidate the Solid Electrolyte Interface on Li Metal in Li\SOCl₂ Batteries

Mohammed Ahmed Zabara, Burak Ulgut
Department of Chemistry, Bilkent University, 06800 Ankara, Turkey
mohammed.zabara@bilkent.edu.tr

The Solid Electrolyte Interface (SEI) plays a very important rule in the stability, safety and voltage behavior of Li based batteries. Lithium Thionyl Chloride (Li\$SOCl_2$) primary batteries are among the most used Li metal-based batteries due to high energy densities. The stability of the Li metal used as anode is governed by the SEI formed from the reaction of Li with the electrolyte $SOCl_2$ [1]. In the voltage performance of the battery, the SEI is shown to have drastic effect on the voltage behavior of the battery during operation [2].

The non-linear data obtained during the performance of Electrochemical Impedance Spectroscopy (EIS) measurements of Li\$SOCl_2$ can be used to study the SEI formed on the Li metal anode. The non-linear data is obtained as higher order harmonics which have certain amplitudes at the multiple frequencies of the excited signal as shown in Figure 1(a). In our previous work, we have shown that the presence of thicker and denser SEI causes non-linearities in the voltage response in the form of second harmonic signals in the non-linear harmonic spectrum shown in Figure 1(b) [3].

In this work, we will show the results obtained from the further investigation of the SEI on the Li anode by non-linear harmonic analysis coupled with temperature and State of Charge variations. The obtained harmonics provide information related to the formation and degradation kinetics and composition of the SEI. Further, the relation of varying electrode/electrolyte composition to the parameters of the SEI will be shown. The results will demonstrate how non-linear harmonics, which are usually avoided in EIS measurements, can be utilized to investigate the SEI in Li based batteries.

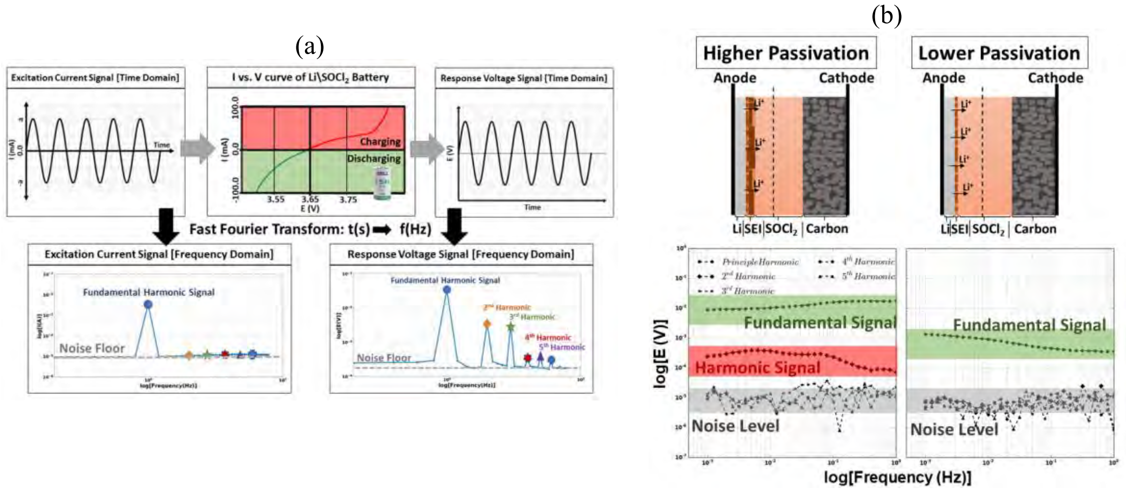

Figure 1. (a) Non-linear Harmonic Analysis for Li/$SOCl_2$ battery, (b) Non-linear harmonic spectra for cells with different Solid Electrolyte Interphase structure

High energy density with safety is important point to develop the large sized batteries for electric vehicle. Safety issues of current lithium ion battery system mainly comes from the oxide cathode and flammable organic electrolyte. All solid state batteries with non-flammable inorganic solid electrolytes have received great attention from electric vehicle companies due to its potential for securing higher energy density and safe characteristics over current lithium ion battery system. A high lithium ion conducting solid electrolytes is core technology to the development of all solid state batteries. Solid electrolytes were mainly synthesized by solid state method with high energy ball milling and het treatment process. A high energy mechanical milling system is not sufficient for large scale synthesis process. Recently, new synthesis method with liquid based system was proposed to avoid milling process. Moreover, new materials might be synthesized via liquid based synthesis method which cannot be successfully obtained by solid state synthesis.

In this study, liquid based synthesis process was examined by controlling kinds of solvents, purity, reaction order, ratio of precursors and vacuum drying process. An argyrodite structure solid electrolytes, Li_6PS_5X (X=Cl, Br) were successfully synthesized by liquid based synthesis method. Crystallinity and ion conductivity was evaluated by X-ray diffraction method and AC impedance technique. All solid state batteries were fabricated by powder pressed type half-cell and electrochemical tests were investigated and the detailed results will be discussed in this presentation.

ferley.vasquez@udea.edu.co

Simple preparation process by microwave heating to obtain composite materials LiFePO$_4$/C olivine (2% w/w) deposited as a coating on LMNO spinel (98% w/w) was studied in order to avoid the spinel phase dissolution in the liquid electrolyte. Microwave radiation allows local melting of the carbon precursor in the LiFePO$_4$/C resulting in a compact protective layer without further phase transition. The composite formation and the phase transitions during microwave heating were characterized by synchrotron XRD, SEM and TEM. The electrochemical performance of composite materials was characterized by charge/discharge cycling, rate-capability and electrochemical impedance spectroscopy (EIS). The degradation process after cycling was also characterized by synchrotron XRD. With a heating of 10W the composite LMNO-2LFP/C was obtained with superior crystallographic order without impurities precipitation, see Fig. 1a. This composite retains the 97% of initial capacity after 100 cycles and higher discharge capacity was achieved (see Fig. 1c). After 100 cycles, the composite material LMNO-2LFP/C-10W retains the lattice parameters of the spinel phase, while olivine phase is partially delithiated and additional peaks at 2θ of 9.35° and 14.85° significantly smaller than those of LMNO appear (see Fig. 1b). At heating power of 100W changes in the lattice parameters of spinel phase take place and impurities precipitate decreasing discharge capacity, possibly due to degradation of the spinel structure by overheating.

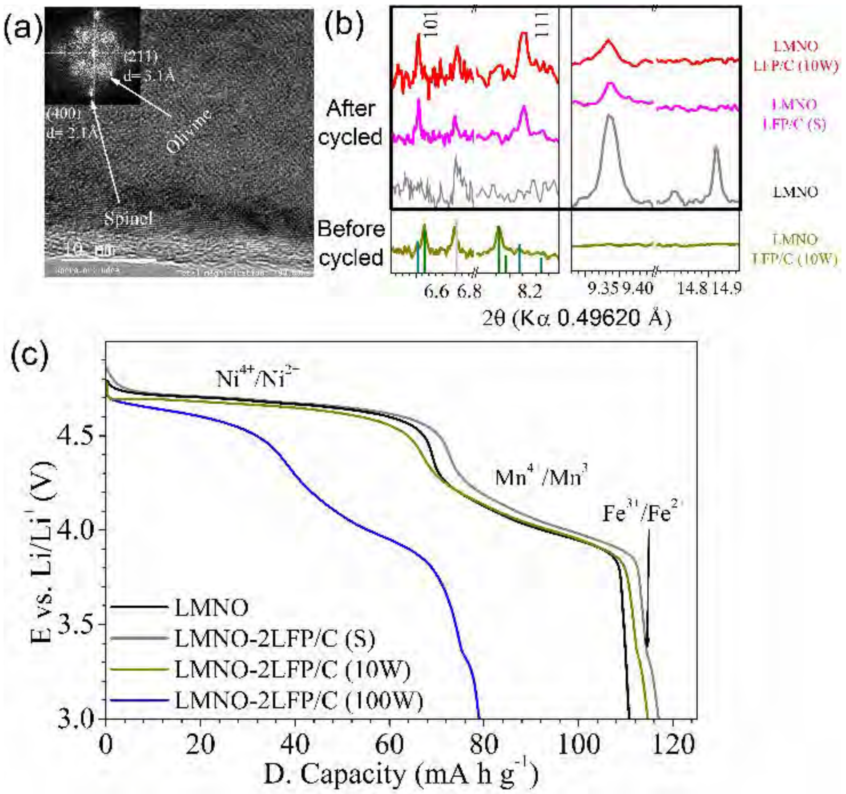

Fig. 1 (a) LMNO-2LFP/C (10W) TEM. (b) Synchrotron XRD of LMNO-2LFP (10W) before cycled and LMNO, LMNO-2LFP/C without heating and heated at 10W after 100 cycles. (c) Discharge profile at 0.5C of LMNO and LMNO-2LFP/C without heating and heated at 10W and 100W.

Understanding the interplay between Li insertion and Li plating in single graphite anode

Tao Gao[1], Dimitrios Fraggedakis[1], Supratim Das[1], William Chueh[2], Ju Li[1], Martin Z. Bazant[1]

[2]Stanford University
Bazant@mit.edu

The potential safety hazards of lithium ion batteries (LIBs), as well as their capacity fade and long charging time, are major challenges that currently prevent the widespread adoption of electric vehicles. These effects are strongly correlated with lithium plating, a parasitic reaction on graphite anodes that competes with lithium intercalation when LiBs are charged at high rates or under low temperature. Li plating is known for depletion of the lithium inventory, cell shorting, and thermal runaway.

Addressing Li plating problem relies on material engineering and battery operation optimization. The efficacy of these approaches lies in the fundamental understanding of Li plating mechanism. Despite Li ion battery has been invented for 30 years, a systematic understanding on the onset and growth of Li in graphite anode is still lacking. Thermodynamics criterion requires the voltage of graphite to be negative vs. Li metal for Li plating to happen. However, in practice graphite is usually able to tolerate certain degree of negative voltage without plating. Such discrepancy necessitates the incorporation of kinetic factors. Several kinetic mechanisms have been proposed, which include electrolyte transport limitation and solid diffusion limitation. However, neither of them are validated experimentally on graphite electrode.

In this work, we test these hypotheses and elucidate the mechanism of Li plating, by investigating the interplay between Li intercalation and Li plating on a single graphite particle, using in-situ optical microscopy coupled with electrochemical test. The results show Li plating happens when the surface of graphite saturates, which shuts down the intercalation reaction. The saturation can happen much earlier than full lithiation of graphite particle due to solid diffusion limitation, resulting in severe under-utilization. The physical picture was discussed by analyzing the energy landscape of the two competing reactions and their kinetics. A theory was proposed, followed by a 1D simulation of the dynamics of Li insertion and Li plating. The discovery sheds light on directions and guidelines of materials innovation or electrode design for reducing the risk of Li plating and extreme fast charging.

The Effect of a Filler Type on the Electrical Percolation Threshold of a Biocompatible Neural Interface Composite

Katarzyna Krukiewicz, Małgorzata Skorupa, Daria Więcławska

katarzyna.krukiewicz@polsl.pl

Electrical stimulation as the way to treat neural tissue disorders has been known in medicine for the last decades [1]. Currently, deep brain stimulation (DBS) is a common tool to treat several neurological disorders, including chronic pain, depression, tremors associated with Parkinson's disease and epilepsy. One of the drawbacks of existing DBS technologies is the lack of the integration between electrode material and neural tissue, leading to foreign body reaction and inflammation. Therefore, current strategies are focused on the development of conducting coatings which could increase the biocompatibility of neural electrodes, while maintaining their high conductivity.

In our studies, we have chosen an aliphatic polyester as a biocompatible matrix, and we have loaded it with selected conducting fillers differing in size, conductivity and surface morphology, namely carbon nanotubes (CNTs), silver nanowires (AgNWs) and conducting polymer microspheres (CPMs). It is known that the addition of a conducting filler can significantly enhance the electrical properties of non-conducting polymers. Usually, the change in electrical properties is not linear with the content of a conducting filler. Hence, even a small amount of conducting filler can dramatically improve the conductivity of the composite material if only this amount is enough to form long range networks, called percolation paths [2].

To determine the minimum amount of conducting fillers that provides conductive behavior to polyester matrix, electrochemical impedance spectra (EIS) and cyclic voltammograms (CV) of composites were collected, and the corresponding charge storage capacities (CSC) were calculated. The percolation behavior of the composites was clearly seen from the changes in impedance and CSC, and was found to be highly dependent on the filler type. The lowest percolation threshold was found for CNTs (0.1 %), but the highest value of CSC (10.7 ± 0.3 mC/cm^2) and the lowest impedance (167 ± 10 Ω) were found for 10 % AgNWs. The results of our work clearly demonstrated the potency of AgNWs to be used as conducting fillers in composite coatings for neural electrodes. AgNWs were shown to form an extended uniformly distributed network within polyester matrix, resulting in advantageous electrochemical properties.

Electroactive Organic Monolayers as Multifunctional Neural Coatings

Katarzyna Krukiewicz, Małgorzata Skorupa

Department of Physical Chemistry and Technology of Polymers, Silesian University of Technology
M.Strzody 9, 44-100 Gliwice, Poland
katarzyna.krukiewicz@polsl.pl

Rapid growth and development at the intersection of neuroscience, computer science, engineering and medicine has allowed the creation of revolutionary neurotechnologies to evaluate and treat nervous system disorders. Neural interfaces have become a major focus in current research in an effort to identify and develop novel approaches to augment human cognitive or sensory-motor functions, to interface with computer systems or to control external devices [1]. The implantation of metal electrodes may, however, lead to persistent inflammation – this is why intensive research efforts have been made to develop biocompatible coatings preventing implant-associated adverse effects [2]. The optimal interface should not only exhibit biocompatibility, conductivity, low interfacial impedance, high stability and high charge injection capacity, but it should also prevent glial scar formation and inflammation [3]. Therefore, the range of biomaterials that can be used in this specific application is limited.

Our aim was to improve the efficiency of neural electrodes through the design of a novel type of coatings based on electroactive monolayers. The objectives of our work included the formation of electroactive monolayers with the use of the electrochemical reduction of diazonium salts (Fig.1). The formation of monolayers was monitored in situ, with the use of electrochemical quartz crystal microbalance and cyclic voltammetry. The as-formed monolayers were extensively investigated in terms of their electrochemical properties (charge storage capacity, charge injection capacity, impedance characteristics, conductivity), surface roughness, mechanical stability and biocompatibility.

The results confirmed that the electrochemical methods can be successfully employed to form and further modify electroactive monolayers. The examination of as-formed monolayers showed the formation of a uniform coating being able to be further modified by electrochemical methods, e.g. surface-induced electropolymerization. Moreover, the monolayers were shown to enhance the growth of neural cells when compared with a bare surface of platinum. Furthermore, unmodified and electrochemically modified monolayers were shown to differ in terms of surface characteristics (roughness), leading to the differences in the interactions with cells.

Combining the advantageous physicochemical properties of monolayer coatings together with their high tailorability for specific needs, we expect that the electroactive organic monolayers could serve as promising materials not only for neuroprosthetic coatings, but also for a variety of applications in the field of molecular scaffolds and medical devices.

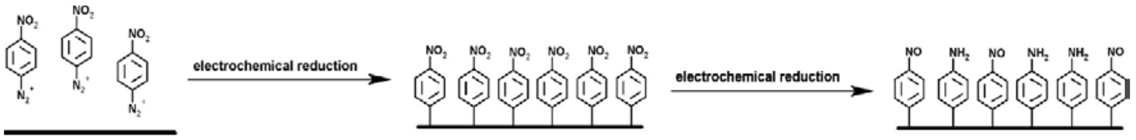

Fig.1. The schematic representation of a two-step process of the formation of a monolayer.

Determination of membrane potential dependent structural changes in of a model of the outer membrane of Gram-negative bacteria

Izabella Brand and Bishoy Khairalla
Department of Chemistry, University of Oldenburg
26111 Oldenburg, Germany
e-mail: izabella.brand@uni-oldenburg.de

Cell envelope of bacteria differs in the composition and structure from cell membranes of eukaryotes. Gram-positive bacteria contain one phospholipid membrane which is surrounded by a 20 – 80 nm thick peptidoglycan film. The cell envelope of Gram-negative bacteria has one of the most complex structure in nature. It is composed of two lipid bilayers. The inner membrane contains phospholipids. The inner membrane is separated from the outer membrane (OM) by a thin (7-10 nm) peptidoglycan layer. The two leaflets of the OM have a distinct composition. Lipopolysaccharides are present in the outer leaflet. They have a complex structure. Lipid A consists the amphiphilic fragment of each lipopolysaccharide. A core fragment of a lipopolysaccharide is bound to the lipid A molecule. It is subdivided into an inner and outer core. The inner core is bound to lipid A via rare sugars: 2-keto-3-deoxyoctulosonate (Kdo) and L-glycero-D-manno-heptose. The outer core is composed of few common sugar residues (hexoses and hexosamines). The polar head group of lipid A and core regions are negatively charged. Divalent cations (Ca^{2+}, Mg^{2+}) are coordinated to the phosphate, carboxylate and hydroxide groups of this rigid fragment of a lipopolysaccharide molecule. A large structural diversity of LPS combined with the complex supramolecular structure of the OM limit biomimetic studies of the cell membrane envelope of Gram-negative bacteria.

In this work Langmuir-Blodgett and Langmuir-Schaefer (LS-LB) transfers were used to deposit a multicomponent asymmetric lipid bilayer, mimicking the composition of the OM of Gram-negative bacteria, onto an Au(111) electrode surface. The inner leaflet is composed of 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphoethanolamine (POPE) whereas the outer leaflet contains di[3-deoxy-D-manno-octulosonyl]-lipid A (KLA). The capacitance of the model OM depends on the potential applied to the Au(111) electrode. At negative membrane potentials, the bilayer desorbs from the electrode surface. The potential-driven adsorption-desorption process is reversible. Molecular scale changes in the model membrane exposed to physiological electric fields were investigated using *in situ* polarization modulation infrared reflection absorption spectroscopy. The orientation of the lipid molecules in the asymmetric OM depends on the membrane potential. The hydrocarbon chains of both lipids POPE and KLA exist in a liquid state. The orientation of the acyl chains in POPE, in the inner leaflet, does not change as a function of the membrane potential. In contrast, the hydrocarbon chains in KLA change their average orientation as a function of potential, reaching the largest disorder at negative membrane potentials, proceeding the bilayer desorption from the Au(111) electrode surface. The polar head groups response also to membrane potentials. The orientation of the line connecting the two O atoms in the carboxylate group slightly change as a function of the membrane potential. The ester carbonyl groups in POPE and KLA lipids have a preferential parallel to the bilayer plane orientation, which is not affected by the membrane potential. Our results demonstrate that electric potentials cause significantly smaller changes in the packing and hydration of lipid molecules compared to pure phospholipid bilayers. To understand interactions of bacterial membranes with antimicrobial peptides or other antibiotics, biomimetic studies of realistic models of bacterial cell envelopes are required.

Choosing the right carbon is of vital importance for high performance Sb-based Na-ion batteries

Electrodes based on alloying reactions for sodium-ion batteries (NIB) offer high specific capacity but require bespoken electrode material design to enable high-performance stability. This work addresses that issue by systematically exploring the impact of carbon properties on antimony/carbon composite electrodes for NIBs. Since the Sb surface is covered by an insulating oxide layer, carbon additives are crucial for the percolation of conductive pathways and to enable the electrochemical activity of Sb based anodes. Instead of using complex hybridization strategies, the ability of mechanical mixing to yield stable, high-performance Sb/C NIB electrodes is shown. This is only possible by considering the physical, chemical, morphological, and structural features of the carbon phase. A comparison of carbon nanohorns, carbon onions, carbon black, and graphite as conductive additives is given in this work. The best performance does not require a high or low surface area, and not a high or low heteroatom content. Instead, the best performance is obtained for electrodes displaying a homogenous distribution of carbon within the Sb matrix. The latter provides an optimum interaction between carbon and Sb and is best enabled by carbon onions. A remarkable rate performance is attained, electrode cracking caused by volume expansion is successfully prevented, and the homogeneity of the solid/electrolyte interphase is significantly improved as a result of it. With this composite electrode, a reversible capacity of 490 mAh/g at 0.1 A/g and even 300 mA/g at 8 A/g is obtained. Additionally, high stability with a capacity retention of 73 % over 100 cycles is achieved at charge/discharge rates of 0.2 A/g.[1]

Over recent year, the range of Li ion battery (LIB) application has been rapidly extended to large scaled uses such as electric vehicles (EVs). This has driven demand for Li ion battery system that can offer higher energy density, higher current drain, and greater safety. All-solid-state batteries (ASB) have received great attention as a next generation power source due to its high energy densitsy with safe characteristics. Whole battery reactions are occurred in solid-state Li+ migration in ASB, therefore the well-contacted interfacial area is critical for battery performance. Solid electrolyte is key materials in ASB. Sulfide solid electrolyte is favorable to form a contact area effectively due to its elastic powder character compared to oxide. However, sulfide solid electrolyte is chemically unstable with humidity in air. It easily generates H_2S gas that is toxic and hazardous. Residual Li_2S and bridge sulfur in structure are known as main cause of H_2S generation. The ionic conductivity is also decreased by the decomposition of solid electrolyte by undesirable H_2S generation. Our previous works proposed the addtive such as zeolite and metal oxide as H_2S scavenger. H_2S gas generation and ionic conductivity after air exposure were greatly imptoved by introducing additive. In this study, we reports new argyrodite-type solid electrolyte that shows improved ionic conductivity at room temperature. The amount of H_2S gas generation was reduced for new arygrodite after exposured in moisture air (Rh50% for 60 min). Decease of ionic conductivity after air exposure is also suppressed. Electrochemical performance such as specific capacity and cycle performance is also improved for new argyrodite. The detailed results will be discussed at the meeting.

In a recent decade, a wealth of new electrochemical ion-separation technologies, such as capacitive deionisation (CDI) and battery desalination, have emerged as energy-efficient alternatives to conventional technologies.[1, 2] Relying on reversible electrochemical reactions as a driving force such as electric double-layer formation and insertion/intercalation, conversion type redox reactions, desired species such as metal and halide ions can be efficiently removed from feed solutions.[2, 3] Furthermore, large facilities based on these technologies can be coupled to grid-scale energy storage systems since the deionisation cell is essentially operated by electrical charging/discharging procedures.

For further development of these ion-separation technologies with reversible electrochemical reactions, the key challenges are to enhance removal selectivity, energy efficiency, operation stability, and production rate, and to reduce the environmental influence and the cost. While the majority of the work has been focused on electrode materials to achieve these requirements, ion-selective membranes have played their conventional role to improve ion removal efficiency. The letter approach, known as membrane CDI (MCDI), prevents the inefficient ion removal process by providing a guided direction for ion flux. Recently, various new roles of membranes have been explored for CDI and battery desalination technologies via innovative cell design and the use of advance new membranes.

Herein, we introduce the new roles of ion-selective membranes for ion-separation processes with reversible electrochemical reactions based on our recent scientific achievements. First, the traditional roles of membranes in terms of providing a guided ion flux will be discussed as well as its novel functions of changing the traditional direction of ion flux.[4-6] Second, we will introduce the new role of solvent separation with our proof of concept study demonstrating the feasibility of applying aqueous/organic bi-electrolyte configuration.[7] Third, we will present how the ion-separation performance can be enhanced by applying concentration gradient with the aid of ion-selective membranes in a multi-channel cell.[8, 9] Finally, we will show how ion-selective feature of the membranes can provide innovative solutions for ion separation technologies with a synergistic combination with the redox-active electrolytes.[4, 10]

Electrochemical impedance spectroscopy (EIS) is widely used for the characterization of proton-exchange-membrane fuel cells (PEMFCs) as it allows researchers to separate physical processes occurring at varying temporal scales [1,2]. The PEMFC impedance spectra often contain a low-frequency inductive loop that is attributed to the electrolyte hydration [2-6]. Since water management plays an important role in achieving high PEMFC performance, better understanding of the physical meaning of this inductive behavior will help in future fuel-cell design.

Developing physical insight by using equivalent circuits to analyze the impedance spectra [1,2] is difficult due to the oversimplification of the physical phenomena. Only a few multi-dimensional numerical models have been used to investigate the inductive behavior of fuel cells [3-5]; however, in-depth parametric studies of water transport were not performed.

In this work, the detailed transient 2D PEMFC model from our recent publication [7] is used to simulate and analyze fuel-cell impedance spectra. The model was thoroughly validated against in-house experimental polarization curves, ohmic resistance, and EIS data, as well as the recent experimental data for the humidity-dependence of the inductive loop [8]. The low-frequency inductive behavior of PEMFCs is shown to be directly affected by the water-transport mechanisms in the membrane and in the ionomer phase of the catalyst layers, including the finite-rate kinetics of water absorption/desorption by the electrolyte. Additionally, an ohmic-resistance breakdown of an in-operando fuel cell is performed with the model. The results indicate that the high-frequency resistance of the PEMFCs does not include the protonic resistance of the conventional carbon-based catalyst layers, while the latter is still significant in the overall ohmic losses.

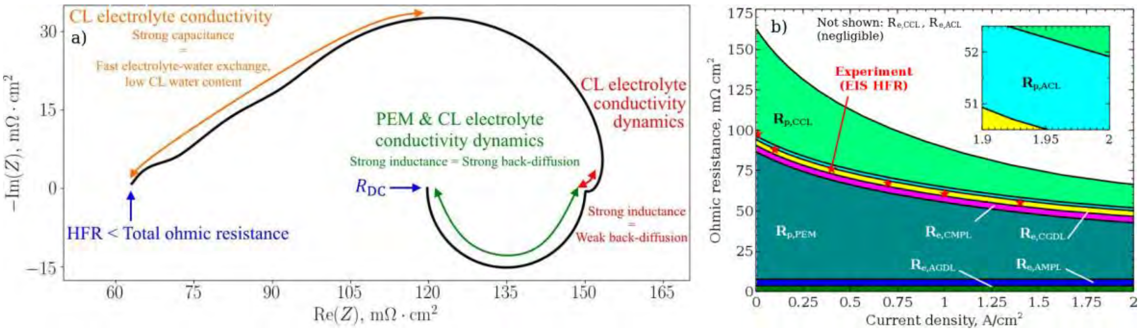

Figure: A PEMFC impedance spectrum simulated at 1 A/cm^2 (a) and ohmic-resistance breakdown (b).

Zirconium is a promising candidate for permanent implants both in orthopedic and dental applications due to its capability of promote the growth of new bone tissue with low cytotoxicity and excellent corrosion resistance [1,2]. Zirconium is covered in air or oxygenated media by a thin surface film of zirconium oxide, responsible of its outstanding *in vivo* and *in vitro* results [3,4]. Anodization represents an efficient route for surface modification that allows the surface design in the nano and micro scales fundamental for the improving implants performance [5]. In previous works, anodic growth of ZrO_2 surface films in phosporic acid resulted beneficial for implant osseointegration due to the modification of the topography and the chemistry of the surface, including P incorporation to the oxide film structure [1,2]. This, in turn, can induce the precipitation of Ca-P compounds on the surface. Furthermore, *in vitro* and *in vivo* tests have shown that the surface of ZrO_2 created by anodic oxidation at 60 V improves cell proliferation and the integration of the material into bone tissue [2,6]. In the past decade, numerous studies have focused on controlling the interaction between tissue and implanted materials by immobilizing functional biomolecules that could stimulate and interact with the extracellular matrix environment [7-9].

In this work, the effect of functionalization of anodized zirconium with a bioactive peptide (RGD) as potential manufacturing material for osseointegrable implants to stimulate early bone integration is presented. The surface modification was evaluated by surface methods including scanning electron microscopy, Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS). Surface analysis shows the presence of ZrO_2 covering the surface. XPS shows the presence of the peptide on the surface after modification. Electrochemical tests were performed in simulated body fluid solution (SBF) in order to determine the effect of functionalization with the organic molecules on the corrosion resistance of anodized zirconium. Anodic polarization curves and electrochemical impedance spectroscopy results indicate that both anodized and functionalized with the RGD peptide surfaces present excellent corrosion resistance in SBF after 24 hours of immersion. EIS results evidences that both surfaces behave as non-ideal capacitors, characteristic of passive films on valve metals. These results demonstrate that the functionalization treatment with RGD peptide does not cause any detrimental effect on the anodic oxide formed on zirconium during anodization.

Ionic liquids (ILs) have recently gained substantial attention as promising solvents for the capture and sequestration of CO_2 and as reaction medium for its electrochemical conversion into valued-added products. It has been reported that ILs can co-catalyze the electrochemical CO_2 reduction reaction (CO_2RR), in particular when Ag or Ag-based materials are applied as the primary metallic electrocatalyst [1]. Despite several attempts to explain the co-catalytic effect of ILs in CO_2RR, the mechanism is not yet fully understood. Recently, the co-catalytic effect was explained by stabilization of CO_2RR intermediate, CO_2 radical anion, with IL cations adsorbed on a Ag electrode surface [2]. In order to broaden this co-catalysis concept and to develop an in-depth understanding of the co-catalytic action of the IL, we present herein a comprehensive study on a number of electrode materials (Pt, Pd, Ag, Au, Bi, Pb, Sn, Ni, Mo, Fe, Zn, Cu, and glassy carbon) exposed to several ILs, differing in the chemical nature of their anions and cations (Fig. 1) [3]. The activity of the electrode/IL combinations towards CO_2RR is examined on the basis of cyclic voltammetry (CV) data recorded in Ar- (blankets) and CO_2-saturated ILs. The voltammetric experiments are further complemented by online gas chromatography analysis of the electrolysis products, demonstrating that CO is the main CO_2RR product for most of the electrode/IL combinations chosen. Based on our analysis we identify three major classes of electrode materials differing in their synergistic interaction with the IL cations and the in resulting CO_2RR activity: (i) non-active (CO_2RR is negligible in the potential range of IL stability), (ii) moderately active (CO_2RR is hindered and proceeds together with the cathodic degradation of ILs), and (iii) highly active (CO_2RR proceeds with nearly 100% faradaic efficiency). We also demonstrate that IL cations have a strong effect on the CO_2RR overpotential (Fig. 1a-c, compare data for [BMP][TFSI] and [BMIm][TFSI]). Moreover, the co-catalytic effect depends on the electrode material: $[BMIm]^+$ promotes CO_2RR on Ag and Sn more than $[BMP]^+$, while the situation is opposite for a Au electrode (Fig. 1a-c). Therefore, co-catalytic effect of ILs in CO_2RR is determined by specific IL cation adsorption, and only particular combinations of electrode materials and IL cations enhance the CO_2RR activity.

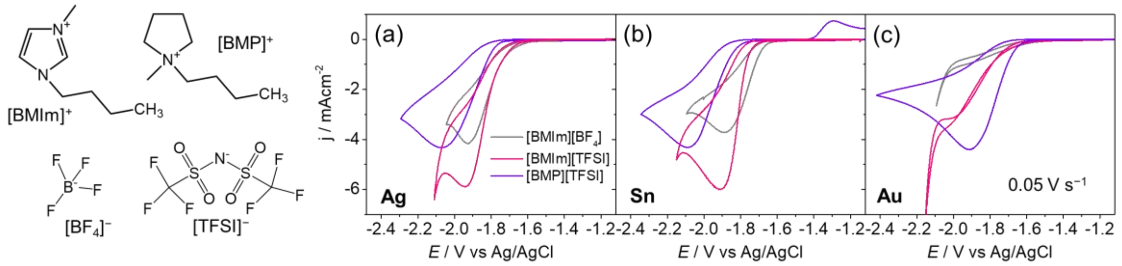

Figure 1. (Left) Cations and anions of ILs used in this work. (Right) Comparison of the CV fragments in CO_2-saturated ILs for the (a) Ag, (b) Sn, and (c) Au electrodes.

Iron is a very abundant chemical element naturally present in the Earth's crust [1]. It plays an important role and has major effects in environment (like in fresh and sea water), in industry (for instance in corrosion problems) or in humans (as it is implied in many biological or metabolic systems). Iron is mainly present as ferrous Fe(II) and ferric Fe(III) in aqueous media. However, Fe(II) is spontaneously oxidized in the presence of oxygen whereas Fe(III) is weakly soluble and forms stable complexes and precipitates at neutral pH [2]. Furthermore, the permissible values of iron concentration in drinking water is between 0.3 – 3 mg L^{-1} (i.e. $5.3\ 10^{-6} – 5.3\ 10^{-5}$ mol L^{-1}). Consequently, the assay of total iron at low concentration as well as the determination of iron speciation is of key interest and still represent an analytical challenge.

Many analytical methods have been developed in routine to detect and quantify iron in natural water involving chromatography, spectrophotometry, fluorescence, chemiluminescence and so on. However, all these techniques are expensive, bulky and time-consuming. Alternatively, electrochemical methods have been advantageously considered since they are low-cost, user-friendly, produce results in real time and can be used *in situ* [3-4]. If polarographic methods are currently not used anymore for evident toxicity reasons, mercury-free electrodes techniques based on adsorptive stripping voltammetry have been extensively developed these last ten years [5-6]. Nevertheless, these imply chelating agents including catechol or cupferron, thus making the procedure complicated and chemical-consuming.

In this work reagentless electrochemical sensors have been considered for the detection of Fe^{2+} and Fe^{3+}. Two amperometric sensors have been developed based on glassy carbon electrodes modified by deposition of a Nafion® cation exchange resin film containing sulfonic groups. Fe^{2+} and/or Fe^{3+} were pre-concentrated at open circuit conditions during 5-10 minutes, allowing ion exchange with protons. Electrochemical detection was then performed by cyclic or square wave voltammetry. In both techniques signals related to iron were recorded, the peak currents of which being proportional to Fe^{2+} and Fe^{3+} concentrations, respectively. Satisfactory calibration curves were achieved in the micromolar concentration range when analyzes were made in synthetic solutions. Limits of detection down to 0.1 and 0.01 µmol L^{-1} were reached for Fe^{2+} and Fe^{3+} respectively and the sensors exhibited a reproducible response for at least 15 measurements. Furthermore, accuracy was verified by comparing electrochemical results with ICP-OES analyzes. Finally, promising results obtained with real water samples from artificial circuits will be presented.

The presence of pharmaceutical compounds in hospital effluents is causing the emergence of bacteria resistant to antibiotics. These effluents have low biodegradability making them potential pollutants. At this point, electrochemical advanced oxidation processes (EAOPs) are an alternative clean and effective to conventional processes. Especially, electro-Fenton process has provided promising results for the removal of pharmaceuticals compounds [1], which involves the use of hydroxyl radicals to oxidize these contaminants. The mechanism of this process consists in-situ hydrogen peroxide electrogeneration via cathodic reduction of oxygen and the generation of OH^* via Fenton´s reaction.

The objective of the present work was the partial elimination of drugs to improve the biodegradability of these effluents using a microfluidic flow-through cell with a pressurized-jet aeration. It was also incorporated a fluidized bed of iron particles, to catalyse the decomposition of H_2O_2 into oxidizing species. Figure 1 shows an outline of the experimental set-up.

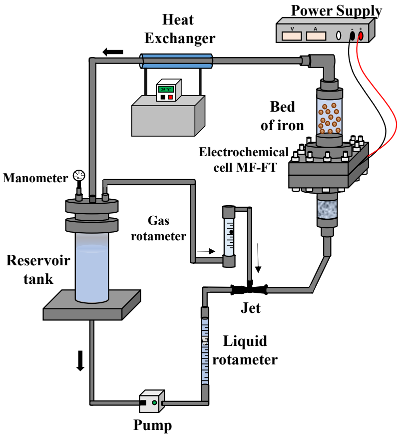

Figure 1. Experimental set-up

Tests were conducted using a 3D-Mixed Metal Oxide (MMO- $IrO_2Ta_2O_5$) as anode and a 3D titanium mesh with a deposition of Carbon Black and PFTE as cathode with different current densities (1 mA/cm^2, 5 mA/cm^2 and 10 mA/cm^2) and pressure ranged from 1 to 4 Bar. Previous experiments have shown that current density and pressure have an important role in the degradation of antibiotics.

The occurrence of antibiotic-resistant bacteria (ARB) in wastewater has become an important concern for today´s society because they are one of the main causes of deaths during the last years. This problem is more dangerous in sanitary facilities where the concentration of ARB is higher due to the different infections of hospitalized patients. Specifically, large concentrations of ARB can be found in urine since many of them are mainly excreted by this way. Therefore, hospital urine can be considered as a target effluent to treat for the removal of ARB before its discharge to sewage. In this context, it is necessary to develop environmentally-friendly and efficient technologies that allow to remove ARB from hospital urines, avoiding the formation on undesirable disinfection by-products (DBPs). One of the technologies that has been proven efficient for disinfection of urban treated wastewater is electrochemical oxidation [1]. This process consists of the production of large amounts of disinfectant species, mainly free and combined chlorine compounds, from the oxidation of the ions naturally found in wastewater. These species attack the microorganisms present in the effluent, causing their death and guaranteeing a persistent disinfection treatment. The process efficiency is clearly affected by the anode material, current density and wastewater composition. Hence, these are the main operating parameters that should be evaluated.

With this background, the present work aims the applicability of electrochemical oxidation as disinfection technology for hospital urines polluted with two different types of ARB: *Klebsiella pneumoniae* (gram-negative) and *Enterococcus faecalis* (gram-positive). Boron Doped Diamond (BDD) and Mixed Metal Oxides (MMO) were tested as anode materials during the electrodisinfection of hospital urines at current densities within the range 5-50 A m^{-2}. Likewise, the removal of ARB with BDD and MMO anodes was studied in urban treated wastewater at different current densities to evaluate the influence of the effluent composition. Results show that it is possible to attain a complete removal of ARB in both effluents, hospital urine and urban treated wastewater. The disinfection efficiency is higher during the process in urban treated wastewater. This behavior can be explained by the higher organic load of hospital urines. Specifically, this effluent contains not only inorganic ions and bacteria but also other organics such as urea, creatinine and uric acid in high concentrations. The oxidation of these compounds can compete with the removal of ARB, decreasing the disinfection efficiency. On the other hand, the formation of DBPs was discarded during the treatment of hospital urines whereas significant amounts of chlorates were detected in urban treated wastewater. This can be related to the higher nitrogen content of hospital urines that favors the production of large concentrations of chloramines instead the promotion of hypochlorite to other hazardous chlorine compounds in high oxidation state. These results reveal that it is more appropriate to remove ARB in hospital urine despite the lower efficiency since it is possible to avoid the formation of DBPs.

Pollution of dyes is a great problem of the environment in many countries and frequently detected in watercourses and groundwater, and may have proven toxicity. The use of textile materials, as substrates for electrodes for dye degradation, offers many possibilities due to its mechanical properties, such as flexibility, and a high specific area. Moreover, graphene has attracted the attention of researchers due to its very high specific surface area (2630 m^2 g^{-1}) and the unique and outstanding mechanical and electrical properties **[1]**. That is why the main objective of this work was to study the behaviour of textile electrodes coated with reduced graphene oxide and platinum nanoparticles in the electrochemical treatment of wastewater containing dyes**[2].** Initially, we determined the adequate experimental conditions to obtain thin layers Pt nanoparticles, with good reproducibility of synthesis. The characterizations of material at the microscopic scale, using Field Emission Scanning Electron Microscopy **(FESEM)** and Energy-dispersive X-ray spectroscopy **(EDX)** have allowed us to deepen our knowledge on the material before his use, and to validate its structural stability after electrochemical treatment.

The degradation of Orange G dye was studied by anodic oxidation with Pt-RGO using sulphate as electrolyte. A significant decrease in total organic carbon (TOC), chemical oxygen demand (COD), and total nitrogen (TN) was obtained. The chromatography and the UV-Visible spectrophotometry assays indicated that decolourisation is obtained at a loaded charge of around 0.17 Ah L^{-1} which is associated with an electric power consumption of 1.28 kWh m^{-3}. These encouraging results were obtained at very low energy costs, allowing us to consider the possible application for wastewater treatments, in addition to existing treatments or directly to the source of pollution. The influence of the presence of chloride in solutions has been also studied.

Keywords: Dyes, Pt nanoparticles, textile materials; degradation, anodic oxidation

Recently, aqueous rechargeable zinc batteries (ARZBs) have received much attention for application in large scale energy storage thanks to their advantages, such as low cost, sufficient abundance, and high safety[1-2]. Aqueous electrolytes have higher ionic conductivity (up to 1 S cm^{-1}) than that of non-aqueous electrolytes, resulting in a higher rate capability and lower activation energy for charge transfer[1]. Meanwhile, the usage of aqueous electrolytes can reduce the manufacturing costs of ARZBs due to their properties such as non-toxic, inflammable, and non-strict humidity control[3-4]. Moreover, Zn has a high specific capacity (820 mAh g^{-1}) and high volumetric capacity (5854 mAh cm^{-3}), making it promising as a negative electrode. Thanks to its high potential (-0.76 V vs. SHE), it can be directly used as a negative electrode in aqueous-based electrolytes. However, the lack of high-performance positive electrode materials and the heavy mass and large polarization of Zn^{2+} hinder the practical applications of ARZBs.

V_2O_5 is considered a promising positive electrode for ARZBs due to its typical layered structure and relatively high capacity. Despite its good electrochemical performance, the structural changes of V_2O_5 during electrochemical processes are still in debate. Three different viewpoints regarding the structural changes of V_2O_5 in ARZBs have been proposed so far: *(i)* Zhou *et al.*[5] reported the formation of a new phase $Zn_xV_2O_5$ upon Zn insertion into V_2O_5 via *ex situ* XRD. *(ii)* Zhang *et al.*[6] proposed the co-intercalation of hydrated Zn ions into V_2O_5 crystal structure based on the *ex situ* XRD, XPS, and TEM experiments. *(iii)* Chen *et al.*[7] reported that orthorhombic V_2O_5 underwent a phase transition to zinc pyrovanadate during the first discharge *via ex situ* XRD, Raman, and XPS. However, the electrochemical reaction mechanism of V_2O_5 in the above-reported works was investigated through *ex situ* techniques. The findings are in controversy with each other and detailed structural changes of V_2O_5 upon Zn-ion insertion/extraction are still missing. Moreover, non-equilibrium or intermediate species/states cannot be detected using *ex situ* studies while *in operando* studies can provide a more reliable understanding of the structural evolution of a battery material in “real time”.

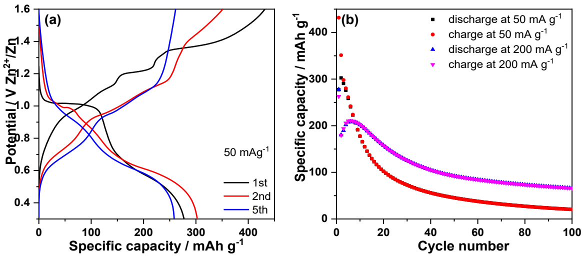

Figure 1 Discharge-charge profiles (a) and cycling performance (b) of V_2O_5 nanowires in 1 M $ZnSO_4$

Besides, it has been frequently reported that a mass of complex byproducts was produced/decomposed during the cycling of vanadium oxides in ARZBs. Interestingly, byproducts were not observed in the three works related to the study of V_2O_5 reported above. To better understand the electrochemical mechanism of V_2O_5 in ARZBs, *in operando synchrotron* characterizations are required. In the present work, orthorhombic V_2O_5 was prepared by a simple hydrothermal method. V_2O_5 nanowires exhibit an initial discharge and charge capacity of 277 and 432 mAh g^{-1}, respectively, at a current density of 50 mA g^{-1} (**Figure 1**). V_2O_5 undergoes quick capacity fading during cycling under both 50 mA g^{-1} and 200 mA g^{-1} current densities. The detailed structure evolution and reaction mechanism of V_2O_5 in ARZBs are studied *via in operando* synchrotron diffraction and X-ray absorption spectroscopy (XAS) together with *ex situ* Raman and X-ray photoelectron spectroscopy (XPS).

Actually, lithium sulfur (LiS) battery system is quite old battery technology since it has been studied since the 1960s. In addition, as a raw material, sulfur is very abundant and environmentally friendly, so it can offer economic benefits in the production cost of Li-S batteries. However, the problems in Li-S battery are very complex mainly due to poor kinetic properties, large volume expansions and dissolution of polysulfides into the electroylte made by aprotic solvent. All of these problems have caused a poor cycle properties and very severe capacity fading in Li-S battery. There are a lot of efforts devoted to enhance the performance of Li-S batteries, includes those are focusing on the sulfur cathodes, lithium anodes, new electrolytes and binders. In terms of the sulfur cathodes, many attempts have been proposed to enhance their electrochemical properties (discharge capacity, rate and cycling capabilities, and Coulombic efficiency) with the addition of heterogeneous materials. One of the most promising materials is the nanostructured carbons such as porous carbon, carbon nanotube or graphene. The nanostructured carbons own some remarkable chemical and physical properties which can contribute to the improved performance of sulfur cathodes in LiS battery system. Those kinds of properties include a highly porous structures provides a high surface area and pores for encapsulation of sulfur, a high electrical conductivity, good mechanical strength and an excellent inert property. N-doped porous carbon with high surface area, high nitrogen content and well connected porous structure has been synthesized from tofu waste by using hydrothermal carbonization and activation method. Due to the mesoporous structure, the carbon product has high surface area of large pore volume of 1.47 cm3 g^{-1} and mesoporous volume of 0.95 cm 3 g^{-1}. Attributed to the simultaneous effect of the mesoporous structure, high surface area and high nitrogen content ratio, the obtained porous carbon exhibits show excellent performance when used as composite cathodes along with sulfur for LiS battery. The carbon-sulfur composite was prepared by a melt diffusion method. The sulfur content in the composite was about 53.8 wt%, when utilized as cathode for LiS battery, the carbon-sulfur composite performs a high initial specific capacity of 1125 mAh·g^{-1} as well as 707 mAh·g^{-1} after 200 cycles at a current rate of 0.2 C.

Preparation of Microalgae Based Hard Carbons as Anode Materials for Sodium Ion Battery

Arenst Andreas Arie[1*], Angela Justina Kumalaputri[1], Livia Nathania[1], Henky Muljana[1] and Lorenzo Stievano[2]

[1]Department of Chemical Engineering, Faculty of Industrial Technology, Parahyangan Catholic University, Ciumbuleuit 94 Bandung 40141, Indonesia

In recent years, sodium-ion batteries (SIBs) have emerged as promising candidate to replace lithium-ion batteries due to the low cost and high abundance of sodium (Na). The SIBs performance is essentially determined by the electrode materials applied. Hard carbon is a type of carbon that is relatively difficult to be graphitized and usually is synthesized from pyrolysis of polymer's precursors such as phenolic resins or epoxy resins. Hard carbon is highly irregular and disordered, and primarily consists of single-layered carbon atoms that are closely and randomly connected. Hard carbon is one component that plays an important role as an anode material in sodium-ion batteries. In this work, one of microalagae species, namely Chlorella pyrenoidosa was used to prepare hard carbons by using hydrothermal carbonizations and pyrolysis. The hydrothermal carbonization process was conducted in the autoclave at temperature of 200 °C for 24 hours. The obtained hydrochars were subjected to the pyrolysis process at pyrolysis temperature of 900 °C. The physical characterizations of hard carbons were done by Scanning Electron Microscope (SEM) and X-Ray Diffraction (XRD) analysis. The as-obtained hard carbons were then used as anode materials for SIBs. Hard carbon can deliver the highest reversible capacity of 228 mAh g^{-1}, and show the high capacity retention of 95% at the current density of 100 mA g^{-1} after 100 cycles.

Electron Transfer and Ion Transport within Attoliter-Volume Nanopore Electrode Arrays

Single entity electrochemistry, a rapidly developing field that tackles one of the most urging questions on the boundaries of modern electroanalytical methods and related disciplines. To effectively implement the single entity detection, the prior task for instrumentation is to fabricate electrode with a comparable size of a single entity that captures small signals with enough temporal and spatial resolution at a reasonable cost. Nanopore electrode, as a widely used nanoelectrode, not only addresses how electron transfer and ion transport in confined volumes, also seeks to understand how ultrasmall volumes impact electrochemical detection. Over the past years, we have observed and described several unusual effects enabled by working in confined volumes. In this presentation, I will describe a novel nanoelectrode developed by our group, *viz.* nanopore electrode arrays (NEAs). I will begin by discussing the design flow of NEAs and the critical points for the device fabrication and post-processing. Then, I will present studies showing significant signal amplification from highly efficient redox cycling and additional sensitivity and selectivity that arise from the migration-induced ion accumulation. Lastly, I will highlight practical applications using NEAs, including *in situ* molecular separation and detection with external stimuli, redox-based electrochemical rectification in individually encapsulated nanopores, and coupled sorters and analyzers for nanoparticles. These examples should provide significant motivation for listeners to pursue work in the area of nanoscale electrochemistry.

Electrodeposition of Rare Earth Metals and Their Alloys from a Dicyanamide Ionic Liquid

A.V. Rudnev, E.B. Molodkina, M.R. Ehrenburg
Institute of Physical Chemistry and Electrochemistry, Russian Academy of Sciences
Leninskii pr. 31, building 4, Moscow, 119071 Russia
rudnev@phyche.ac.ru

Rare-earth elements (REEs) are one of the most important raw materials and are of great importance for the modern high-tech industry [1]. Low-temperature electrochemical deposition of REE-containing materials for the purpose of recycling and obtaining functional materials can provide a real alternative to the currently used high-temperature processes of molten salt electrolysis. The growing interest in ionic liquids (ILs) as media for electrochemical deposition of metals and semiconductors is due to their excellent physicochemical properties, including non-volatility, intrinsic conductivity, thermal and electrochemical stability [2]. The possibility of electrodeposition from IL-based solutions was demonstrated for various metals and semiconductors from the first to sixteenth groups of the periodic table [2]. However, studies on electrodeposition of REEs from ILs are scarce. Here, we present the investigation of electrochemical deposition of some chosen REEs in the 1-butyl-1-methylpyrrolidinium dicyanamide IL ([BMP][DCA]) at room temperature. Analysis of literature data shows that the dicyanamide ILs can be a proper choice as a medium for lanthanide deposition due to their relatively low viscosity (for [BMP][DCA], 50 mPa s at 293 K [3]) and good solubilizing ability [3]. The electrodeposition of REEs is studied on different single crystal electrodes with a controlled surface structure (Pt(111), Au(111), HOPG) as well as on a polished glassy carbon electrode. Cyclic voltammetry and chronoamperometry in the absence and presence of REE ions are used to identify REE-related electrochemical processes, while atomic force microscopy (AFM) is employed to characterize the deposit morphology obtained after potentiostatic polarization of the working electrodes. The voltammetric results demonstrate clear reduction of REEs at potentials more positive than reductive degradation of the IL (see the data for Eu deposition on Pt(111) in Fig. 1a). The AFM data confirm the REE deposition and reveal a strong dependence of deposit morphology on the substrate material and electrode potential, at which the deposit is formed (Fig. 1b-d). We also use the obtained data as a basis for studies on electrochemical deposition of REE–transition metal (TM) alloys from the dicyanamide ILs. As demonstrated in literature [4], TM with a more positive reduction potential can induce REE co-deposition with its reduction onset shifted to less negative potentials.

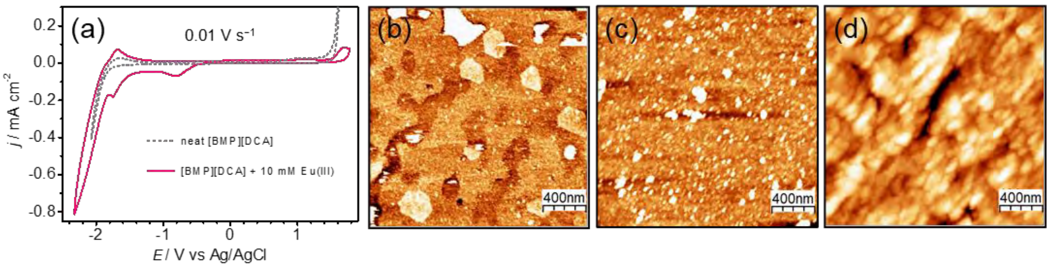

Figure 1. (a) Cyclic voltammograms of Pt(111) in pure [BMP][DCA] and in the presence of 10 mM Eu(OTf)$_3$. (b-d) AFM images of Eu deposits formed at different potentials: (b) -1.0 V, (c) -1.5 V, (d) -2.0 V) for 1200 s. The morphology changes from quasi-2D triangular or hexagonal islands to a compact granular deposit, depending on the overpotential.

Unravelling the Capacity Fading Enigma of Spinel $Li_xMn_{2-y}Ti_yO_4$ by using Distribution of Relaxation Times (DRT)

Franky Bedoya-Lora, Nerly Mosquera, Victoria Vásquez, Ferley A. Vásquez, Jorge A. Calderón

franky.bedoya@udea.edu.co

The demand for high capacity and inexpensive batteries is increasing rapidly with the upcoming energetic needs of an ever-increasing population, especially in the transportation sector. Spinel-type $Li_xMn_{2-y}Ti_yO_4$ cathode materials have been proposed as an alternative to the more expensive and toxic $LiCoO_2$ for Li-ion batteries [1]; however, stability issues persist [2] and the interaction between the active material and electrolyte at potentials below 3 V vs. $Li|Li^+$ is still a matter of discussion. We present an analysis of electrochemical impedance spectroscopy (EIS) using distribution of relaxation times (DRT) [3] as a method to reveal new insights regarding the capacity fading of $Li_xMn_{2-y}Ti_yO_4$ cathode materials.

A facile and improved sol-gel method was used to synthesised optimised $Li_xMn_{2-y}Ti_yO_4$ while maintaining nanostructured features. The stoichiometry $LiMn_{1.8}Ti_{0.2}O_4$ exhibited the best initial specific capacity (215 mAh g^{-1}) at 30.8 mA g^{-1} in a cycling window potential of 4.6 – 2.0 V vs. $Li|Li^+$. The incorporation of Ti increased the number of Li^+ diffusion pathways in the structure; adding Ti to replace a '*y*' amount of Mn in the spinel, i.e. $Li_xMn_{2-y}Ti_yO_4$ improves the specific capacity of the cathode materials by allowing both transitions, $Mn^{4+}|Mn^{3+}$ and $Mn^{3+}|Mn^{2+}$, to take place [1].

The effect of Ti incorporation and the underlying degradation processes during cycling were studied by cyclic voltammetry, cycling and electrochemical impedance spectroscopy (EIS), the latter was analysed by widely used equivalent electrical circuit and the more recent method of distribution of time constants (DRT), see Fig. 1. Cathode materials were also characterised at different cycling stages by XRD, Synchrotron XRD and SEM. Additionally, cathode materials were characterised by XPS, Raman and BET surface area. The results showed a clear indication of undesired structure modifications when the transition $Mn^{3+}|Mn^{2+}$ occurs, i.e. characteristic feature of topotactic two-phase reaction, and formation of irreversible tetragonal phase of the spinel which increases the charge transfer resistances at the active material | electrolyte interface. The presence of Ti did not inhibit completely undesired structure transformations, even after several strategies were implemented, e.g. addition of HF scavengers, different calcination temperatures and active material:binder ratios. A comparison between equivalent electrical circuit and DRT analysis is also presented. The investigation here offers a better understanding of the cathode materials and their correlations with electrochemical properties, which are of utmost importance for future researches on reaction kinetics and Li^+ transfer mechanisms in Li-ion batteries.

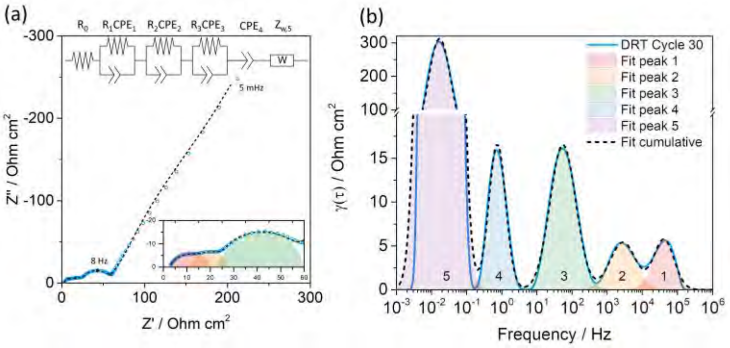

Fig. 1. (a) Nyquist plot of impedance spectra of $LiMn_{1.8}Ti_{0.2}O_4$ | 1.2 M $LiPF_6$ EC:DMC 1:2 | Li recorded at 4.0 V vs. $Li|Li^+$ after 30 cycles through a window potential of 4.6 – 2.0 V vs. $Li|Li^+$, (b) Computed DRT spectra and respective deconvoluted peaks.

Theoretical Analysis of the Oxygen Reduction Reaction Limited by Surface Diffusion at a Rotating Ring-Disk Electrode

Antonio M. Chaparro
Dep. of Energy, CIEMAT
Avda. Complutense, 40, 28040, Madrid, Spain
antonio.mchaparro@ciemat.es

The oxygen reduction reaction (orr) is the limiting process for power production in many electrochemical devices, like proton exchange membrane fuel cells and metal-air batteries. High orr rates in these devices can be attained with high active area cathodes based on catalyst nanoparticles supported in a porous matrix. In their reaction path, oxygen molecules diffuse in the gas and electrolyte phases until they arrive at the pores walls where they may interact with an active catalyst center or an inactive site. In the second case, orr may proceed either by successive desorption/adsorption steps until arriving at a catalyst center, or by surface diffusion towards a nearby catalyst site. The later may be the principal path with a low density of catalyst sites and sufficient surface diffusivity.

In this communication, a previously developed surface diffusion model [1][2][3][4] is applied to the orr at a dispersion of catalyst centers. The orr mechanism is depicted in Fig. 1a. The oxygen molecule adsorbs reversibly (k_1, k_2) on the supporting area by electrochemical or chemical reaction, where it may be partially reduced to hydrogen peroxide (k_i), or diffuse towards a catalyst center for complete reduction.

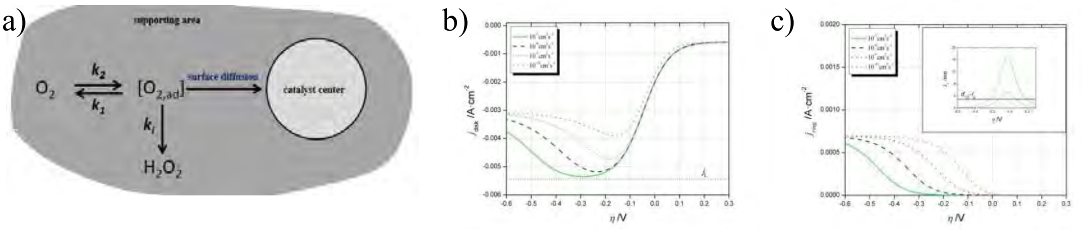

Fig. 1. a) Scheme of the orr mechanism mediated by surface diffusion. b) Disk current and c) ring current densities for orr on a dispersion of catalyst centers, under surface diffusion limitation, at four surface diffusivities. Inset in c: diffusion length as a function of overpotential (η). Overpotentials in b and c are referred to the electrosorption/desorption potential.

The model provides analytical expressions for the currents at a rotating ring-disk electrode, including disk (Fig. 1b) and ring (Fig. 1c) current densities as a function of surface diffusivity and parameters of the catalyst dispersion. Surface diffusivity is characterized by a diffusion length (λ_s), which depends on reactivity and overpotential (Fig. 1c, inset). The disk current may show a slope at high overpotential and/or a peak when maximal surface diffusivity is attained (Fig. 1b). Low surface diffusivity increases hydrogen peroxide reaction probability as observed in the ring (Fig. 1c). The analytical model shows how the efficiency of an electrode improves by increasing the surface diffusivity over supporting areas, which has high technological interest in the search for low catalyst loading electrodes.

Photoelectrochemical (PEC) water splitting is considered as one of the most promising technologies in clean and renewable energy production. Numerous semiconductor materials have been intensively studied as photoelectrodes in PEC systems. Among them tungsten trioxide (WO_3) nanomaterials have received considerable attention due to the ability of capturing 12% of the solar illumination, band gap energy of around 2.5-2.7 eV, high crystallinity, moderate hole diffusion length, good chemical stability, low cost and low toxicity [1].

In this study, nanostructured layers of WO_3 on fluorine-doped tin oxide (FTO) substrate were formed by sol-gel method. Six different reductants were used to investigate their influence on photoelectrochemical activity and properties of WO_3 photoanodes. Peroxytungstic acid was synthesized using sodium tungstate (Na_2WO_4 x $2H_2O$), HCl and H_2O_2 as precursors and $(NH_4)_2C_2O_4$ as capping agent. Subsequently, methanol, ethanol, propanol, isopropanol, butanol or acetic acid was added separately as reductant, which slowly and controllably reduced peroxotungstates to form uniform and ordered $WO_3 \cdot H_2O$ films on FTO under soft water bath conditions at 85°C. After coating procedure, samples were annealed at 500 °C for 2 h with heating rate of 1°C/min to obtain a crystalline nanostructured WO_3 films and to remove residual carbon. The crystallographic structure of the calcined WO_3 films was characterized by X-ray diffraction (XRD) and photoelectrochemical behaviour of the samples was investigated by cyclic voltammetry (CV) (Fig. 1).

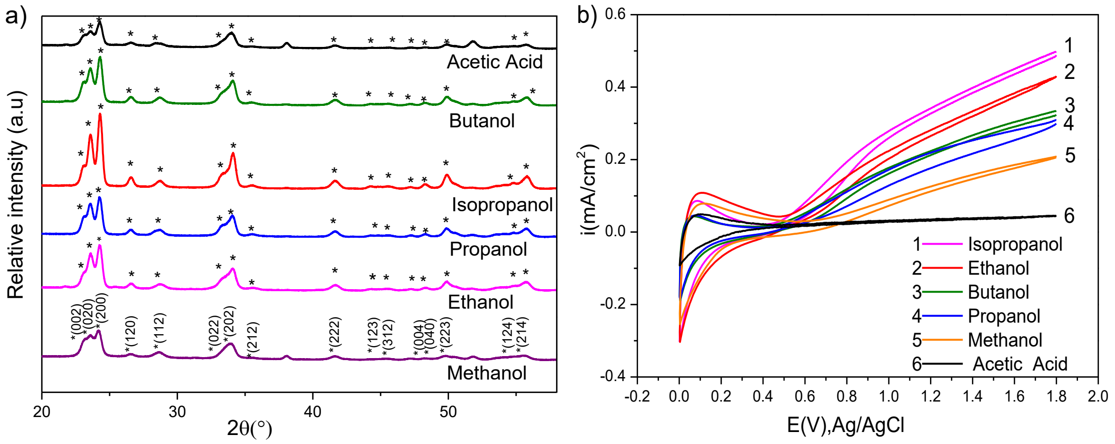

Fig. 1. a) XRD spectra of sol-gel derived WO_3 films formed using different reductants, b) cyclic voltammograms of the same films in 0.5 M H_2SO_4 solution, 50 mV s^{-1}, illumination P ~ 100 mW cm^{-2}

Fig.1a shows the XRD patterns of WO_3 samples formed using six different reductants. Films formed with isopropanol have the most intensive peaks in the whole range of 2θ which is attributed to the highest crystallinity. Cyclic voltammograms of FTO/WO_3 photoanodes recorded in 0.5 M H_2SO_4 under illumination represent typical response of WO_3. Using isopropanol as a reductant in the reported synthesis has been found to be the most effective route to increase the photoelectrochemical activity of WO_3 photoanodes, as these films showed the highest photocurrent density at 1.8 V (Fig. 1b). Photoelectrochemical activity of FTO/WO_3 electrodes prepared with six different reductants decreased in the following order: isopropanol > ethanol > butanol > propanol > methanol > acetic acid. Correlation between PEC activity and morphology, structure, phase composition of sol-gel derived WO_3 films will be discussed at the conference.

Interactions between Oligonucleotides and Daunorubicin, Doxorubicin and Their Formamidino Derivatives Studied by Voltammetric and Spectrometric Methods

Adriana Palińska-Saadi[1], Magdalena Łukasiewicz[2], Iva Marinović[1,2], Magdalena Maj-Żurawska[1,2]*

Anthracyclines, such as doxorubicin (DOX) and daunorubicin (DAU), are anticancer drugs widely applied in therapy because of their cytostatic and cytotoxic activity [1,2]. Although they are very useful in chemotherapy, they reveal high toxicity inducing i.e. cardiac effects, gastrointestinal and hepatic effects, as well as bone marrow suppression and secondary malignancies [3]. For these reasons, seeking novel compounds with better biological properties is extremely important.

A new group of anthracycline derivatives has been synthesized [4,5]. In obtained formamidino anthracycline derivatives, the $–NH_2$ group in the daunosamine moiety was replaced by the amidine group ($–N=CH–NR^1R^2$) containing the rest of cyclic secondary amine ($–NR^1R^2$), a rest of morpholine or hexamethyleneimine. The first part of our studies on novel derivatives of anthracyclines have shown that daunorubicin and its two formamidino derivatives interacts differently with DNA chains containing GC and AT base pairs [6]. However, we have broadened our researches including doxorubicin and its derivatives, as well as using other spectrometric methods.

The purpose of the presented work was to investigate the interactions of DAU, DOX and its formamidino derivatives with oligonucleotides using voltammetric and spectrometric methods. They were investigated by monitoring changes in the UV-Vis and the Circular Dichroism spectra of the anthracyclines interacting with oligonucleotides in the solution, as well as by monitoring the changes in redox properties of oligonucleotides interacting with anthracyclines on the surface of screen-printed graphite electrodes by square wave voltammetry (SWV).

Our observations point to changes in DNA conformation caused by its interactions with anthracyclines and to dependence of these interactions mainly on two factors: the DNA sequence and the detailed structure of the daunosamine moiety of anthracycline. The influence of these factors on the interactions is discussed.

constanzabuenog@outlook.com

Acid-base flow batteries (ABFBs) are receiving increasing attention due to their promising advantages for low-cost, utility-scale energy storage [1]. By using bipolar membranes in addition to cationic and anionic membranes, the concentration gradient across the key boundary can be increased, providing higher voltages than conventional reverse electrodialysis systems using concentrate and dilute water streams. During the charge process, water is dissociated into an acid and a base at the bipolar membrane. During discharge, a spontaneous neutralization takes place, generating electricity as a result of ionic transport processes. ABFBs use extremely low-cost and abundant reactants and the cell stacks have no bipolar electrodes (in contrast to redox flow batteries), but instead mesh separators and two monopolar electrodes [2]. ABFBs are closed systems, recirculating the electrolytes between their respective tanks and the stacks. As a result, the purity of the solutions can be guaranteed, eliminating problems such as 'up-hill transport' and biological fouling. The main challenges consist in the development of cost-effective membranes with very high selectivity in order to prevent capacity loss [3], and in the substitution of the inefficient water electrolysis taking place at the electrodes with the interconversion of fully reversible redox species.

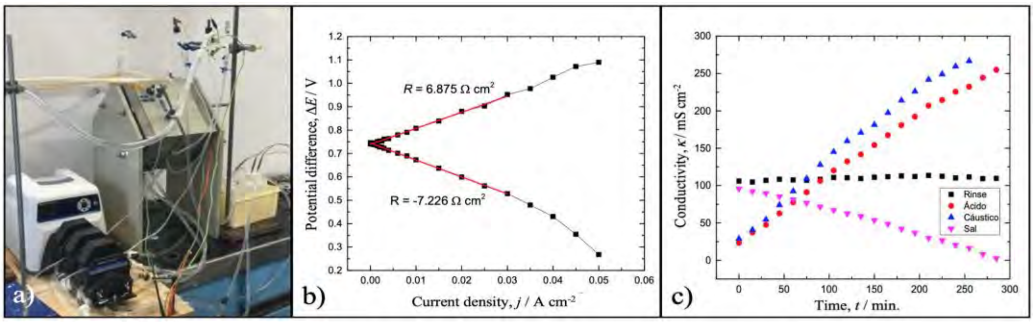

Figure 1. ABFB based on bipolar electrodialysis. a) Experimental arrangement with a 100 cm^2 cell and Luggin capillaries. b) Potential difference across an individual bipolar membrane during charge and discharge. c) Conductivity *vs.* time of the acid, alkaline, saline and *rinse* electrolytes during charge.

This work describes the advances made at the National Institute of Electricity and Clean Energy (INEEL) towards the development of ABFBs. As shown in Fig. 1a), an experimental arrangement with 5 L tank capacity per electrolyte controlled by a 30 A battery analyzer has been established for the study of individual membranes, unit cells and stacks. Performance and efficiency has been studied by OCP monitoring, polarization curves and by the measurement of conductivity and concentration of the electrolites during charge and discharge; see Fig. 1b). and Fig. 1c). Cross-over of ionic species and pressure drop over the mesh spacers have been also studied [4], with more advanced electrode and stack designs on the work.

Electrochemical flow cells provide a well-defined experimental environment for applied electrochemistry, given the possibility of controlling both current/potential distribution and mass transfer conditions [1]. Recently, innovative uses of these cells beyond the classical conversion of ions in solution have been proposed, involving novel design-optimization processes [2], and the electrodeposition of composite coatings in tailor-made flow cells [3]. Nickel coatings prepared by electrodeposition are of paramount importance in many technical applications. Given the two-phase composition of nickel baths for composite coatings and the need to achieve a high dispersion of particles, it is desirable to produce the coatings under reproducible hydrodynamic conditions and current/potential distributions [4].

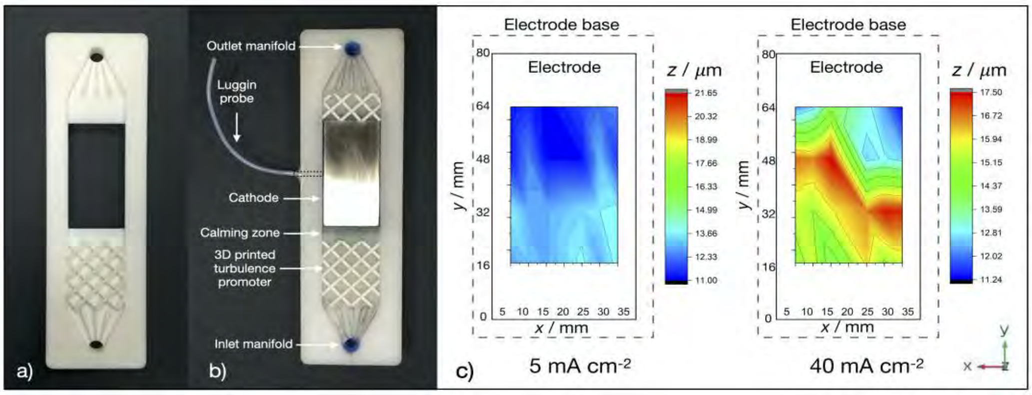

Fig. 1. Ni coatings produced on mild steel using a 3D-printed flow cell with a controlled hydrodynamic environment. a) 3D-printed frame and turbulence promoter. b) Components of the cathodic half-cell, showing a mild steel electrode. c) Coating thickness at the cathode surface for two current density values.

This work presents an analysis of the thickness uniformity of nickel coatings produced on mild steel substrates in a tailor-made flow cell by electrodeposition from a Watts bath. SEM images of cross-sectional samples of the coatings at different locations of the work pieces were collected and used to produce thickness maps. The results suggest that coatings prepared in this way can have a thickness variability below ±2 micrometres at relatively low current densities of 5 mA cm^{-2}. The coatings were less uniform at higher current densities of 40 mA cm^{-2}, displaying a variation of ±6 micrometres.

Manganese Dioxide Film for Supercapasitors

Giorgi Tsagareli, Shota Makhatadze, Marina Soselia and Nino Maisuradze

R.Agladze Institute of Inorganic Chemistry and Electrochemistry of the Iv.Javakhishvili Tbilisi State University, 11 Mindeli str. 0186, Tbilisi, Georgia)
Presenting author's email: gitsagareli@gmail.com

Manganese dioxide (MD) due to its electrochemical properties and availability is a promising material for use in supercapacitors (SC). There are many modifications of MD and not all of them have the necessary activity. As a modifying agent, we used iron to obtain a MD film with properties acceptable for SC. MD films on the platinum surface were obtained by the electrochemical method at room temperature from acidic solutions of manganese sulfate with the addition of Fe(II) or Fe(III). The addition of iron increased the film capacity, improved the shape of the cyclic voltammogram, and enhanced cycling stability. In order to elucidate the mechanism of iron incorporation into the MD film, the iron-free film obtained was anodically polarized in 0.5 M Na_2SO_4 at a potential of 1.2 V (all potentials were given vs silver chloride electrode). Then, Pt/MnO_2 electrode was kept in a solution containing only Mn(II), Fe(II), or Fe(III), and after washing in distilled water, the anode voltammogram was recorded in a solution of 0.5 M Na_2SO_4. When the electrode was preliminary kept in a Mn(II) solution and washed, an anode current peak was observed in the region of the electrodeposition potential of MD in 0.5 M Na_2SO_4 solution. We explained this behavior by the chemisorption of Mn(II) ions on the surface of MD:

$$MnO_2 + [Mn(H_2O)_6]^{2+} \rightarrow MnOOH[Mn(H_2O)_5OH]^{2+}_{ads.}$$

Afterwards, when the polarization curve was taken in Na_2SO_4 solution, the resulting particle was oxidized to MD. When the electrode was kept in a Fe(II) solution, a similar chemisorption of its ions on the surface of the MD occurred with the formation of Fe(III) and Mn(III). Therefore, the oxidation current of Mn(III) was observed on voltammogram, but the peak was less because less amount of Mn(III) was formed during the chemisorption of Fe(II). Keeping Pt/MnO_2 electrode in a Fe(III) solution did not lead to the formation of Mn(III), therefore, anodic peaks were not observed on the polarization curve. However, Fe(III) ions are adsorbed, without charge transfer, on the surface of the MD and thus pass into its structure. This conclusion is confirmed by the calculation of the current efficiency of the MD by the amount of consumed electricity for electrodeposition and the electrochemical dissolution of the films. The current efficiency of iron-free MD was 97%, doped with Fe(II) - 83%, and doped with Fe(III) - 110%. During the electrochemical dissolution of the film, part of the electricity was also spent on the reduction of Fe(III). Therefore, the current efficiency of the MD film exceeded 100%. The film capacity was calculated by the equation $C=I\Delta t/\Delta Vm$.

The best results were obtained by electrodeposition of a film in the presence of Fe(III). The capacity increased if the film was preliminarily polarized at a potential of 1.2 V in 0.5 M Na_2SO_4 and increased even more when it was then kept in a solution of 0.005 M $MnSO_4$. The specific capacity of a 70 nm thick MD film doped with Fe(III), preoxidized at a potential of 1.2 V in 0.5 M Na_2SO_4 and kept in a Mn(II) solution was 470 F/g.

martinj@ichf.edu.pl

Ion transfer has been explored directly for the detection of a large number of analytes but taking the technique out of the laboratory has been hampered by the mechanical sensitivity of the interface. A common approach to ensure a more stable organic-aqueous interface is also using gelled organic or aqueous phases, [1] but we recently showed that both phases can be stabilised in the cellulose matrix of paper [2].

Figure 1 Photo of the Electrochemical pen and paper device.

Here we combine a paper-stabilised aqueous phase with a gelled organic phase. The organic phase is held in a pen-like device comprising a glass-tube sealed with a porous plastic membrane in one end. Measurements are performed by pressing the pen against the paper. We demonstrate that the device functions as expectedly by measuring facilitated transfer of small inorganic ions. But we also show unique capabilities by "dip and pick" pre-concentration, where a sample is concentrated in the gel from several spots on the paper and then measured through stripping voltammetry.

Finally, we show that the EC pen can be used for electrochemical detection of proteins chromatographically separated in a paper-based flow channel. In this way we can get a direct electronic readout without the need for protein staining.

We envision that the concept of the electrochemical pen will move liquid-liquid analysis closer to practical application, where a sample can be spotted on paper or collected by swabbing and then measured using the pen device.

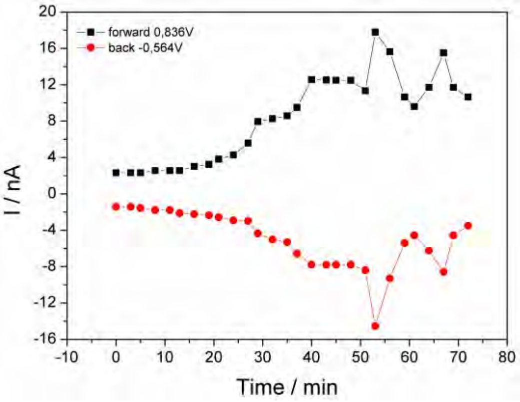

Figure 2. Electrochemical chromatogram. Dependence between the current and time plotted for chosen forward and backward sweep potentials for 5µl of Lysozyme and BSA mixture injected into the flow system.

Microbial Fuel Cell (MFC) belong to the larger category of bio-electrochemical systems (BES). MFCs oxidize organics on the anode and on the cathode an oxidant is reduced. Among several oxidants, oxygen is the most used due to the large availability in the atmosphere and it does have high reduction potential. Due to its sluggish kinetics and low concentrations of reagents, oxygen reduction reaction (ORR) is one of the main bottlenecks the system, therefore several investigations have been conducted in order to improve the performance.

At the cathode, in order to accelerate the reaction kinetics, a catalyst is used. Diverse biological, enzymatic and inorganic catalysts were adopted. Biological catalysts require high overpotential to operate. Enzymatic catalysts are very active but they are expensive and not durable in harsh environment. Inorganic catalysts are therefore the most used. This category can be divided in other three sub-categories: i) platinum group metal (PGM); ii) carbonaceous based; iii) platinum group metal-free (PGM-free) containing transition metal. PGM catalysts are expensive and are prone to get inactivated when in contact with pollutants. Carbonaceous based catalysts are cheap and durable but operates at high overpotentials. PGM-free composed by a transition metal (Fe, Co, Ni, Mn, etc) coordinated with nitrogen in pyridinic environment over a carbon backbone structure are the most promising.

In this work, the effect of pyrolysis process steps during the fabrication of Fe-N-C catalyst on: i) surface chemistry; ii) electrocatalytic activity towards ORR; iii) MFC performance were studied. Fe-N-C was synthesized using sacrificial support method (SSM) technique. The pyrolysis process followed six steps: 1) precursors mixing with silica; 2) first pyrolysis in reducing atmosphere (hydrogen rich); 3) ball milling of the obtained catalyst; 4) silica template etching using HF; 5) second pyrolysis in reducing atmosphere (ammonia rich); 6) ball milling.

The surface chemistry of the Fe-N-C catalyst varied after the high temperature processes and after the acid washing. The electrocatalytic activity was studied through rotating ring disk electrode (RRDE) experiment showing an improvement in the half wave potential and limiting current after each pyrolysis step. Performance in MFC were also evaluated. Particularly, power density was measured to be 167 ± 2 μWcm^{-2} when the catalyst subject to first pyrolysis was used. The power density increased after ball milling and silica etching measuring 181 ± 8 μWcm^{-2} and 185 ± 3 μWcm^{-2}, respectively. The second pyrolysis improved more importantly the power density produced, that was recorded to be 214 ± 5 μWcm^{-2}. The final ball-milling occurring after the second pyrolysis did not improved the performances that remained approximately stable at 212 ± 3 μWcm^{-2}. The change in catalyst surface chemistry was also related to the increase in ORR electrocatalytic activity and overall MFC performance.

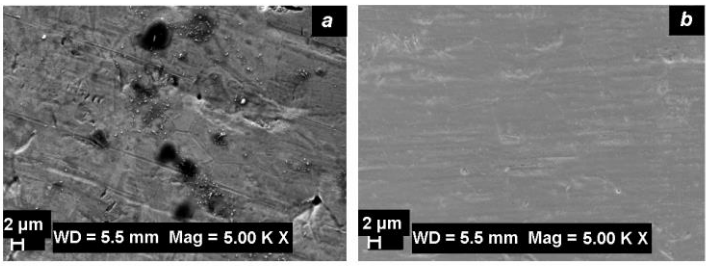
Titanium and its alloys are widely used to produce biomedical implant devices, since they combine high strength, inert behavior and low elastic modulus close to the bone elasticity, corrosion stability and good biocompatibility. However, commercial titanium and its alloys do not meet high requirements for biomaterials and medical equipment without preliminary special treatment of their surfaces (mechanical, chemical or electrochemical). The electrochemical surface treatment (electropolishing) is one of the most efficient methods of improving surface morphology and corrosion characteristics, but most common polishing electrolytes for the electropolishing of Ti and Ti-alloys are based on concentrated acidic solutions that often contain toxic additives, which create danger for the environment and human health.

In the present work, a deep eutectic solvent, Ethaline, was used as an environmentally friendly electrolyte for the electropolishing of Ti-based alloy (98.2% Ti, 0.30% Al and 1.50% C). Ethaline, a eutectic mixture of choline chloride (vitamin B4) and ethylene glycol, can be considered as a promising alternative to "conventional" electropolishing electrolytes. A unique combination of such properties of this deep eutectic solvent, as high viscosity and relatively high electrical conductivity, allows conducting electropolishing procedure under diffusion control, providing highly efficient surface leveling and improving corrosion resistance.

We established the optimal conditions for electropolishing of biomedical Ti-based alloy in deep eutectic solvent Ethaline as follows: the electropolishing potential of +3.0 V, the treatment duration of 30 min and the electrolyte temperature of 25 °C. It should be noted that the best results of electropolishing can be achieved by using Ethaline-based bath at ambient temperatures, where as common aqueous electropolishing electrolytes for the treatment of titanium require the use of either very high or very low temperatures. As shown in Figure, electropolishing in Ethaline contributes to a noticeable improvement in surface morphology. After electropolishing, the surface of Ti-based alloy samples exhibit the reduction in the amount of surface defects that are dissolved during anodic processing. The results of AFM analysis showed that a decrease in the surface roughness by more than 30% is observed after electropolishing.



SEM images of unpolished (a) and electropolished (b) Ti-based alloy (electropolishing was carried out in Ethaline at E=3 V, τ=30 min, and t=25 °C).

The linear polarization measurements revealed that electropolishing in Ethaline affect not only surface appearance and surface roughness, but also corrosion resistance (in NaCl aqueous solution). Electropolished samples of Ti-based alloy showed an enhanced corrosion resistance as compared with unpolished ones. The results of EDS measurements demonstrated that improved corrosion resistance after electropolishing may be associated with changes in both the surface morphology and surface chemical composition of Ti-based alloy.

Thus, deep eutectic solvent Ethaline can be considered as an available, eco-friendly and cheap electrolyte for the high-efficient surface treatment of biomedical titanium alloys that allows improving their surface appearance, surface roughness, corrosion properties and wettability.

Development of Graphene-Based Supports for Direct Methanol Fuel Cells.

A. J. Sabejeje and N. A. Adebare
Department of Chemistry, University of the Western Cape, Bellville 7535, South Africa.
3872155@myuwc.ac.za

Palladium catalysts supported by graphene oxide, reduced graphene oxide, n-doped graphene oxide and reduced n-doped graphene oxide have been synthesized in this study. The graphene oxides and their reduced counterparts were obtained through modified hummer's method and thermal reduction using hydrazine hydrate, respectively. The catalysts were synthesized using modified polyol method. The structures were examined using Fourier Transform Infrared Spectroscopy (FTIR) and X-ray Diffraction (XRD) for the prepared supports and prepared catalysts respectively. The FTIR showed that the surface of the supports exhibit oxygen containing functional groups (carboxyl, nitrosyl and hydroxyl) which serve as the anchor sites for metal deposition while the XRD confirmed that the catalysts exhibit face-centered crystal structure. High Resolution Transmission Electron Microscopy (HR-TEM) image showed spherical and agglomerated Pd nanoparticles and narrow particle size distribution dispersed on the support materials. The particle size and crystalline size of the prepared electrocatalysts were determined using HR-TEM and XRD techniques. From HR-TEM, the particle sizes are in the range of 4.685nm to 6.860nm while the crystalline sizes from XRD ranged from 3.286nm to 6.568nm. The surface areas of the supports were analyzed using Brunauer-Emmett-Teller (BET) Technique. Reduced graphene oxide (rGO) showed the highest surface area compared to other supporting materials. Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) was used to estimate the Pd metal loading for the prepared electrocatalysts and it was observed to be closest to that of Vulcan XC-72. Cyclic voltammograms showed Pd/rGO to be the most electroactive due to its higher electroactive surface areas than other catalysts. Furthermore, chronoamperometry and electrochemical impedance spectroscopy showed that catalyst supported on rGO proved to be most stable with highest kinetic rate compared to other supported catalysts examined. Hence, rGO has been proven in this study to be the best material for supporting electrocatalyst for direct methanol fuel cells.

Keywords: graphene oxide, reduced graphene oxide, n-doped graphene oxide, reduced n-doped graphene oxide, palladium catalyst, methanol oxidation, direct methanol fuel cell.

A Flexible Approach to Parameter Estimation of Physics-Based Battery Models with Bayesian Optimization

Yannick Kuhn, Birger Horstmann, Arnulf Latz
Helmholtz Institute Ulm, German Aerospace Center, University of Ulm
Helmholtzstraße 11, 89081 Ulm, Germany
Yannick.Kuhn@dlr.de

A wealth of measurement techniques are available for determining transport or thermodynamic properties of batteries. Some examples are GITT [1], pulse experiments [2] or least squares with impedance spectroscopy [3], which are excellent at automatically retrieving a subset of model parameters with relatively low computational cost. They achieve this at the cost of accuracy and compatibility, since each employs a different approximation in order to obtain analytic expressions.

So it remains a challenge to study the interactions and effects of multiple model parameters at once, since various measurement techniques would need to be combined into one so-called cost functional. This cost functional is a function of the measurement data and the battery model parameters and can be used to determine the parameters that best describe the data. The automated computation for this usually leverages the derivative/gradient of the cost functional by the parameters. Beyond some degree of complexity, this gradient would become intractable or unfeasible to analytically calculate, making the computation expensive and/or numerically unstable.

We want to eliminate the need for those gradients. The goal is to enable automated material screening with flexible selection of various measurements. Our approach uses the existing specialized techniques (e.g. [1-3]) as a starting point and refines their results by performing simulations with randomized parameters and comparing them with all available measurements. This Monte Carlo approach is made computationally feasible by utilizing Bayesian Optimization for sparse sampling and preprocessing the measurements into intuitive features. The latter also enables us to use measurements that are most often fitted by hand, e.g. discharge curves. Additionally, we make use of a single particle model with electrolyte from [4] and/or PyBaMM [5] to make the simulations as efficient as possible, but any 1D+1D model can be used thanks to the sparse sampling approach.

In developing countries, stainless steel is still a material that is employed for the fabrication of permanent implants as fixation plates and hip prosthesis. The aim of these implants is to replace the lost mechanical function of the damaged hard tissue, and to generate a bond with the existing bone to avoid movement and loosening. The main disadvantage of stainless steel is regarding its corrosion behaviour and the release of potentially toxic ions to the surrounding tissues when implanted [1], [2]. Besides, stainless steel does not present bioactivity and it does not exhibit any antibacterial behaviour [3]. In this context a challenge to improve the material appears: to modify the surface implant to improve the osseointegration process when cement-less implants are used to improve bone fixation and stabilization together with the searching for antibacterial properties of the material to be implanted. Since corrosion is a surface phenomenon, the implant surface and its engineering, play a key role in the performance in service of the implant.

In this work, stainless steel plane samples were coated with a hybrid organic inorganic silica based layer made by sol-gel method. The system consists in a two- layer coating of tetraethylorthosilicate, (TEOS) and methyl trimethoxysilane (MTMS). The first layer is a protective one, and the second is a functionalized one: this is achieved by the incorporation of silicate (13-93) and borosilicate (BS) glasses as a bioactive phase. Also a copper-borosilicate (BS-Cu) glass was used as an attempt of giving antibacterial properties to the surface as well as bioactivity. Surface behavior and corrosion resistance of the generated systems were analyzed by roughness measurements, adhesion of the coatings, FTIR, SEM and corrosion tests in simulate body fluid solution at 37 °C. Also antibacterial behavior was evaluated.

All coatings with the addition of silicate and borosilicate glasses showed bioactivity after 14 days of immersion in SBF. Also 13-93 glass presented the faster rate of dissolution, generating pits or holes in the coatings surface.The coatings presented a good electrochemical response, with high breaking potential and lower current density than the bare material. Although the dissolution rate of the BS-Cu and BS particles was high, the coatings presented excellent corrosion resistance.

Iron(II) 2,3,9,10,16,17,23,24-octa(cyano)phthalocyanine (OCNFePc), was tested as a catalyst for the oxygen reduction reaction (ORR) adsorbed on carbon nanotubes. The composite was analyzed spectroscopically and electrochemically characterized at pH 13 and pH 1. The composite showed close to 4 electron processes at pH 13. Computational analysis indicates that the O_2 molecule binds end-on to the metal center and that the dioxygen molecule is dissociated on both the Fe metal center and the corral ring. An Analysis of the molecular electrostatic potential confirms the behavior of cyano residues as electron-withdrawing moieties in OCNFePc. As a result of its catalytic behavior and theoretical analysis of its O_2 binding energy, OCNFePc was placed in a high position on a volcano correlation of similar phthalocyanine composites.

Effect of Thioabiraterone and Thioabiraterone-Modified Nanoparticles on Hepatocytes or Human Prostate Epithelial Cells

Gold nanoparticles (AuNPs) conjugated with drugs are used in diagnostics and therapies [1-4]. For many years research has been carried out to form efficient drug carriers. We present novel modification of gold nanoparticles: AuNP conjugated with thioabiraterone (AuNP-S-AB) (Fig. 1). The synthesis of AuNP-S-AB and new analytical procedures are described based on the application of UV-Vis, TEM, IR, NMR and TGA. Our synthetic approach involves ligand exchange of citrates to thioabiraterone on gold nanoparticles and shows that citrate anions preadsorbed on AuNPs can be readily displaced by thioabiraterone. The biological part of the work is done on hepatocytes or human prostate epithelial cells and proved that newly synthesized thiol derivatives of abiraterone, as well as AuNP-S-AB, are more biocompatible than the original abiraterone. Biological studies have established a safe concentration of AuNP-S-AB (IC_{50}) for the vital cell functions, up to 25 μM of AuNP-S-AB can be safely used in the therapy. The idea of delivering abiraterone in the form of AuNP-S-AB is hence a promising candidate for the application in cancer therapies.

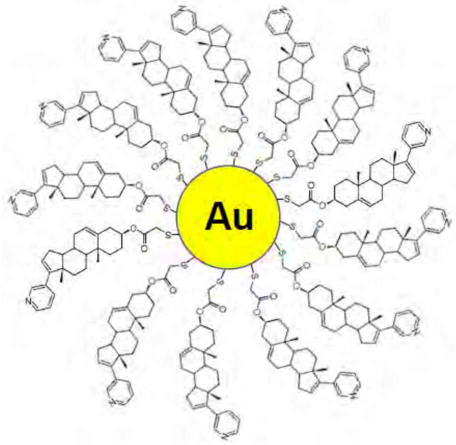

Fig. 1 Scheme of AuNP-S-AB

Pt surfaces modified with non-noble metal hydroxide clusters have been examined: the Pt surfaces offer optimal hydrogen adsorption energy, whereas the non-noble metal hydroxides support water dissociation.[1] According to the Bronsted-Evans-Polanyi principle, the ability of a catalyst to dissociate water is correlated with the OH-adsorption energy. On the other hand, a too strong OH-adsorption is undoubtedly counter-productive, as the active sites get blocked. As the state-of-the-art, Pt surfaces modified with Ni-hydroxide clusters showed the best HER activity. The current understanding of the origin of such high activity is that the hydroxides facilitate water dissociation, while at the same time Pt promotes H_2 generation. Moreover, various studies on the Ni-Fe hydroxides, which are among the best catalysts for the oxygen evolution reaction (OER), proved that the addition of iron to the Ni-hydroxide films can improve their conductivity by more than 30 times.[2] It was further shown by X-ray absorption spectroscopy and coulometric titration that the addition of iron can in general increase the oxidation state of Ni atoms in the vicinity of Fe,[3] which implies an improved water dissociation ability due to the increased OH binding energy[4]. Herein, we demonstrate an easy way to improve the hydrogen evolution reaction activity of Pt electrodes in alkaline media by introducing Ni-Fe hydroxide clusters to their surfaces. As a result, the overpotential needed to achieve the current density of 10 mA cm^{-2} in 0.1 M KOH is reduced down to ~70 mV. To the best of our knowledge, these modified electrodes outperform any other reported electrocatalysts tested under similar conditions. Moreover, the influence of (i) Ni to Fe ratio, (ii) cluster coverage, and (iii) the nature of the alkali metal cations present in the electrolyte on the resulting electrocatalytic activity has been investigated. The observed catalytic performance likely originates from both the improved water dissociation at the NiFe-clusters and the subsequent optimal hydrogen adsorption and recombination at Pt atoms present at the NiFe/Pt boundary.[5]

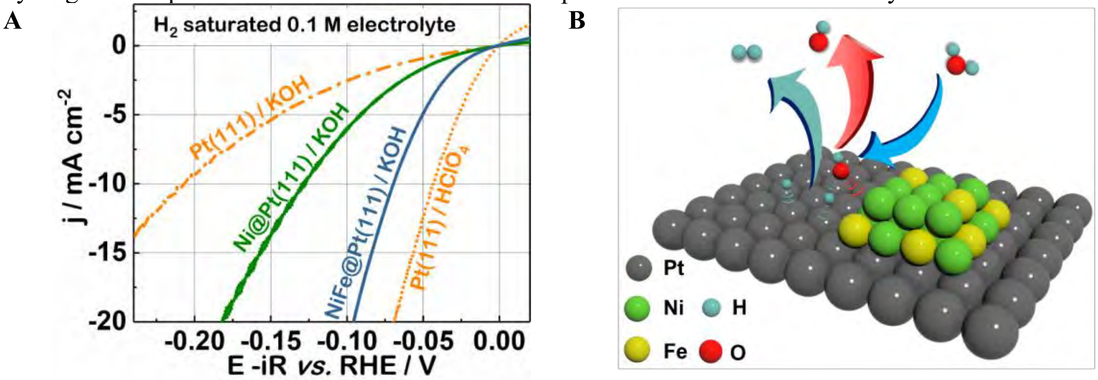

Figure. (A) Typical polarization curves of Pt(111), Ni@Pt(111), and NiFe@Pt(111) recorded in H_2 saturated 0.1 M KOH aqueous electrolytes at a scan rate of 50 mV s^{-1} and a rotational speed of 1600 rpm. (B) Proposed mechanism of HER on NiFe@Pt(111) electrodes in alkaline media.

Nucleic acids are the biompolymers which carry genetic information for protein production essential to all known forms of life. Deoxyribonucleic acids (DNA) are promising subjects for a point-of-need testing as markers of environmental contamination or human deseases. In a search for robust, portable, and sensitive DNA detection systems for *in situ* applications, the development of electrochemical sensing principles for nucleic acids is of high interest [1].

DNA are known to be electoactive through their nitrogenous bases: guanine, adenine, cytosine, and thymine [2, 3]. However, the direct electrochemistry of DNA characterizes by high oxidation/reduction potentials and low values of registered currents. Guanine possessing the lowest electrooxidation potential among nucleobases oxidizes at 0.6–0.8 V (*vs.* Ag/AgCl) [2]. Electroreduction of nucleobases takes place at the potentials over –1.5 V [3]. The signals of DNA are severely affected by the molecular weight of biopolymer [4] and the formation of double helix – nucleobases linked together by hydrogen bonds inside the DNA double helix become hardly accessible for electrode reactions [1]. To overcome this problem, we are suggesting a novel strategy for detection of double stranded DNA (dsDNA) through the tyrosine (Tyr) oxidation. As it was shown previously, there is an intercalative interaction between tyrosine and dsDNA with the binding constant of 4×10^3 mol^{-1} L [5].

In this work, oxidation of free Tyr in the presence of native DNA and Zn(II) ions was studied by square wave voltammetry on carbon screen printed electrodes. The addition of DNA to the Tyr or Tyr + Zn(II) samples induced the significant decrease of the oxidation signal at 0.6 V, especially in the presence of Zn(II) ions. The calibration curves in coordinates 'I_p (Tyr), μA – lg(c(DNA), M)' were linear from 2 to 500 μM of herring sperm DNA with different slopes in the absence and in the presents of Zn(II) ions. At the same time, direct electrochemical detection of the DNA through the oxidation of guanine residue (Gua) at the potential of about 0.8 V gave a linear calibration curve in coordinates 'I_p (Gua), μA – c(DNA), M' from 10 to 500 μM. Other amino acids tested, namely cysteine (Cys) and tryptophan (Trp), which electrochemical oxidation occurs in the same potential range as Tyr (0.5–0.7 V), demonstrated no pronounced effect of DNA on their signals both in the absence and the presence of Zn(II) ions. The oxidation signals of Cys or Trp just slightly decreased and shifted to more positive potentials in the presence of DNA. Interesting, that these amino acids demonstrated unequal responses to addition of Zn(II) ions (DNA free controls): oxidation peaks of Tyr and Trp decreased, while the signal of Cys became more developed. To detect DNA, instead of Tyr, well-known redox indicator $K_3Fe(CN)_6$ was studied as well, but found less sensitive to the presence of DNA than free Tyr. Finally, two possible mechanisms of registered decrease of Tyr oxidation peak may be suggested: (i) a formation of the complex between Tyr, DNA, and Zn(II) ions; (ii) the blockage of Tyr oxidation by the DNA adsorption on electrode surface, enhanced by Zn(II) ions.

The detection of nucleic acids – macromolecules that store genetic information and enable protein production – is of a great interest for fundamental and applied biochemical studies. Nuclec acids are promising subjects for a point-of-use testing as markers of environmental bacterial and viral contaminations or human deseases. Deoxyribonucleic acids (DNA) are known to be electoactive through their nitrogenous bases: guanine, adenine, cytosine, and thymine [1]. However, the direct electrochemistry of nucleic acids suffers from high oxidation/reduction potentials and low values of registered currents. Guanine possessing the lowest electrooxidation potential among nucleobases oxidizes at 0.6–0.8 V (*vs.* Ag/AgCl), while 2'-deoxyguanosine-5'-triphosphate (dGTP) oxidizes at 0.9–1.0 V [1]. The oxidation current is strongly affected by the length of a nucleic acid strand [2] and the formation of double helix – nucleobases linked together by hydrogen bonds inside the helix become hardly accessible for electrode reactions [1]. To overcome these problems, an exciting strategy of electrochemical sensing of nucleic acids has been suggested by M. Hocek and M. Fojta with coworkers [3]. They inserted a palette of electrochemically active moieties into nucleic acid sequences by polymerase incorporation of chemically modified nucleotides.

In this work, we present a set of 2'-deoxyuridine-5'-triphosphates (dUTP) modified with amino acid side chains attached through a linker at the C5 position of the pyrimidine ring which can be introduced into double stranded DNA (dsDNA) by polymerase chain reaction (PCR) [4, 5]. The modified nucleotides and corresponding PCR products were studied by square wave voltammetry on carbon screen printed electrodes suitable for *in situ* analysis. A strong effect of all additional functional groups on the electrochemical behavior of dUTP was revealed. Compared to the 2′-deoxythymidine-5′-triphosphate (a natural substrate for DNA polymerases), oxidation of dUTP derivatives took place at less positive potentials. In particular, 5-aminoallyl-dUTP derivatives modified with indole acetic, indole-3-propionic, indole-4-butyric, or 4-hydroxyphenylacetic acids demonstrated well-defined oxidation peaks at 0.5–0.7 V, similar to tryptophan and tyrosine amino acids, respectively. These signals were about 0.2–0.3 V less positive than the oxidation potential of dGTP. Moreover, PCR-generated dsDNA fragments (amplicons) with modified nucleotides showed novel oxidation signals at micromolar concentrations, while no peak was observed for unmodified dsDNA at the same conditions. Therefore, the tested dUTP derivatives well complement the existing collection of electroactive 'labeled' nucleotides for direct electrochemical detection of nucleic acids. The main advantage of the developed dUTP is a good compatibility of amino acid side chains with polymerase enzymes including those used in PCR.

Forensic electrochemistry: A voltammetric screening method to identify selected synthetic cannabinoids

Anaam Ameen, Lynn Dennany
Dept. of Pure and Applied Chemistry, Centre for Forensic Science, Technology and Innovation Centre,
University of Strathclyde, 99 George Street, Glasgow, G1 1RD, UK
anaam-r-m-rameen.2017@strath.ac.uk

At present, numerous synthetic cannabinoid (SC) products are emerged and available for sale online as well as off-line with a variety of street names 'spice' and K2, and in the form of herbal incense. It is extremely important to identify these SC which are described as new psychoactive substances (NPS) presented in the herbal mixtures, to control the health, regulatory and legal risk associated with the production, sale and consumption of these products.[1] These illicit drugs can result in binding cannabinoids receptors CB1, and CB2 relatively with higher empathy and effectiveness of 100 times stronger compared to natural cannabis marijuana Δ^9-tetrahydrocannabinol (Δ^9THC).[2] Forensic scientist finds it challenging to identify SC in biological and street samples. Although gas chromatography-mass spectrometry (GC-MS) is considered as a gold standard in forensic field specifically for the identification and quantification of SC. However, it is a bulky, expensive and laboratory-based instrument. In addition, these compounds do not have screening methods such as presumptive test that can be used. [3] Thus, there is a need for new portable screening tools to detect these NPS with no conventional drug screening methods available to fulfil this task and thus, require developing a necessary on-site screening tool for NPS detection that can be utilised for street and toxicological samples. Currently, electrochemical techniques have shown promising results for the detection of 5F-ADB-PINACA and STS-135 which are indazole and indole derivatives of SC. Initial results for the detection of SC are explored here. Differential pulse voltammetry (DPV) provides excellent sensitivity with limits of detection of 0.3 nM and 0.5 pM of indazole and indole-base respectively. Practical responses to the challenges such as the availability of reference standards and validation methods cannot match the increase in varieties of NPS reported by laboratories.[4] A rapid and a non-destructive analytical method is needed in forensic drug and toxicological analysis and this works highlights the promise of electrochemical sensors to address this gap.

Feasibility of demand response in the chemical industry

N. Milojević, R. Schomäcker
Technische Universität Berlin,
Department of Chemistry, Strasse des 17. Juni 124, D-10623 Berlin
natasa.milojevic@campus.tu-berlin.de

Abstract

In the field of power generation, the aim is to increase the part of renewable energy. This brings an increase in fluctuations in power supply, which leads to a higher need for adaptability, meaning more flexibility in production and consumption of electricity. Load changes in energy-intensive industries as seen in the chemical industry would be a way to provide this. In the joint project ChemEFlex the feasibility of demand response in various electrochemical processes of the chemical industry is analyzed. In this work, two processes with different levels of development were studied by evaluating suitable operating parameters and their tolerable limits. The commercialized process for the electrohydrodimerization of Acrylonitrile (ACN) to Adiponitrile (ADN) was the first case considered suitable for further studies:

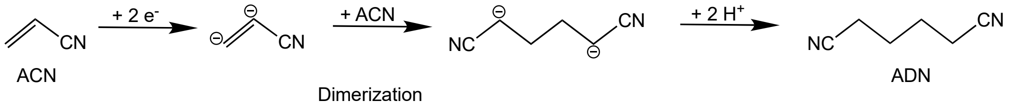

Fig. 1: Electrohydrodimerization of Acrylonitrile to Adiponitrile.

Adiponitrile is an intermediate in the production of Nylon. Worldwide the production rate of ADN is around 1,31 Mio. t/a, of which 300.000 t are made through cathodic hydrodimerization. This makes the so-called Monsanto-Process the most important electroorganical synthesis.

The second case is the piloted process of the electrohydrodimerization of Formaldehyde to Ethylene glycol.

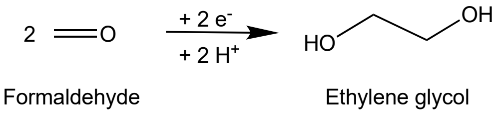

Fig. 2 : Electrohydrodimerization of Formaldehyde to Ethylene glycol.

Ethylene glycol nowadays is almost exclusively made from direct oxidation of Ethylene, followed by hydrolysis of Ethylene oxide. Even though this process has a poor selectivity and is high in energy consumption, the use of mineral oil results in a very low price. Still, with increasing prices for crude oil and the additional profit from the control energy market, the electrochemical process could be a good alternative.

Experimental section

Two experimental plants were built in a laboratory scale [1], [2] to test the application of demand-side management. The changes in selected parameters like aging of electrodes, product quality, etc. are documented and evaluated while various flexibility profiles (load changes in seconds or minutes, adapted to the requirements of the control energy market) were applied.

Experiments were carried out in Microflowcells by ElectroCell AB (Sweden). For the Monsanto-Process the effects on an undivided cell were studied, whereas for the synthesis of Ethylene glycol, a Nafion 324 membrane was used for separation.

lucia.alvarado@ugto.mx

The metals in aqueous state are substances commonly found in water from various processes, such as electroplating and mining, among others. Some of the metals found in this kind of effluents attract attention because they have an adverse effect on the environment and on health, such as substances as chromium, cadmium, arsenic and lead, mainly; this is why the discharges with the presence of these metals are regulated through environmental standards [1]. However, it is a fact, that there is a growing need to develop better methods for the removal of metals, and thus avoid a negative impact on the environment. In the particular case of chromium, it is known that it is an element used for decorative purposes and protection against corrosion and in its trivalent form it is necessary during the human metabolism. However, this element has the peculiarity that, being in a more oxidized state, Cr (VI) has characteristics that relate it to diseases such as cancer, being that this is one of the most stable states of chromium and very much used in the processes described above, as pigments industry [2].

In this sense among the methods that exist for the elimination of metal ions is the electrodialysis, which is an electrochemical technology that allows the separation of aqueous ions, releasing the effluent of these and allowing to recover the component in question [3, 4]. Therefore, the present work addresses a study of hexavalent chromium removal, from a synthetic solution of 100 ppm of Cr (VI) using an electrodialysis small cell, with electrodes of stainless steel and titanium mesh, of 30 cm^2 of effective area, seeking to have a free effluent of the metal. The results obtained showed an energy consumption of 1.14 kWh per m^3, with a total removal of the pollutant. The above shows the potential of the technique to be used with other types of ionic contaminants and be scaled and the obtaining of valuable sub products.

Galvanic Cell Operated with Hexavalent Chromium to Remove It

José Guadalupe Cruz Arellano, Guadalupe Vázquez Rodríguez, J. Carlos Baltazar Vera, Lucía Guadalupe Alvarado Montalvo
Department of Mining Engineering, Metallurgy and Geology, Engineering Division. University of Guanajuato.
Ex. Hda. San Matías s/n, Frac. San Javier, C. P. 36020, Guanajuato, Gto., Mex.
lucia.alvarado@ugto.mx

Hexavalent chromium is considerate a toxic compound to the human health [1], this is why, find new strategies to remove it become important. Traditional methods involve the use of chemicals to achieve the precipitation of this compound, which implies filtration systems and solids waste generation [2]. In other hand, some electrochemical methods to remove it have been showing efficiency: as electrochemical filtration [3] or electrodialysis; nevertheless, although the results are promising, ever that implies the use of an external potential application, which means an extra energy cost. This is a limiting, since that it mean that the use of this technologies are exclusively in places with access to electricity.

In this work, we proposing a system that does not need external potential, conversely, the system gives it. The main goal was the removal of hexavalent chromium from a synthetic solution, but without the use of an external electric field applied. For this, we use a membrane´s electrochemical cell, where by two compartments, of 30 cm^2 of effective area, separated by ion exchange membranes, synthetic solution of potassium dichromate were recirculated at 20 mL per min, and a third compartment with hydrogen peroxide were recirculated. We add a salt in one compartment to promote a chemical reaction in the electrodes compartments and so an electrical field between them and the pH were adjusted. After 22 hours of operation, the system removed 90% of the hexavalent chromium from one channel, and at the same time, energy was generated.

Simultaneous monitoring of the electrochemical behavior of both positive and negative carbon electrodes of electrochemical double layer capacitors in different electrolytes

Vedran Petrić[1], Zoran Mandić[1]
[1]*Faculty of Chemical Engineering and Technology, Department of Electrochemistry, University of Zagreb, Croatia*
Savska cesta 16, Zagreb, Croatia
vpetric@fkit.hr

Despite their high power and high energy contents comparing to other capacitor technologies, electrochemical double layer capacitors still suffer from several drawbacks which limit their widespread use. In order to boost their performance in the applications where batteries are currently used, the electrical and electrochemical properties, such as energy content, ohmic resistance and self-discharge rate, need to be improved.

The testing of supercapacitors is routinely done by electrochemical methods in two-electrode system. With such methods overall properties of supercapacitors are obtained. However, in order to make further improvements of supercapacitors properties, it is of key importance to separate the processes occurring at both electrodes during charging/discharging reactions. Such measurements would reveal electrodes of limiting capacitance, potential distribution through the supercapacitor as well as the occurrence of various resistances within different parts of the cell. The aim of this work was to simultaneously test the electrochemical properties of both electrodes of self-assembled supercapacitors in different electrolytes by inserting a Pt wire as a reference electrode inside the separator.

Supercapacitor carbon electrodes consisting of activated carbon (AC), carbon black (CB), and poly (vinylidene fluoride) (PVDF) as a binder, were made in the lab by mixing the aforementioned ingredients in the ratio of 80:10:10. The dry mixture were then dissolved in N-mehtyl pyrrolidone (NMP) to form a paste which were painted at to an aluminum current collector in the form of a thin film. After drying the film was cut into circular electrodes. The electrodes were then used in the construction of a supercapacitor with different electrolytes consisting of different tetraalkylammounium and lithium salts in an EL-CELL three electrode cell. The supercapacitor had a layered structure consisting of two electrodes on each side of a fiberglass separator. The reference electrode was Pt foil aligned to the side of the separator so that it was in contact with it but did not interfere with the charge flow between the electrodes.

Both DC and AC techniques have been used to determine the behavior and status of each electrode during the operation of the supercapacitor. Firstly, a large number of charge/discharge cycles were performed with “staircase” impedance measurements at regular charge/discharge intervals. The aim was to observe the changes of potential and the impedance response on each electrode during the initial “conditioning” of the supercapacitor. Secondly, the charge redistribution was monitored on each individual electrode by letting the supercapacitor rest when fully charged and also by keeping either electrode at a constant potential while observing the potential changes of the other electrode.

Significant differences between the responses of positive and negative electrodes of the supercapacitor were noticed, primarily in the discrepancy between the potential ranges of both electrodes during cycling in each electrolyte. Also it was observed that the negative electrode possesses higher resistance values in the impedance measurements.

Mathematical Modeling of Temperature Dependent Degradation of Supported Pt-based Electrocatalyst in Voltage Cycling Experiment

ambroz.kregar@fs.uni-lj.si

Hydrogen fuel cells, employing carbon-supported platinum-based materials to catalyze oxygen reduction reaction, represent one of the most promising technologies of future energy conversion. However, their wider adoption is currently limited due to the relatively fast degradation of the membrane electrode assembly during their operation, decreasing their performance and limiting their life-time.

To improve the understanding of degradation phenomena in the fuel cell catalyst, recently developed mechanistic model [1] of platinum particle degradation was used to describe the decrease in electrochemical surface area (ECSA) during accelerated stress tests on supported platinum based electrocatalysts in thin film rotating disc electrode setup. The model describes several degradation processes by mathematically modeling the rates of electrochemical phenomena, i.e. platinum and carbon surface oxidation and corrosion, which strongly depend on the local electric potential and temperature according to Arrhenius law. The dissolution of platinum from smaller particles and its redeposition on larger particles, the so-called Ostwald ripening, leads to the net growth of platinum particles and consequent decrease of ECSA [2], while the corrosion of carbon support results in detachment of particles and their eventual agglomeration into larger clusters, again causing the loss of ECSA. Both of these phenomena are described by mathematical modeling of platinum particle size redistribution resulting from aforementioned electrochemical processes.

The model is calibrated based on the changes in ECSA of Pt/C catalyst from Tanaka Kikinzoku Kogyo (TEC10E50E) with 46.3 wt% of Pt on high surface area carbon during long-term accelerated stress test. Changes in ECSA were measured by cycling voltammetry several times during aging at various temperatures (RT, 40, 50 and 60 °C) and using two different potential windows (0.4 - 1.2 V and 0.8 - 1.2 V) for voltage cycling [3]. As shown in Figure 1, the model is capable of describing the change of ECSA for all six experiments using the same set calibration parameters, proving its merit in mechanistically describing all relevant processes of catalyst degradation. The results indicate strong effect of temperature on the rate of degradation. According to the model, low ECSA loss, detected at voltage cycling at high potential window (0.8 - 1.2 V) is attributed to the high coverage of platinum surface with oxides, reducing the rate of Ostwald ripening, and lower rate of carbon corrosion, emerging from complex dynamic interplay between surface oxide groups on platinum and carbon surface.

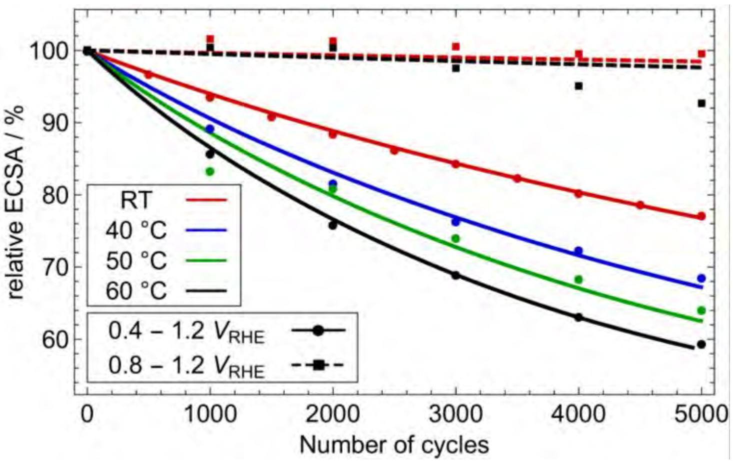

Figure 1: Comparison between measured (points) and modelled (lines) change in ECSA during voltage cycling experiment at different potential windows and temperatures.

Gouy-Chapman versus Reality:
An Interpretation of Diffuse Capacitances using Mean-Field Methods

Katharina Doblhoff-Dier
Leiden University, Netherlands
PO Box 9500, 2300 RA Leiden, The Netherlands
k.doblhoff-dier@lic.leidenuniv.nl

The capacitance of the electric double layer is often described via the Gouy-Chapman-Stern equation as that of two capacitances in series $1/C_s=1/C_H+1/C_{GC}$, where C_H is expected to be independent of ion concentration and C_{GC} can easily be derived from thermodynamic principles for non-interacting point like particles. For concentrated electrolytes, deviations from this theory are expected and have been shown. Dilute electrolytes, on the other hand, are generally expected to follow this Gouy-Chapman-Stern behavior. In recent experiments, however, Ojha, Koper et al. [Angew. Chem. Int. Ed. 2020, 59, 711] have shown that a deviation from the Gouy-Chapman behavior can also be observed in dilute electrolytes.

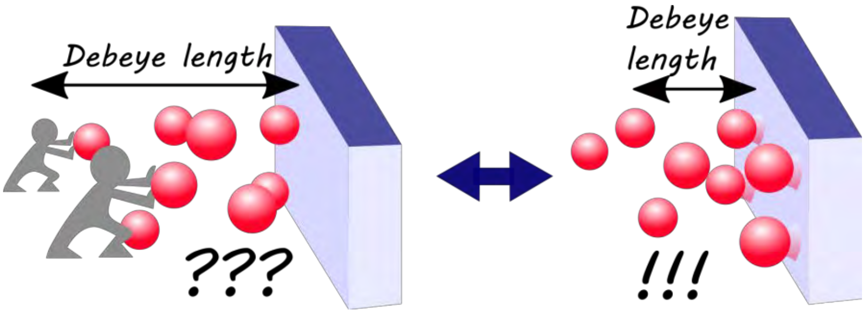

Figure 1: Experimentally, shorter screening lengths than expected are observed on Pt and Au. Our mean-field model can explain this somewhat unexpected behavior by ion adsorption.

While the ideal behavior is observed for Hg and while for all metal electrodes studied the screening length is suggested to scale with 1/√c, the inverse root of the ion density, as predicted by the Gouy-Chapman theory, the overall magnitude of the screening length seems to be considerably reduced on gold and platinum (i.e., $C_{diffuse}=\alpha C_{GC}$).

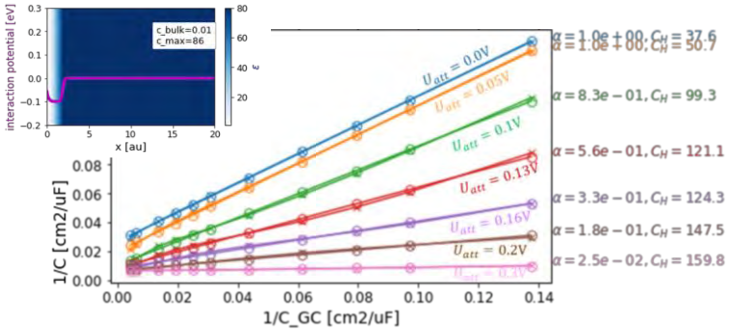

Figure 2: Results of mean field simulations for different ion adsorption strengths (crosses); circles: fit to $1/C_H+1/(\alpha\ C_{GC})$. A value of α smaller than 1 suggests a reduced effective screening length. The inset schematically shows the model used in a generalized Poisson-Boltzmann approach.

We show that such an increased screening length can be captured in mean-field theories when taking ion adsorption close to the interface into account. Extremely simple, analytical models can be used to capture this effect in idealized situations, but would lead to a non-linear scaling of the screening length with 1/√c in contradiction to experiment. Using a mean-field, modified Poisson-Boltzmann description, however, we can qualitatively reproduce the experimental data, giving a tentative interpretation to the experimental observations. Interestingly, we only observe a behavior similar to that found experimentally if ions can adsorb in regions of strongly reduced dielectric constant as shown schematically in the inset of Fig. 2, thus providing additional information on the atomic-scale behavior of the interface.

New Strategies for the Evaluation of the Anti-tumor Effect of Some Drugs using Electrochemical Techniques

Mihaela Tertiş, Iulia Rus, Bianca Melean, Robert Săndulescu and Cecilia Cristea
Analytical Chemistry Department, Faculty of Pharmacy, Iuliu Haţieganu University of Medicine and Pharmacy
4 Louis Pasteur Street, 400349 Cluj-Napoca, Romania
mihaela.tertis@umfcluj.ro

Doxorubicin is an antitumor drug from the group of anthracyclines widely used in the treatment of various malignancies like breast and bladder cancer, Kaposi sarcoma, Hodgkin and non-Hodgkin lymphoma, acute lymphoblastic and acute myeloid leukemia. It can be found on the market in different formulations, starting from lyophilized powder for injection to liposomal doxorubicin and other types of delivery systems in which it can be incorporated alone or in combination with other molecules (1).

Simvastatin is an inhibitor of HMG-CoA reductase, the most important enzyme from the process of cholesterol biosynthesis. It is use in the treatment of hypercholesterolemia to reduce serum levels of cholesterol and therefore to reduce the risk of cardiovascular diseases. There are several studies in the literature which demonstrated the decrease of cellular proliferation in the presence of high dose simvastatin and that this molecule potentiates the cytotoxic activity of antitumor drugs. Therefore, various types of drug delivery systems containing both antitumor drug and statin started to be investigated for the improvement of cancer therapy (2).

The aim of this study was to develop a disposable, simple, fast and sensitive sensor for the simultaneous electrochemical detection of doxorubicin and simvastatin, which could be used in preclinical studies of the development of a new pharmaceutical formulation for drug delivery. Firstly, the electrochemical behavior of each molecule was analyzed regarding the influence of electrode material, electrolyte solution and scan rate. After this, the proper electrode material, electrolyte solution and scan rate for both medicines were chosen and a LSV (Linear Sweep Voltammetry) procedure was optimized for the simultaneous detection. In the same time, two chronoamperometry procedures were tested, one for the detection of doxorubicin in the presence of simvastatin, and the other one for the detection of doxorubicin and simvastatin together. Finally, calibration curves for doxorubicin and simvastatin in the presence of each other were obtained using both electrochemical methods and the results obtained were compared.

This detection strategy represent a promising tool in the development of a new pharmaceutical formulation for targeted drug delivery containing both drugs, whose association was proved to bring benefits in the treatment of cancer.

State of Health Identification of Lithium-ion Battery by Advanced Instantaneous EIS

Xinhua Zhu, Benny Wouters, Raf Claessens, Annick Hubin
Research Group Electrochemical and Surface Engineering, Department Materials and Chemistry
Vrije Universiteit Brussel, Pleinlaan 2, 1050 Brussels, Belgium
Xinhua.Zhu@vub.be

Electrochemical impedance spectroscopy (EIS) is the most popular non-destructive method for lithium ion batteries (LIBs) diagnosis and materials characterization. Generally, EIS is operated on a non-operational steady state of the battery system in order to satisfy the basic principles of EIS measurements, i.e., causality, linearity and stationarity [1]. In this work, EIS characterizations of LIB systems in a non-steady state or an operando condition are explored by using the in-house developed multisine technique (including both hardware and software): Odd Random Phase EIS (ORP-EIS) [2] with the time-resolved instantaneous impedance calculation [3]. This approach provides mechanistic insights into the dynamic interfacial properties of LIB systems and, therefore, can be applied for the online monitoring of battery conditions. Moreover, the in-house designed hardware is potentiostat-free setup, which shows potential to be integrated in battery management system (BMS).

This work is based on the state-of-the-art $LiNi_{0.80}Co_{0.15}Al_{0.05}O_2$ (NCA) cathode material, and ORP-EIS experiments are operated in the galvanostatic mode. In the non-steady state experiment, the ORP-EIS is measured directly after charging or discharging pulses. The time-resolved impedance spectra during the relaxation period can be calculated as shown in Figure 1. The charge-transfer resistance (R_{ct}), the dominant impedance response in the low frequency region (< 10 Hz), changes with the relaxation time. The phenomena can be correlated to the alternation of ionic concentration in the interfacial vicinity. Cycling aged NCA electrode materials are measured with the identical approach. A more significant evolution of the R_{ct} during the same period of relaxation time is observed, indicating a deteriorated interfacial microstructure of NCA electrodes. This ΔR_{ct} could work as a stand-alone SoH identification parameter, which is dependent only on the interfacial condition of electrode materials.

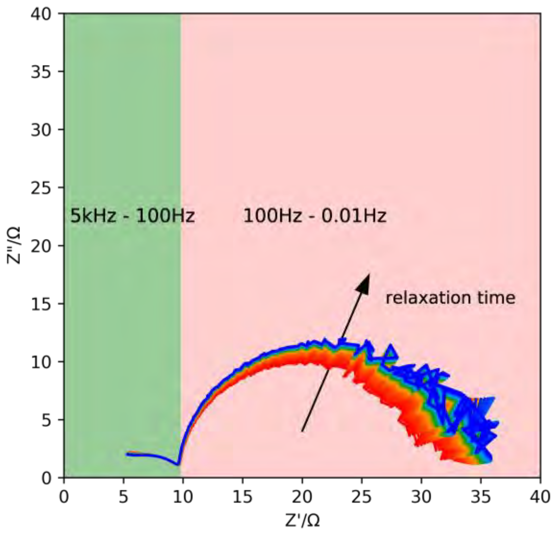

Fig.1. Nyquist plot of the time-resolved instantaneous impedance of an NCA/lithium cell during the relaxation period after the charging pulse.

Paper-based electrochemical biosensors are able to provide diagnostics and immediate health information near the patient [1]. Ideally, these point of care devices could be used by the patient with no need for laboratory instruments or trained specialists, allowing patients to self-diagnose and self-care monitoring from their own homes, enhancing their quality of life and decongesting the overloaded healthcare system. However, these devices generally require external power sources or expensive readout units [2, 3]. A new paradigm of autonomous, sustainable and cost effective, single use electrochemical biosensors is needed. One of the main difficulties in the fabrication of an autonomous sensor is the development of transducers to effectively convert the electrochemical response to a user recognizable signal without using complex electronics or sophisticated equipment.

In this work, a cost-effective, fully printable, stand-alone glucose-sensing system has been developed with an enzymatic fuel cell as the only power source and with no need for an external readout unit. A novel and simple approach to transduce the electrochemical signal from an enzymatic fuel cell into a digitalized response. A self-powered single use device for the diagnosis of gestational diabetes mellitus has been designed, fabricated and tested. The self-powered device consists of: i) an enzymatic fuel cell, which acts as both the glucose sensor and the energy source; ii) an electronic circuit, which transduces the biological response into an electrical response and ultimately into electrochromic displays that show the result; iii) and an electro-fluidic timer, which times the sequence of events and allow the connection of the different parts of the electronic circuit at specific times. The working principle of this electrochemical sensing device is based on the fuel cell response, while charging a capacitor. By monitoring the capacitor built-up voltage, the concentration of glucose can be determined. The device was able to determine whether the concentration of glucose in a sample was within healthy levels (< 140 mg/dl, 7.8 mmol/l), indicates pre-diabetes (≥ 7.8 mmol/l and < 11.1 mmol/l) or provisional diagnosis of diabetes (≥ 11.1 mmol/l) [4]. The results show reproducibility and selectivity, turning on the displays according to the glucose concentration.

This self-powered, autonomous glucose bio-sensing device offers an energy saving, environmentally friendly and low cost solution for the point-of-care testing systems. This approach is a conceptual pathway that can lead to instrument-free electrochemical biosensor design. It could potentially be used for the diagnosis of human diseases besides diabetes, by measuring concentrations of other health care parameters such as lactate, urea, ammonia, creatinine, cholesterol and uric acid. This measuring approach could dramatically contribute to the early detection and palliation of life threaten diseases in developed and developing world, in remote areas and emergency situations, since it does not need trained specialist, laboratory infrastructure or external power source.

Influence of carbon support modification on non-noble MNC catalyst for oxygen reduction reaction

M. Primbs, Y. Sun, M. Dalkilic, P. Schroeer, J. Schmidt, D. Bernsmeier, J. Huebner, A. Thomas, P. Strasser
Technical University Berlin
Strasse des 17. Juni 124 Berlin
mathias.primbs@tu-berlin.de

Metal nitrogen carbon catalysts (MNC) are a promising alternative for platinum based catalysts in the oxygen reduction reaction (ORR) in PEM fuel cells, but at the moment state of the art MNC catalyst still suffer from low activity and instability. Wang *et al.* showed the positive effect on catalyst activity, by using carbon supports as basis to depose and polymerize the precursors.[1] In this work we studied interactions of surface functionalization on the polymer deposition and their characterizations in regards to their activity.

The surface of two commercial carbon supports, Ketjenblack EC-600JD and MWCNT were functionalized by two methods: oxidizing and grafting of functionalized benzenes. Functionalities such as sulfonic acid and nitrate groups were achieved by radical grafting via *in situ* formed diazonium compounds. The modified carbon supports were characterized by infrared spectroscopy, XPS as well as elemental analysis.

The functionalized carbons were used as support for later oxidative polymerization with different nitrogen containing monomers: *m*-phenylenediamine, *p*-phenylenediamine, aniline and melamine. In order to obtain the final catalyst, the support/monomer mixes were polymerized, impregnated with iron precursor, pyrolyzed at 950 °C and acid leached of unspecifically bound iron species.

The final catalysts were characterized for their electrochemical activity in rotating ring disc setup, their site density via CO-chemisorption and their respective turnover frequency. The physicochemical characterization consists of the analysis of surface area and pore structure via nitrogen physisorption, SEM and TEM; for the surface structure and compositional analysis via elemental analysis, ICP-OES, and XPS.

We could show improved mass activities up to 0.95 A g^{-1} at 0.85 V_{RHE} with surface modification of the used carbon supports in comparison to the unmodified carbon supports or no carbon support. The good dispersion of nitrogen containing monomers is assumed to lead to increased surface area and high site density. Applying this highly scalable method of surface functionalization to different synthesis methods for MNC catalysts could be a viable way to achieve high performance catalysts for ORR.

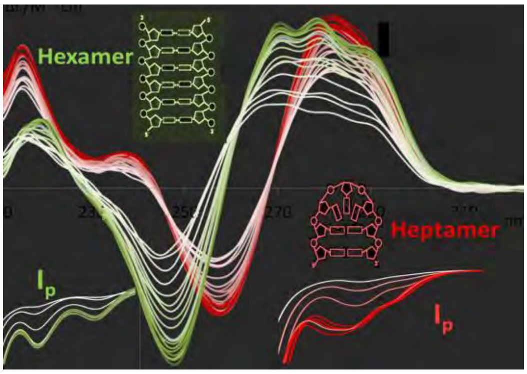
Dramatic electrochemical and spectroscopic differences, caused by the loss of the adenine nucleotide residing in the middle of the heptamer d(GCGAAGC), were revealed [1]. Based on comparative voltammetric, circular dichroic and electrophoretic studies of the hexamer (Hx) - d(GCGAGC) and the heptamer (Hp) - d(GCGAAGC) we illustrate how a single nucleotide sequence and a neighbouring nucleotide species in ODNs strongly affect their secondary structure.



Dedicated studies suggest that the heptamer (Hp) possesses a hairpin structure, whereas the hexamer (Hx) appears to be rather a duplex. Both of the structures exhibited completely different adsorption behavior at the hanging mercury drop electrode, and this factor was readily confirmed by means of elimination voltammetry with linear scan (EVLS) [2]. We established that the Hp hairpin (~ -1300 mV), compared to the Hx duplex (~ -1360 mV), is the thermodynamically favored electron acceptor. The adsorption isotherms were constructed based on the voltammetric peak height values, reflecting the reduction of the adenine (A) and cytosine (C) moieties as well as the oxidation of the 7,8-dihydroguanine (7,8-DHG) moieties [3,4]. The comparative spectroscopic and electrochemical studies of heptameric and hexameric DNA fragments showed that not only the Hx structure but also the Hp structure (denoted as a thermodynamically very stable formation in solutions [5]) is vulnerable by an electrode field.
Finally, as revealed by both the spectroscopic and electrochemical results, Hx forms a bimolecular antiparallel homo-duplex carrying both Watson–Crick base pairs (CG or GC) and mismatched edge-to-edge base pairs (GA or AG).

In 2015, World Health Organization (WHO) published a detailed report of an estimation of the global burden of foodborne diseases. According to this, there are four leading causes of unsafe food due to the presence of viruses, harmful bacteria, parasites or chemicals [1]. The latter is further categorised into aflatoxins, arsenic, cassava cyanide, peanut allergens and dioxins. Food allergy affects 1-10 % of the population and reports show that its prevalence in children increased by 50% between 1997 and 2011 [2]. Peanuts are one of the most common allergic reaction-induced foodstuffs as being often introduced in human dietary. The most frequently allergenic protein which is responsible of peanuts allergy is Ara h1, 2, 3, and 6 triggering to an immunological response in more than 50% of the allergic population representing the first leading cause of anaphylactic fatalities worldwide [3]. Symptoms can occur from minutes to hours after exposure, and may include difficulty in breathing, low blood pressure, itchy rash, swelling of the tongue, and life-threatening systemic reaction called anaphylaxis. As there is no cure for peanuts allergy yet developed but only effective care and emergency treatments, the only viable solution is a free peanut-based diet. ELISA is the most commonly used method for determining low levels of food allergens in food (ingredients, processed foods and beverages) [4], but lacks of simplicity and reduced costs and oftentimes leads to delays in acquiring results. Therefore, risk management and mandatory labelling system of food allergens are critical steps in food industry to guarantee consumers safety. For these reasons, the development of an easy-to-use, fast and accurate device for peanuts allergen detection is fundamental to prevent life-threatening reactions in sensitized subjects.

This work presents the electrochemical detection of Ara h1 by means of a biomimetic approach using oligonucleotide-modified microarray gold chips. The sensing strategy for the production of DNA microarrays was performed using a 32-electrode chip comprising of (70 × 70 μm^2) gold electrodes [5] and synthetic DNA strands with sequences specific to Ara h1. The affinity reaction was performed on microarrays consisting of 32 individually addressable modified gold microelectrodes. The affinity reaction between the DNA strands and Ara h1, followed by conformational and structural changes in the recognition layer, was triggered by means of electrochemical mediators labelled at the DNA sequence. Each step of electrode modification was characterized by electrochemical techniques such as cyclic voltammetry, electrochemical impedance spectroscopy, and chronocoulometry for determination of DNA coverage. Possible applications on food sample analyses will be presented.

Polypyrrole is widely used in various electronic, electrochemical, and membrane technologies as an electroactive polymer with high electrical conductivity and high chemical stability [1]. For the vast majority of polypyrrole applications in various electrochemical devices is the fundamentally important question of the range of electroactivity potentials and conductivity of the polypyrrole chain, a change in these parameters during redox transitions from a charged to an uncharged state, as well as concomitant changes in other polymer parameters.

Recently, an interesting experimental effect for thin films of polypyrrole noticed by authors of work [2]: the electroactivity region expands into the negative potential region when such films undergo multiple charge/discharge cycling in a monomer-free solution of the background electrolyte. In this case, the questions arise - does the expansion of the electroactivity potentials range correlate with a conductivity change of the material during multiple cycling of thin polypyrrole films, and what is the reason for this correlation? It was found that at the first stage of this process, the characteristics of the system (redox charges, shape of voltammetric response) noticeably change, and then reach saturation, which can be caused by structural changes in the polymer. This work aims to find out whether the conformational changes of macromolecular complexes with anions can cause the observed behavior.

We considered the change in the shape of the polypyrrole chain upon interaction with strong acceptors (for example, BF4–) and during the formation of neutral oligopyrrole complexes with a different number of anions. The quantum chemical modeling was performed using the density functional B3LYP and basis 6-31G*. It has been shown that in such complexes, it is energetically favorable to reorient the pyrrole rings closest to the anion from the trans to cis position, which leads to the formation of meanders, including 3–5 pyrrole rings per loop. It was noted that a decrease in the loop size would decrease the interaction energy with the acceptor. Contrary, an elongation of such a loop reduces the number of attached anions with a slight energy change of interaction of each of them with the polypyrrole chain.

The vibrational spectra of oligopyrrole complexes with a different number of BF_4^- anions were calculated, and the prospects for the experimental detection of calculated conformational states by IR spectroscopy were evaluated.

Polyaniline (PANI) is a conducting polymer highly sensitive to pH changes in its microenvironment and its conductivity is known to increase by 8–10 orders of magnitude on doping with acids. This is due to the transition of its emeraldine salt (ES) form to emeraldine base (EB) which is also accompanied by colour change from green to blue [1].

In this work, we present a smartphone-based naked eye one spot biosensor utilizing the unique colorimetric properties of the poly(aniline-co-anthranilic acid) (ANI-co-AA) composite film coupled with tyrosinase (Tyr), horseradish peroxidase (HRP) and bi-enzymatic horseradish peroxidase-glucose oxidase (HRP-GOx). The enzyme is immobilized on the composite polymer film by physical adsorption and in the presence of its substrate, catalyzes a reversible redox color change in the host polymer from green to blue (Fig. 1). A Google Play Store, free of charge software application, was used to enable easy and clear display of the sensors' response indicating remarkable changes in the optical features. Transmission Electron Microscopy (TEM) and Attenuated Total Reflectance-Infrared Spectroscopy (ATR-IR) were used for the characterization of synthesized composite. The poly(ANI-co-AA) enzyme-modified films were applied to colorimetric detection of catechol, hydrogen peroxide and glucose, respectively. The developed colorimetric biosensor was studied and optimized in relation to different experimental parameters by using a 96 micro-well plate plastic support and different polyester strips were imagined. A linear correlation between the analytes concentration (0-200 μM) and the Hue value of the colored modified film was observed after only 2 minutes reaction in the case of Tyr- and HRP-based sensor, and 8 minutes for HRP-GOx sensor. The results were confirmed by the spectrophotometric measurements performed at 655 nm. By smartphone camera readout and analysis, LODs of 12.31 μM, 51.20 μM and 49.42 μM were obtained for catechol, hydrogen peroxide, and glucose, respectively. Different molecules with similar structure were tested as interferences for glucose determination. Moreover, the sensor being disposable, its applicability to food and pharmaceutical analysis was demonstrated. It has been shown by these studies that the naked eye biosensor is promising as quick and simple test for handheld analysis in various fields [2].

Cobalt oxide is a highly active electrocatalyst for the oxygen evolution reaction (OER)[1] and a model system in electrocatalysis.[2, 3] In order to study the stability and dynamics of cobalt oxide we investigated well defined CoO_x nanoislands on Au(111) by complimentary electrochemical in-situ methods and surface science techniques. We prepared the CoO_x nanoislands by physical vapor deposition (PVD) in ultra-high vacuum (UHV) using a procedure described previously.[1] We characterized the system in UHV by scanning tunneling microscopy (STM). After transferring the sample from UHV into the electrochemical environment, we studied the system by electrochemical STM (EC-STM), on-line inductively coupled plasma mass spectrometry (ICP-MS), and cyclic voltammetry (CV). The studies were performed at pH 10 (phosphate buffer) in a potential region from -0.4 to 1.8 V_{RHE}.

After preparation, we observed two types of nanoislands, which we assign to bilayers and double bilayers. At 0.7 V_{RHE} the nanoislands are stable and do not show mobility. By decreasing the potential to 0.5 V_{RHE}, we observe that the bilayers become dynamic and start to dissolve. Online ICP-MS measurements show that Co dissolution is highest for potential steps from 0.8 to 0.5 V_{RHE}, while the dissolution rate decreases by stepping from 0.8 V_{RHE} to lower potentials. This indicates that the dissolution process is transient. Close to the reduction potential of Co^{2+} to Co^0, we observe the redeposition of (adsorbate covered) Co aggregates on the Au surface.

Scanning from 0.8 V_{RHE} in the positive scan direction bilayers and double bilayers are stable up to a potential of 1.0 V_{RHE}. At 1.1 V_{RHE} striped features appear on the bilayers which we assign to oxygen adatoms. These oxygen adatoms fully cover the bilayers upon increasing the potential further. At 1.5 V_{RHE} we observe oxidation of the Au(111) support.

Isopropanol (IPA) and its dehydrogenated counterpart acetone (ACE) can be used as a rechargeable electrofuel. In this concept IPA is oxidized to ACE in a fuel cell and, subsequently, hydrogenated again catalytically.[1]

Addressing this concept, we investigated the IPA oxidation on catalysts with different levels of complexity, ranging from single crystal surfaces to commercial alloy catalysts. Specifically, we used Pt single crystals as well as polycrystalline and nanostructured Pt electrodes.[2] Further we studied carbon supported Pt and PtRu model electrocatalysts, which we prepared in ultra-high vacuum,[3] as well as commercial Pt and PtRu electrocatalysts.[1]

We investigated the reaction mechanism of the isopropanol oxidation as well as the catalyst stability using complimentary in-situ techniques. Namely, we used electrochemical infrared reflection absorption spectroscopy (EC-IRRAS), cyclic voltammetry (CV), differential electrochemical mass spectrometry (DEMS), electrochemical real-time mass spectrometry (EC-RTMS), electrochemical scanning tunneling microscopy (EC-STM), and online inductively coupled plasma mass spectrometry (ICP-MS).

We observe the onset for the IPA oxidation on Pt electrodes at 0.3 V_{RHE}, yielding ACE formed with high selectivity. At potentials above 0.9 V_{RHE}, the formation of Pt oxide inhibits the reaction. The only side reaction observed is the formation of small amounts of CO_2. We show that the product ACE adsorbs at the Pt electrodes poisoning the surface. On nanotubular electrodes with high surface area, ACE stays mainly adsorbed on the surface and only a small fraction desorbs. These observations suggest that poisoning of the Pt electrode by adsorbed ACE limits the oxidation of IPA. However, we did not observe any influence of the IPA oxidation on the stability of the electrocatalysts. By using PtRu alloy catalysts, the onset potential is shifted down to 0.1 V_{RHE} and the poisoning can be reduced.

Choline chloride-ethylene glycol (1:2) ionic liquid (ILEG) has been used as electrolyte to study nickel-cobalt alloy electrodeposition process and the influence of multi wall carbon nanotube (MWCNT) presence on NiCo MWCNT composite deposition processes.

Cyclic voltammograms were recorded at different scan rates in the range 10-200 mV s^{-1} on platinum electrode in Choline chloride-ethylene glycol (1:2) electrolyte containing 0.5 M Ni^{2+} and 0.5 M Co^{2+} ions. The cyclic voltammograms illustrated that nickel-cobalt and nickel-cobalt MWCNT reactions involve quasireversible processes. The experiments were recorded at a constant temperature of 70^0C.

The electrochemical cell contained a Pt electrode as working electrode, a Pt plate as auxiliary electrode, and an Ag wire immersed in the ionic liquid as quasi-reference electrode.

In order to demonstrate the mass-transport control (diffusion control) of cathodic process, we represented the plots of cathodic peak current (I_p) *versus* the square root of scan rate ($v^{1/2}$). (Fig. 1)

The deposits surface shows a rather rough surface with irregular cone deposits that increase with increasing current density. In the case of composite films, the carbon nanotubes incorporated in the film can be observed.

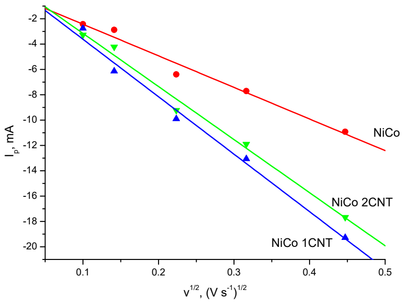

Fig. 1 The current densities of cathodic peaks *versus* scan rate for NiCo and NiCo MWCNT deposition in ILEG

The presence of MWCNT leads to an increase of the current density and an increase of the diffusion coefficient from 0.56 $\times 10^{-7}$ cm^2 s^{-1} for NiCo alloy to 1.85×10^{-7} cm^2 s^{-1} for NiCo MWCNT composite.

The obtained results of diffusion coefficients are at the same order of magnitude as calculated for Ni by Urcezino et al [1] and Co by Cojocaru et al [2].

Deep Eutectic Solvents Based on Lithium Nitrate and Acetamide as Electrolyte in High-Temperature Electric Double-Layer Capacitors

Adam Maćkowiak, Przemysław Galek, Krzysztof Fic
Poznan University of Technology, Berdychowo 4, 60-965, Poznan, Poland
adam.mackowiak@put.poznan.pl

Electric double-layer capacitors (EDLCs), have received much attention in recent years because of their outstanding properties such as long cycle life (cyclability) and high power density sustained. Currently, the most commonly used electrolytes in EDLCs are aqueous solutions, as far as the sustainability is concerned. However, solvent evaporation and components corrosion are major drawbacks at elevated temperatures, e.g. 100°C. Organic solvents, because of their flammability and environmental toxicity, could be also discarded for high-temperatures applications. Ionic liquids may be another solution, but their production price is too high for commercial use yet. Therefore, a promising solution for high-temperature operating capacitors is the use of electrolytic solutions based on deep eutectic solvents (DESs). These electrolytes can be easily obtained just by mixing two compounds in specific molar ratios. Usually, DES are thermally and electrochemically stable and have negligible vapour pressure. Furthermore, by using high temperatures, one can eliminate several problems related to the viscosity of liquids, and thus even improve the conductivity or ionic mobility.

In this work, the properties of DES made of lithium nitrate and acetamide as the electrolyte for high-temperature capacitors were examined. A mixture of acetamide and $LiNO_3$ in the molar ratio of 78:22 is observed to form a DES with freezing point below room temperature. Basic electrochemical tests were carried out, such as cyclic voltammetry, galvanostatic charge/discharge and impedance spectroscopy; the capacitance values obtained for symmetric capacitors with porous carbon electrodes was ca. 133 $F \cdot g^{-1}$ at mild current regimes. In further studies, optimal capacitor operating conditions were determined, i.e. voltage - 1.4 V and current density - 0.2 $A \cdot g^{-1}$. Under these conditions, it has been shown that the DES mixture has better capacitance than individual components separately. The addition of organic solvents or water reduces the quality of the electrolyte at 100°C. Lithium nitrate and acetamide mixture was compared with 5M $LiNO_3$ aqueous solution as electrolytes in EDLCs and proved the advantage of DES over aqueous solutions at elevated temperatures. The processes occurring on both electrodes were also explained. Furthermore, it has been shown that changing the Li^+ cation to K^+ or Na^+ does not significantly affect the quality of the capacitor, while the change of the NO_3^- anion to NO_2^- causes a significant deterioration of capacitance properties. The cycle life of the capacitor and the effect of the addition of inorganic salt on conductivity were also investigated. The tests were carried out on various electrode materials, however, microporous Kynol ACC-507-20 turned out to be the most suitable one. Moreover, detailed analysis has been conducted using gas chromatography, DSC, Raman and FTIR spectroscopy.

The European Research Council is acknowledged for the financial support within the Starting Grant project (GA 759603) under European Unions' Horizon 2020 Research and Innovation Programme.

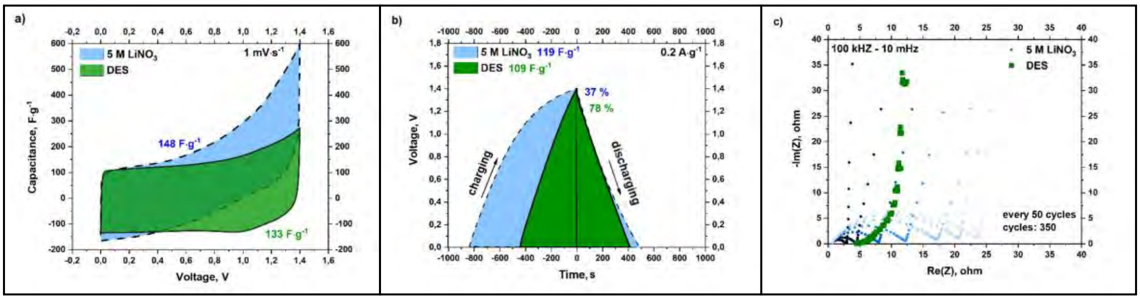

Figure 1: a) cyclic voltammograms ($v = 1\ mV \cdot s^{-1}$, $I = 0.2\ A \cdot g^{-1}$) with current values recalculated prior to scan rate; b) galvanostatic charge/discharge ($I = 0.2\ A \cdot g^{-1}$); c) Nyquist plot (100 kHz – 10 mHz) in first 350 cycles of EDLCs based on 5M $LiNO_3$ and DES at 100°C.

The reprocessing process of spent fuel is carried out in France using the Purex process. The first chemical step of this process is the dissolution of the spent fuel in aqueous concentrated and hot nitric acid. Corrosion is an electrochemical process involving oxidation and reduction reactions in which the anodic reaction is influenced by material factors, whereas the cathodic reaction is influenced by environmental factors. Corrosion of stainless steels in nitric acid is strongly affected by the cathodic reaction. [1-2]

The silicon-rich stainless steel X1 Cr Ni Si 18-15-4 evaluated in this study, spontaneously forms a protective oxides film that is composed of mixed chromium and silicon oxides. This film ensures good durability of the industrial facilities operating with hot and concentrated nitric acid in the presence of oxidizing species. In particular, it has been shown that this alloy is not subject to transpassive intergranular corrosion [3-4].

In the present work, the impact of nitrates on the reduction and oxidation mechanisms of the silicon-rich stainless steel in concentrated and hot nitric acid has been investigated using electrochemical techniques (Linear sweep voltammetry, chronoamperometry, electrochemical impedance spectroscopy) coupled with surfaces analyses (SEM, XPS,…).

Linear polarization curves (Figure 1) show the influence of nitrates at boiling temperature. Despite a constant proton concentration, current and corrosion rate increase with the addition of nitrates to the medium. Nitrates are directly involved in reduction mechanisms of nitric acid, which can explain the increase in the cathodic current. It seems that nitrate ions could also play a role in the anodic dissolution of the considered alloy as the anodic current is significantly enhanced. Further experiments were performed by examining the variation of the oxide layer properties. XPS measurements show variations in the oxide layer formation depending on nitrates concentration.

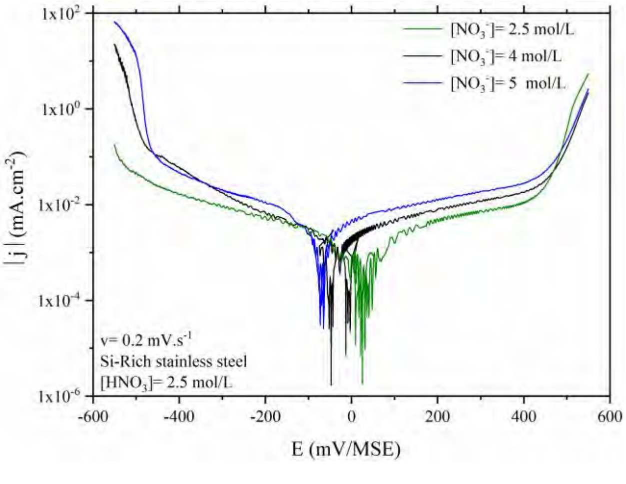

Figure 1: Linear polarization curves of the Si-rich stainless steel in nitric acid media $[H^+]_{fixed}$=2.5mol/L with different nitrate concentrations at boiling temperature. v= 0.2 mV.s^{-1}

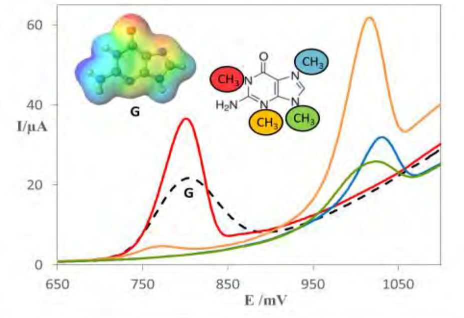
The oxidation of guanine (G) plays a major role in the redox processes of DNA due to the relative ease with which this nucleobase may be oxidized [1,2]. The general mechanism of G oxidation has been examined on different graphite electrodes depending on the environment, such as pH, ionic strength, and the type of a supporting electrolyte [3-5]. In our study, we show how the established mechanism is changing when G will be methylated. We investigated the oxidation processes of four N-methyl derivatives of G (1N, 3N, 7N, and 9N) on a polymer pencil graphite electrode (pPeGE) [6] to ascertain the relationship between the position of the methyl group and the corresponding oxidation behaviour. In the context of the oxidation peak potentials it was found that energetically easier oxidation can be expected in the case of methyl substitution at the pyrimidine ring rather than at the imidazole one. The position of the methyl affects the rapid protonation/deprotonation and tautomeric equilibria that are present in the oxidation processes. The assumption was proved by our theoretical study. The voltammetric data were completed with quantum chemical calculations: (i) the HOMO energies of all N-methylGs, (ii) the SOMO energies of the corresponding cations, and (iii) the theoretical oxidation potentials obtained from thermochemical cycles. Possible tautomeric structures of all the methyl derivatives were optimized using COSMO solvation models at B3LYP/6-31+G(d) level [7]. While 1-, 7- and 9-mG tautomers of lowest energy resemble G, guanosine and GMP derivatives in the sense that their species have hydrogen atoms located on N1 and N9 atoms [8], 3-mG prefers to have N7 atom protonated. This finding will be discussed in more detail with respect to specific electrochemical properties of 3-mG reported from experiments.



The voltammetric oxidation signals of N-methylguanines on a polymer pencil graphite electrode (pPeGE); the ESP map of G (the isosurface level = 0.03).

Understanding the Reconstruction of Ni Nanoparticles on N-Doped Carbon Materials

Paulina Prslja, Nuria Lopez
Institute of Chemical Research of Catalonia (ICIQ)
Avinguda dels Països Catalans 16, 43007 Tarragona, Spain
nlopez@iciq.es

The development of efficient and selective electrochemical carbon dioxide reduction reaction (eCO_2RR) catalysts is an important but challenging task. Metal-nitrogen-carbon (MNC) materials, where the single metal atom is coordinated to pyridinic or pyrrolic nitrogen atoms, are promising candidates to achieve high activity and selectivity towards CO and can proceed to alcohols and hydrocarbons. Among them, the Ni derivative (NiN_xC) exhibits the highest efficiency for producing CO, at the different potentials and industrial current densities. [1,2]

The variation in the synthesis of defects can change the surrounding electronic structure and coordination environment of metals, where directing features are the size of vacancies and N unsaturated and saturated coordination sites. The metal can change its oxidation state depending on these variables. Therefore, the need for different potentials. Furthermore, it has been shown that Ni nanoparticles supported on carbon materials can reach the same selectivity as single-metal atom catalysts when the reaction is consistently performed under electrochemical condition.[3]

In the present work, with Density Functional Theory (DFT) we focus on the Ni nanoparticle reconstruction, taking CO_2 reduction as an example. We have evaluated the activity and selectivity of potential NiN_xC active sites together with the reconstruction and redispersion of supported nanoparticles under electrochemical conditions. We show that such reconstruction occurs due to the disintegration of $Ni(CO)_x$ complexes on low N saturated materials. The selectivity, on the other hand, is higher on N saturated materials.

The Polymer Pencil Graphite Electrode – the Most Sensitive Tool for the Simultaneous Determination of Purine Metabolism Products

Iveta Triskova, Libuse Trnkova
Masaryk University, Faculty of Science, Department of Chemistry
Kamenice 5, CZ-625 00 Brno
175126@mail.muni.cz; libuse@chemi.muni.cz

Xanthine (XA), hypoxanthine (HXA) and uric acid (UA) are degradation products of purine metabolism. It is commonly known, that abnormalities of the metabolite concentrations in human serum and urine are sensitive indicators of many disorders, such as gout, xanthinuria, hyperuricemia, and perinatal asphyxia. The detection and quantification of XA, HXA and UA in body fluids is very important in the study of homeostasis of the xanthine oxidase (XOD) system and clinical diagnostics [1, 2]. Many techniques were developed for the simultaneous determination of the purine degradation products, e.g. enzymatic methods [2 ,3] high-performance liquid chromatography (HPLC) [2, 4, 5], capillary electrophoresis (CE) [2, 6], and also electrochemistry based methods [2, 7-14].

In the context of electrochemistry, it has been shown that the oxidation processes of purines can be observed and studied using different types of graphite electrodes, e. g. pyrolytic graphite, polymer pencil graphite electrode (pPeGE) or screen printed graphite electrode (SPGE), with good reproducibility. In addition, this electroanalysis is fast, cheap and applicable in medicine and food industry.

The aim of our research was the electrochemical determination of HXA, XA and UA at chosen graphite electrodes by using linear sweep voltammetry (LSV) and cyclic voltammetry (CV) in connection with the elimination voltammetry with linear scan (EVLS). The oxidation behaviour of the above-mentioned purine derivatives was investigated not only with respect to pH (pH 2-9; phosphate – acetate buffer) and (micromolar and submicromolar) concentration but also with respect to the type of the graphite electrode used (pPeGE – polymer pencil graphite electrode, BPPGE - basal plane pyrolytic graphite and EPPGE - edge plane pyrolytic graphite). As results from the voltammetric experiments, the oxidation behaviour of purine derivatives is strongly pH-dependent. However, the position of the oxidation signals of XA, HXA, and uric acid allows to distinguish these three important derivatives at all pH values. Based on the concentration dependences, it can be concluded that polymer pencil graphite electrode (pPeGE) is the most sensitive sensor for the determination of purine metabolites, as follows from the comparison of different types of graphite electrodes.

All-solid-state batteries (ASSB) are experiencing a growing scientific interest in recent years as potential next-generation high-voltage batteries with great intrinsic safety. Using polymer electrolytes in ASSBs can solve problems with current battery technologies, such as dendrite growth [1] and flammability [2]. Particularly with regard to mechanical properties and stability, polymers are promising compared to other solid electrolytes. A large number of different polymers are currently being discussed [3].

In this contribution, we investigate the processes in block copolymer electrolytes [2] by a multi-physics continuum transport model. The methodological framework for thermodynamically consistent modeling is given in previous work of Latz et al. [4].

The description of the polymer electrolyte material is based on the specific free energy, which includes contributions due to mechanics, configuration and polarization. For the configurational free energy, the Flory-Huggins solution model is applied to catch the entropic behaviour of a polymer solution. In contrast to transport theories of other electrolytes, we formulate our model with respect to the polymer velocity. This enables us to parameterize the model with data from simulations on the atomic scale, e.g. from molecular dynamics simulations [5].

We investigate the behavior of ASSBs with polymer electrolytes under different operating conditions and compare our simulations to experiments as well as simulations of other types of electrolytes. The most prominent differences are expected for the configurational and mechanical properties.

This is a first step towards the theory-based spatially and time-resolved description of processes in ASSBs with block copolymer electrolytes.

The rapid detection of bacterial strains represents a hot topic thoroughly discussed across the biomedical field. Together with the existence of nosocomial pathogen agents that impose extreme medical and financial challenges throughout diagnosis and treatment, the development of rapid and easy-to-use sensing devices has gained an increased amount of attention. Moreover, antibiotic resistance considered by World Health Organization one of the "biggest threats to global health, food security, and development today" enables this topic as high priority. *Pseudomonas aeruginosa*, one of the most ubiquitous bacterial strains, has various quorum sensing systems that are a direct cause of their virulence. One of them is represented by pyocyanin, a blue pigment with electroactive properties synthesized from early stages of bacterial colonization. Thus, the sensitive detection of this biomarker could enable a personalized and efficient therapy (1, 2).

A thermosensitive polymer, modified with Au/Ag nanoalloy was employed for the rapid and accurate detection of pyocyanin, a virulence biomarker of *Pseudomonas aeruginosa*. The sensor displayed a linear range from 0.12 to 25 μM, and a limit of detection of 0.04 μM (signal/noise=3) and was successfully tested in real samples spiked with the target analyte without any pretreatment other than a dilution step. The detection of pyocyanin with high recovery in whole blood in a time frame of 5-10 minutes from the moment of collection was performed with this electrochemical sensor.

Electrochemical and in situ XAS/XRD Investigations of Nitride-Stabilized Non-Noble Metal Core - Pt Shell Nanocatalysts

X.Zhao[1], K.Sasaki[2], N.Marinkovic[3]

[1]Tianjin University, Tianjin, China; [2]Brookhaven National Laboratory, Upton, NY, USA and [3]Columbia University, New York, NY, USA

Emil addresses: xueruzhao@bnl.gov; ksasaki@bnl.gov; marinkov@bnl.gov

The inadequate activity and stability of Pt as a cathode catalyst under severe operation conditions are the critical problems facing the application of proton exchange membrane fuel cells (PEMFCs). Novel route to synthesize highly active and stable oxygen reduction catalysts involves deposition of Pt monolayer on an appropriate metal/alloy core. Platinum monolayer electrocatalysts offer ultimately low Pt content, complete utilization of Pt atoms and tunable activity induced by a suitable underlying structure [1]. Nitrogen atom in the core of the metal nitride (M = Fe, Co, Ni) nanoparticles covered by a thin Pt shell promotes the Pt ORR activity and provide a stabilizing effect under high oxidizing conditions suppressing the core dissolution during potential cycling [2]. Nitriding metal nanoparticles in ammonia enhances the corrosion resistance of the cores, and simultaneously encapsulating them by one to two Pt monolayer shells. $Pt_{ML}NiN$ core-shell nanoparticle was found to have properties that meet or exceed the DOE 2020 target.

The Synchrotron Catalysis Consortium (SCC) is partnered with the QAS and TES beamlines at the National Synchrotron Light Source II at Brookhaven National Laboratory to promote the utilization of synchrotron techniques for cutting-edge catalysis research under in-situ conditions. SCC provides dedicating facilities, in situ reactors gas, delivery and analysis systems and offers a variety of combined techniques including IR, Raman and electrochemical spectroscopies combined with X-ray absorption spectroscopy (XAS) and X-ray diffraction (XRD) [3]. Electrochemical and *in situ* XAS and XRD experiments were conducted in the attempt to clarify processes of the formation of nitride cores and Pt shell during thermal annealing, the correlation to the activity to the core-shell structures and the effects of electronic states on the stability of the catalyst. Octahedral PtNiN was found to have excellent performance and improved stability over other Pt catalysts. As shown in the XANES spectra of Fig.1, electrochemical excursion into oxide region does not induce changes in NiN core as it is protected by the Pt shell. The catalyst is also stable to the accelerated electrochemical cycling test as shown by XRD spectra of Fig. 1.

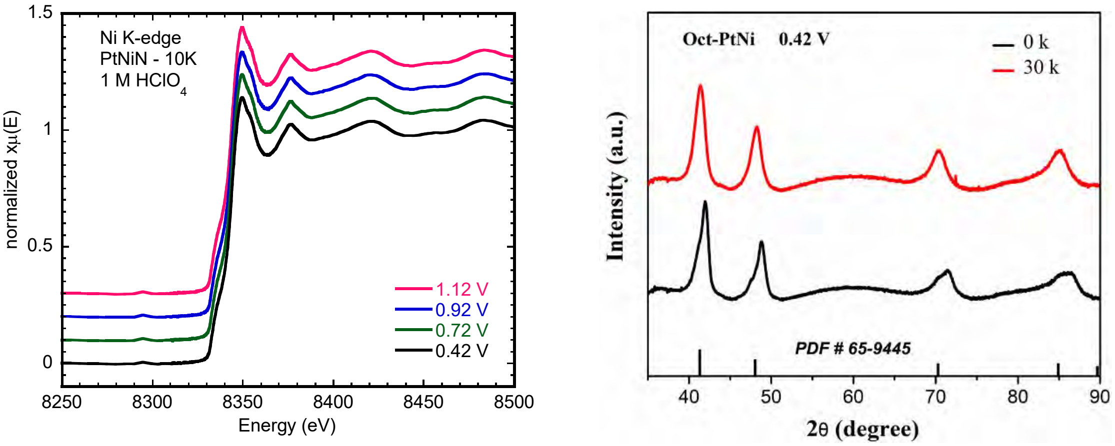

Fig.1 In situ spectra of PtNiN catalysts: XANES spectra after accelerated electrochemical cycling to 10,000 cycles and electrochemical excursion to oxide region (left), and XRD spectra of uncycled and cycled to 30,000 cycles catalysts at 0.42 V.

Bridging the Gap Between Fundamental and Applied Fuel Cell Electrocatalysis Using a Gas Diffusion Electrode Half-Cell

Konrad Ehelebe [a,b], Serhiy Cherevko [a]
(a) Forschungszentrum Jülich GmbH, Helmholtz Institute Erlangen-Nürnberg for Renewable Energy (IEK-11), Egerlandstr. 3, 91058 Erlangen, Germany

E-Mail: k.ehelebe@fz-juelich.de, s.cherevko@fz-juelich.de

Although modern fuel cells are based on the utilization of solid membranes, fundamental catalyst research is mainly done in aqueous solutions via rotating disk electrode (RDE) or similar techniques. However, due to low solubility of reactant gases in those electrolytes mass-transfer limitation occurs at potentials relevant for the fuel cell operation. Hence, kinetic parameters are estimated in a narrow potential region of low currents and further extrapolations are required to achieve kinetic data in the relevant potential ranges. There are many open questions on the validity of such extrapolations. Therefore, in addition to RDE measurements, membrane electrode assemblies (MEA) tests are employed to evaluate catalysts in realistic fuel cell conditions. These experiments are complex (as they include a variety of different parameters), time-consuming and require large quantities of catalysts and expensive test equipment. To close the gap between fundamental and applied research intermediary testing methods need to be introduced, which combine the advantages of both approaches. Half-cell measurements using gas diffusion electrodes (GDE) have recently shown to be the most suitable method to enable high mass transport catalyst screening in relevant potential ranges and realistic electrode structures. [1, 2]

This work will concentrate on activity and stability evaluation for oxygen reduction reaction (ORR) catalysts. A proof-of concept on Pt/C GDEs reveals that, using this approach, current densities of up to 2 A/cm² can be achieved [3]. In contrary to other formerly used methods [2], it is possible to overcome mass transport limitations at relevant fuel cell operating potentials. The experimental shows good compliance with MEA experiments proving the method´s suitability for catalyst evaluation in realistic fuel cell potential ranges.

In a next step the method is transferred to alkaline media for the first time reported. [4] Thereby Fe-N-C cathodes with Aemion^{TM} ionomer are evaluated towards there ORR activity for anion exchange membrane fuel Cells (AEMFC). The impact of ionomer activation on the electrode's performance is revealed and the long-term stability of these non-noble catalyst layers in alkaline media successfully proven.

To gain deeper insights into stability of electrocatalysts in realistic electrode structures, the setup is coupled to an inductively coupled plasma mass spectrometer (ICP-MS). It will be shown that using solid electrolytes, the dissolution of Pt is minimized in comparison to aqueous electrolytes mostly used for stability experiments. This exhibits the necessity for intermediate techniques between MEA and RDE. Besides that, also the mobility of Pt-ions through Nafion is further investigated.

Thus, it can be concluded, that a new powerful experimental tool for decidedly catalyst layer evaluation for fuel cells or other electrochemical three-phase reactions (e.g. CO_2 reaction) is developed and successfully applied in fuel cell research. In the further development this approach will be transferred to enable high-throughput screening of catalysts. For this, a modification to a scanning flow cell (SFC) [5] setup is suggested. With this new device it is possible to rapidly screen the activity and stability of electrocatalyst layers depending on different material properties (e.g. catalyst loading gradients on one axis and structural property gradients such as pore size, ionomer content of membrane etc. on the other axis) using GDEs. Thus the most suitable electrodes under realistic fuel cell conditions can be worked out in a fraction of the time required for conventional methods.

Water electrolyzers based on anion-exchange membranes (AEMs) have gained attention in the last years due to promising cost reductions and greatly improved performances.[1] However, most anion-exchange ionomers still lack stability, as membranes and specifically when employed as a binder in the catalyst layers upon AEM water electrolyzer (AEMWE) operation.[2]

Here, we focus on the stability of catalyst layers for AEMWE and on measures to reduce the loss of catalyst due to poor adhesion and mechanical and hydrolytic stability issues of the ionomer binder. Fabricating catalyst-coated membranes (CCMs) using a spray coater allows the exact control of the layer-by-layer deposition rate of the catalyst layer on the membrane. By adjusting the deposition rate and hot plate temperature following experiences published recently by Klose et al. [3], as well as the ink composition, the stability of the catalyst layers was improved. As can be seen in (Figure 1 b), the catalyst layer integrity was mostly maintained after ion-exchange to the OH$^-$-form and exposure to water, while non-optimized spraying results in poor adhesion and areas without any catalyst (Figure 1 a). To quantify and compare the degradation of full MEAs under operating conditions short-term current holds and performance evaluations were performed in a water electrolyzer employing 0.1 M KOH at 60 °C (Figure 1 c). This work summarizes the recent achievement in the establishment of a stable AEMWE based on Aemion™ ionomer.

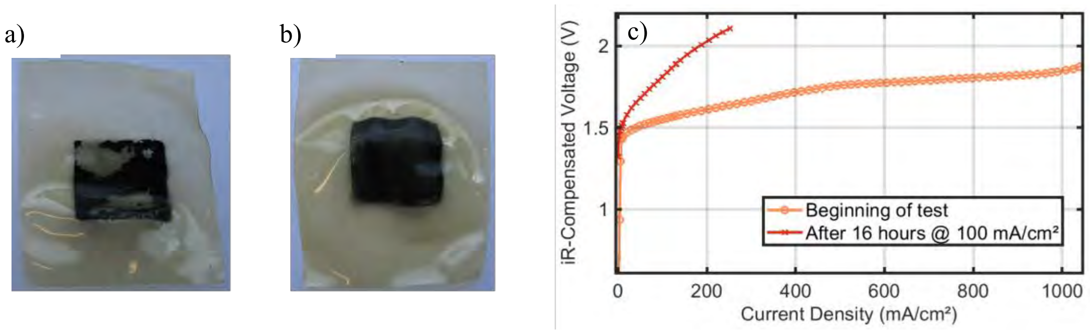

Figure 1: The IrOx catalyst layer sprayed on an Aemion™ membrane shows significant loss of catalyst upon ion-exchange to the OH$^-$-form and subsequent washing with deionized water (a), while optimized spray parameters result in a maintained cover with catalyst (b). This instability of the catalyst layer also contributes to the degradation observed when measuring CCMs in an AEM water electrolyzer overnight, as indicated by the changes in recorded polarization curves (c).

Rheological changes of polypyrrole films from “salt in water” to “water in salt” solutions

Thiago T. Obana, Marina M. Leite, Vitor L. Martins, Roberto M. Torresi
Instituto de Química da Universidade de São Paulo
Avenida Professor Lineu Prestes, 748, Butantã, São Paulo,SP
ttobana@iq.usp.br

Pseudocapacitive materials, together with carbonaceous ones, hold the promise for high-performance electrochemical capacitors, since they display high energy density due to fast faradaic reactions on electrode surface (pseudocapacitive processes)[1]. Among them conductive polymers (CP) figure as interesting materials, since they present many advantages as low cost, high voltage window and redox activity, being the last one dependent on chemical modifications[1]. However, CP major disadvantage consists of polymeric chains structure breakdown along redox process, due to volumetric changes caused by ions and solvent exchange. Such fading compromise CP-based device cyclability[1]. Several attempts were made to circumvent it, such as 3D nanostructuring and CP-carbon composites[1]. Nevertheless, solvent effects seem to be scarcely explored. In this sense, the present work explores the volumetric changes of Polypyrrole/Dodecylbenzenesulfonate (Ppy/DBS), assisted with electrochemical crystal quartz microbalance with dissipation (EQCM-D), in traditional “salt-in-water electrolyte” and other one “water-in-salt electrolyte” (WiSE)[2], both based on LiTFSI salt. EQCM-D measurements shown that, in LiTFSI 1.0 mol L^{-1} solutions, Ppy behaves as a viscoelastic film during oxidation (high dissipation (ΔD) values) and contrary during reduction. Such viscoelastic change is attributed to water exchange during oxidation and the variation of film stiffness. On the other hand in WiSE, the same film behaves as a rigid one ($\Delta D \sim 0$), showing that, in WiSE, solvent exchange barely affects film stiffness and indicates lower volumetric changes. To explore that effects, the motion of freestanding PPy/DBS in both electrolytes were studied. Since it is well known that such movements mainly stems from water exchange[3]. Figure 1 shows the bending angles differences during oxidation and reduction for PPy at both electrolytes. It is noticeable that PPy bending in WiSE is negligible in comparistion with the one in LiTFSI 1.0 mol L^{-1}.

Figure 1: Freestanding Ppy films bending angle at LiTFSI 1.0 mol L^{-1} (left) and LiTFSI 7m (right)

Tetracycline (TC) is one of the most common used antibiotics for the treatment of infectious diseases in veterinary medicine and due to its high accumulation, important levels can be found in animal based products and environmental samples [1]. Therefore, there is an imperative need to develop highly sensitive and selective methods with easy operation and *on-site* applications for TC.

An electrochemical sensor for TC selective detection based on a gold nanopatterned platform and DNA-sensing strategy was developed.

Firstly, gold was electrodeposited on glassy carbon electrodes, after a previous polystyrene beads deposition, from a $HAuCl_4$ solution to obtain a 3D-nanostructured gold nanovoids (AuNVs) platform (**Fig.1**). The platform generation steps were optimized to obtain the best platform design which was characterized by electrochemical (CV, EIS) and microscopy analysis (SEM, AFM, EDX).

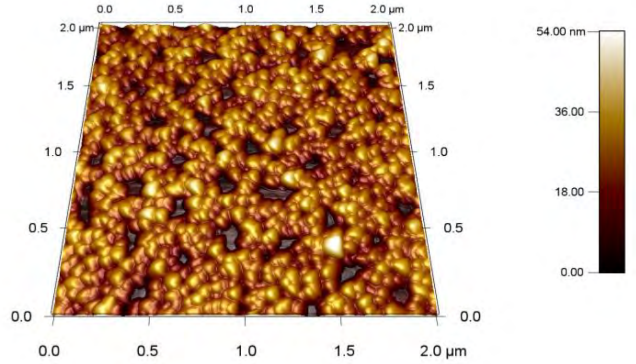

Fig. 1. AFM image of the Au-nanovoids platform resulted after the polystyrene dissolution.

A thiolated Ferrocene-labelled DNA sequence specific to TC was further covalently immobilised on the optimized AuNVs/GCE platform. Different strategies for Fc-DNA immobilization at AuNVs/GCE platform were investigated; multipulse amperometry (-0.5 V to +0.2 V profile pulses for 10ms, 32s total time) showed the highest peak intensities in terms of Ferrocene signal I(µA)/STDEV ratio. The next step was represented by the free active gold binding sites blocking using an unspecific short-thiol was electrochemically immobilized at the Fc-DNA/AuNVs/GCE platform, followed by the affinity reaction with TC. The optimized sensor was able to selectively detect TC in the nanomolar range with very low interference from similar antibiotics. A signal-off ferrocene-labelled DNA-sensor for tetracycline detection was developed based on a gold nanopatterned platform and possible applications on sewage, river and food samples will be presented.

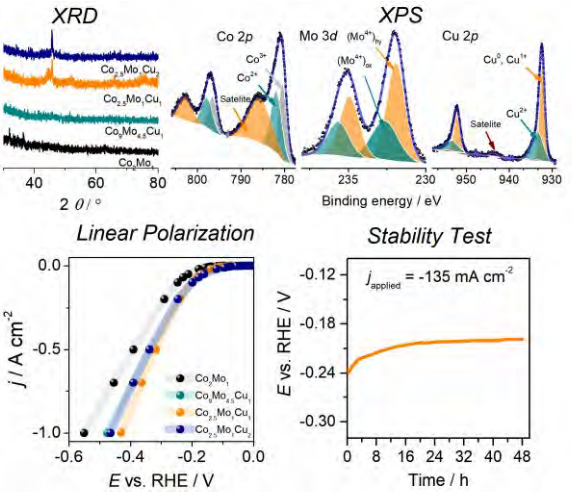
e-mail: hugolssantos@outlook.com



The most of energy expended in the world originates from fossil fuels. However, it is expected the future shortage of these fuels as a result of the depletion of oil sources. Besides that, the high consumption of petroleum derivatives discharges a huge amount of toxic and polluting substances for the environment. In this context, fuels with high energy densities and that do not harm the environment, for example, molecular hydrogen (H_2) are indicated as ideal substitutes for petroleum products.[1,2] This work reports the investigation of the electrodeposition of Co-Mo and Co-Mo-Cu coatings as a catalyst for the hydrogen evolution reaction (HER). Four deposition baths were proposed in the molar ratios of 2:1:0, 2:1:0.01, 1.5:1:0.05, and 1.5:1:0.2 of Co:Mo:Cu using sodium citrate as complexing agent and pH 8.7.[3] Co-Mo-Cu coatings were obtained in constant current of -30 mA cm^{-2} for 40 min on a glass embedded 1010 steel billet substrate with a 0.2 cm^2 exposed area. The electrocatalytic activities of the coatings were evaluated by stationary cathodic polarization curves (and Tafel curves), electrochemical impedance spectroscopy (EIS) and continuous electrolysis in 6.0 mol L^{-1} KOH aqueous solution. The amount of cobalt, molybdenum, and copper in the coatings varied from 67 to 43, 33 to 22 and 35 to 7 at. %, respectively. Co-Mo deposit exhibited a smooth morphology with spherical nodules and cracks across the surface. On the other hand, Co-Mo-Cu presented an irregular surface with well-defined grains, which are in rounded sha of different sizes. The XRD diffractograms with few peaks suggesting that all coatings present an amorphous or nanocrystalline structure, even though the peak near to 45° is correlated for fcc cobalt. The XPS analysis showed that Co, Mo and Cu are present on the surface of the coating. The deposit obtained in the molar ratio bath 2:1:0.05 of Co:Mo:Cu showed better activity for HER, with current of the order of -100 mA cm^{-2} obtained in only -200 mV overpotential. In addition, Co-Mo-Cu coatings exhibited excellent HER stability. At 48 h continuous electrolysis at -135 mA cm^{-2} the potential varied only 3.7% for more positive potentials. The slopes of Tafel near 40 mV dec^{-1} and the EIS experiments indicated a Volmer-Heyrovsky type mechanism with Heyrovsky being the rate-determining step.

In the last couple of years, most of the work was devoted to synthesize new sensing nanocomposites to improve a sensor performance in terms of sensitivity, selectivity, and biocompatibility. Of those synthesized nanomaterials, conducting polymer composites have been widely used in the construction of sensor surfaces. Several conducting polymers *i.e.* polythiophene, polyaniline, polymethylene blue, polyanthranilic acid, polypyrrole, and poly(o-phenylenediamine) display advantages due to their charge transport properties and electrochemical redox efficiency, which are attributed to the delocalization of π-electrons over the polymeric backbone [1, 2].

For a greater enhancement of the electrochemical sensor performance, different electrode systems have been developed based on surface modification with nanomaterials. The synergy of multifunctional materials, recognition elements, and electrochemical methods is improving the selectivity, stability, and reproducibility, thus promoting the development of sensors for assays and bioassays.

Polyaniline (PANI) was used to obtain a nano/micropatterned surface at graphite screen printed electrodes (GSPEs) with applications in the biosensors field. The obtained polymeric film was electrochemically characterized by cyclic voltammetry and electrochemical impedance spectroscopy in different redox probes. Different architectures were obtained by depositing noble metal nanoparticles (AuNPs, PtNPs, Au-PtNPs) at the modified electrodes and the performance of the hybrid composites was assessed. An application of the newly developed polymer-based electrodes will be presented.

Arsenic (As) is one of the most abundant mineral and one to the most toxic compounds. The chronic exposure to arsenic can cause DNA mutation, which can lead to aberrant gene expression and carcinogenesis. Platforms based on Au-PtNPs/GSPE and Au-PtNPs/PANI/GSPE were tested for direct detection of As[III] by means of square wave anodic stripping voltammetry(SWASV). The first platform allowed the As(III) determination in the range of 0-200 nM As(III) while the second one in the range of 0.1-1.25 mM As(III). Interference studies were performed in the presence of Cu(II), Pb(II), Hg(II). Novel and easy to use nanohybrid platforms based on a mixed film of PANI and bimetallic composite Au-PtNPs for As(III) electrochemical fingerprinting was obtained [3].

Solid oxide fuel cells (SOFC) represent a key technology for the transition to renewable sources of energy due to their high efficiency. The main advantages of SOFC compared to other fuel cells are the use of non-precious metal electrodes and fuel versatility. Nonetheless, the high operation temperatures lead to degradation processes and the need for expensive materials, thus much effort is focused on reducing operation temperatures [1]. Two main approaches involve the use of proton conductors as electrolytes and nanoparticle exsolution from mixed ionic and electronic (MIEC) electrodes [2,3]. SOFC work under high temperature, oxidizing/reducing atmospheres and under polarization potential. These conditions greatly affect properties such as the electronic and atomic structure of electrode surfaces and electrode/electrolyte interfaces. In this sense, the combination of complementary advanced characterization techniques for *operando* studies is essential to understand the complex processes occurring on the fuel cell components.

In this work, the two aforementioned approaches to lowering SOFC operation temperatures are addressed: The nanoparticle exsolution processes in $Sr(Ti,Fe)O_{3-\delta}$ (STF) and Ni-doped STF (STFN) MIEC electrode model cells are studied using ambient pressure X-ray photoelectron spectroscopy (AP-XPS) and electron-yield X-ray absorption spectroscopy (AP- XAS) in combination with electrochemical impedance spectroscopy (EIS) and electrode polarization. These techniques give information on the surface chemistry of the electrodes under reducing and oxidizing atmospheres at device operation temperatures, allowing to follow nanoparticle exsolution processes, its reversibility, and its effects on the electrode performance. The second approach, the use of proton-conducting electrolytes, is examined in a study of $BaCe_{0.4}Zr_{0.4}Y_{0.2}O_{3-\delta}$ (BCZY) proton conductors by a combination of in-situ X-ray diffraction combined with EIS, taking advantage of the H/D isotopic effect to determine the range where this electrolyte is a pure proton conductor and where it coexists with O-ion conduction. Furthermore, neutron-based techniques, such as neutron powder diffraction (NPD) and quasi-elastic neutron spectroscopy (QENS) were used to elucidate the crystalline structure and proton transport mechanism, respectively.

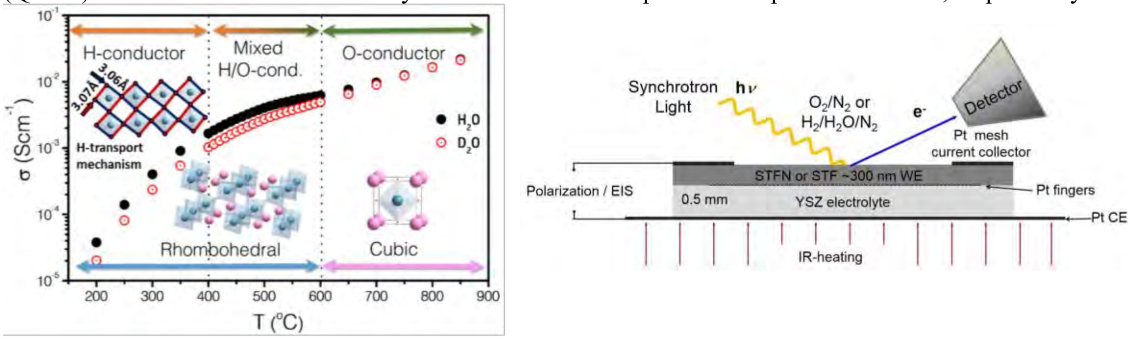

Figure 1. a) BCZY conductivity vs. temperature under H_2O- and D_2O-containing atmospheres and rhombohedral-to-cubic phase transition, and b) STF/STFN cell setup for *operando* characterization.

Enhancement of Electrocatalytic Formic Acid Oxidation on Au(111) by the Pyridine Group

Johannes M. Hermann, Timo Jacob, Ludwig A. Kibler
Institut für Elektrochemie, Universität Ulm, 89069 Ulm, Germany
johannes.hermann@uni-ulm.de, timo.jacob@uni-ulm.de, ludwig.kibler@uni-ulm.de

The use of structurally well-defined Au(111) electrodes allows for a better understanding of the influence of adsorption processes on electrocatalytic reactions. The formic acid oxidation (FAOR) on Au(111) electrodes exhibits current density-potential curves indicating a self-inhibition due to the blocking of active sites by strongly adsorbed formate (Figure 1a, blue curve) [1]. Similarly, the specific adsorption of phosphates also lowers the activity [2]. For platinum electrodes, the presence of bismuth adatoms leads to a CH-down adsorption of formate facilitating the abstraction of the hydrogen atom, which is supposed to be the rate determining step of the reaction [3]. The systematic modification of the electrode surface by adsorption of suitable molecular species allows to influence the adsorption behavior of formate and to tailor the interfacial structure.

In this study, the effect of two prominent organic adsorbates, pyridine (Py) and 4-mercaptopyridine (4-PyS) on the FAOR on Au(111), is discussed. Both molecules form ordered adlayer structures in the potential range where the electrocatalytic reaction occurs [4,5]. The irreversibly adsorbed 4-PyS (S-bonded) exposes its pyridinic nitrogen to the solution, which leads to an enhanced activity towards FOAR. The hysteresis observed for the positive and negative potential sweep is due to a change in configuration of the adlayer (Figure 1a, red curve). The significance of the pyridinic nitrogen for the reaction mechanism is stressed by the comparison with the strongly blocking and inactive thiophenol (black curve). While pyridine is reversibly adsorbed with the nitrogen bonded to the Au(111) surface, it causes a surprisingly strong enhancement in FAOR activity (Figure 1b, compare red and blue curve) [5,6].

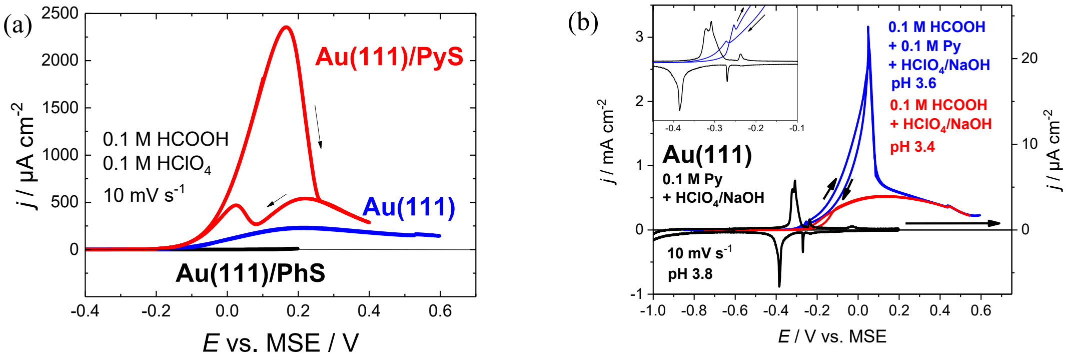

Figure 1: (a) Comparison of current density-potential profiles for SAM-modified Au(111) surfaces in 0.1 M $HClO_4$ + 0.1 M HCOOH. While 4-mercaptopyridine (PyS) enhances FAOR, thiophenol (PhS) inhibits the reaction.

(b) Current density-potential curves for formic acid oxidation on Au(111) in 0.1 M HCOOH + 0.125 M NaOH + 0.075 M $HClO_4$ (pH 3.4, red curve) and for Au(111) in 0.1 M pyridine + 0.1 M HCOOH + 0.05 M $HClO_4$ + 0.1 M NaOH (pH 3.6, blue curve) at a scan rate of 10 mV s^{-1}. The black curve displays the behavior of Au(111) in 0.1 M pyridine + 0.3 M $HClO_4$ + 0.2 M NaOH.

m.roehe@tu-braunschweig.de

Gas diffusion electrodes (GDE) are utilized in many technical applications in order to avoid an early limitation by mass transport. An example is given by oxygen depolarized cathodes (ODC), which are used in advanced chlor-alkali electrolysis and enable high current densities despite the poor solubility of the reactant oxygen in the liquid electrolyte. As shown lately, the composition and structure of ODCs is of high importance for achieving small potential losses and high limiting current densities [1]. Furthermore, it has been shown that the electrode structure as well as the position of the three-phase boundary within the ODC are highly inhomogeneous [2].

In this work, the influence of the ODC structure on the performance is investigated. Electrochemical Impedance Spectroscopy (EIS) spectra and polarizations curves were recorded for ODC with various binder and silver catalyst compositions. A dynamic one-dimensional three-phase ODC model [3] has been extended to simulate the influence of an inhomogeneous electrode structure. The model considers inter alia Tafel-equation for kinetics, Nernst-equation for open circuit potential, Stefan-flow in the gaseous phase, Maxwell-Stefan-diffusion in the liquid phases as well as the oxygen dissolution by Henry's law and the water evaporation by Raoult's law.

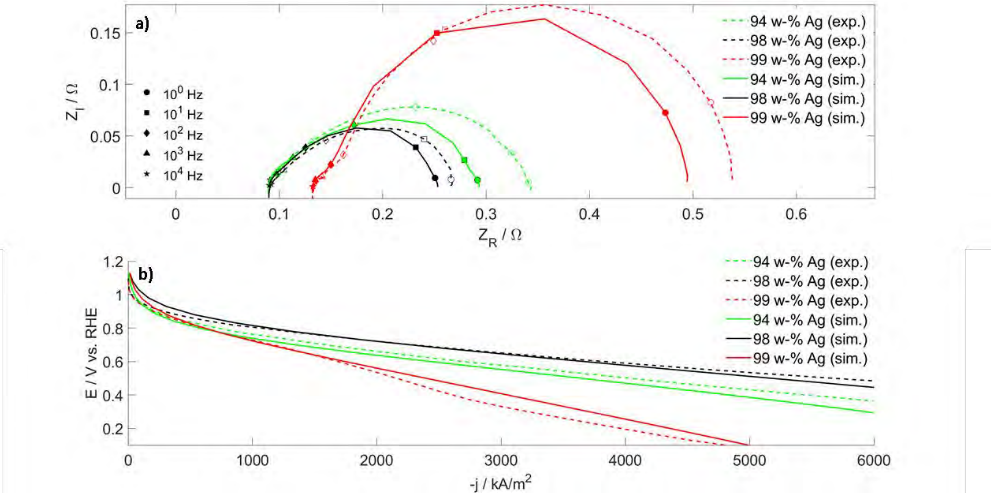

Fig. 1: a) Simulated (-) and measured (--) a) EIS at 2 kA m^{-2} and b) polarization curves of ODC with different catalyst contents.

The polarization curves show high limiting currents densities, whereas the EIS indicates relatively high charge transfer resistances. These contrasting observations are explainable by the inhomogeneous electrode structure: Some pores are highly active, which leads to high current densities. Other pores show a poor activity, which increases the impedance and enlarges the measured charge transfer resistance. This behaviour is illustrated by the distortion of the semi-circles in the Nyquist-plot and can be reproduced well by the extended model (cf. fig, 1 a)). Since all processes are stimulated at high frequencies above 1 Hz, which is the frequency range of double layer charge, no influence of mass transport has been detected. A comparison of ODC of different composition leads to the conclusion that the main indicator for a high electrode performance is the size of the three-phase boundary. Due to these new insights, on the one hand the distortion of the semi-circles in the Nyquist-plot is understood; on the other hand based on the identification of inactive pores, a fundamental for further improvement of the ODC is laid.

Oligonucleotide detection-based tests, including safety screening for environmental chemical toxicity and healthcare management, are increasingly being adopted in the fields of environmental and biological evaluation. Micro RNAs (miRNAs), short non-coding RNAs with a length of 20–25 bases, have recently been attracted as biomarkers for potential applications to evaluation of stresses caused by environmental chemicals and diagnosis of lifestyle-related diseases or cancers. Rapid and simple detection methods are needed to permit the application of these miRNA detection tests in these fields as fast screening tools.

In this study, we investigated sequence-specific and simultaneous miRNA detections by surface plasmon resonance (SPR) imaging measurements on SPR chips possessing an Au spot array modified with probe DNAs based on a miRNA-detection-selective SPR signal amplification method. SPR chips were fabricated by deposition of Au/Cr thin films to a mechanically polished glass covered with a stencil template of the SPR chip pattern (16 spots with diameters of 0.8 mm). The Au spot surfaces were modified with DNA-NH_2_miR17 and DNA-NH_2_miR21 as probe DNAs (targeting miRNA biomarkers of hsa-miR-17 and hsa-miR-21 for lung cancer, respectively), mPEG-NH_2 (a negative control), and A_{30}-NH_2 (a positive control).

When the fabricated SPR chips were soaked in 5 μM hsa-miR-21, only DNA_miR21 (a complementary probe)-modified spots showed a sequence-specific SPR signal. Extension reaction of polyadenine (poly(A)) tails by poly(A) polymerase selectively enhanced this signal. The difference of the SPR signals between complementary and non-complementary probes amplified about five times before and after the poly(A) extension. For more sequence-specific SPR signal enhancement, we used a ternary complex of T_{30}-biotin/horseradish peroxidase (HRP)-biotin/streptavidin. Binding of the complex to the poly(A) tails showed larger responses for spots of the complementary probe than those for the positive control. In contrast, responses for the non-complementary probe and negative control were revealed to be quite small.

Then, oxidation reaction of tetramethylbenzidine (TMB) via HRP was utilized to enlarge the observed SPR signal. The SPR signal for the complementary probe remarkably increased, while those for the non-complementary probe and negative control slightly increased. These results show TMB was oxidized on HRP of the ternary complex to be changed to blue precipitation of Ox-TMB. The difference of SPR signals between the complementary and non-complementary probes showed another 4.5 times-amplification. We concluded that this process sequence-specifically and dramatically amplified the SPR signals. Moreover, further experiments of dependence of SPR signal on concentrations of miRNA solutions revealed the detection limit of this method is the attomole (10^{-18} mole) level. This is a simple, cost-effective, and feasible signal amplification method based on the organic compound TMB instead of metal nanoparticles.

Detecting oxygen in catalyst layers by scanning electrochemical microscopy (SECM)

Mahdi Moghaddam, Pekka Peljo
Research group of Physical Electrochemistry and Electrochemical Physics, Aalto University
Kemistintie 1, 02150 Espoo, Finland
mahdi.moghaddam@aalto.fi

Scanning electrochemical microscopy (SECM) is a powerful scanning probe technique for tracking the local electrochemical activity of an electrolyte-immersed substrate, by employing an ultra-micro-electrode. As the Thin Layer Electrochemistry regulations apply for the SECM setup, high spatial and time-related resolution is obtained, providing the SECM with the ability of being employed in various applications in the fields from biology to energy materials.

In this research SECM feedback mode is used to detect the presence of excess of oxygen in the catalyst inks drop-casted on an electrode. Catalyst inks containing either carbon supported Pt nanoparticles or carbon black were drop-casted on a glassy carbon electrode, with Nafion ionomer as binder.

SECM approach curves obtained by ORR-potential biased Pt tip (a = 12.5 μm, RG = 8) displayed positive feedback type behavior when approaching electrodes covered with catalyst layers, both in H_2SO_4 and KOH solutions (Figure 1). Approach curves on clean glassy carbon electrode showed negative feedback. As it is unlikely that true positive feedback would be observed on a catalyst layer, these measurements indicate that the increase in the tip current when approaching the catalyst layer results from excess oxygen present in the catalyst layer due to hydrophobicity or the porous surface structure of the layer. A similar observation has been reported when approaching a porous poly(vinylidene fluoride) membrane[1,] or CNT-based catalyst. As the tip depletes oxygen from the solution, oxygen from the porous film partitions into the solution, resulting in similar behavior to that observed when approaching a water–air interface. Simulations were performed to reproduce this effect.

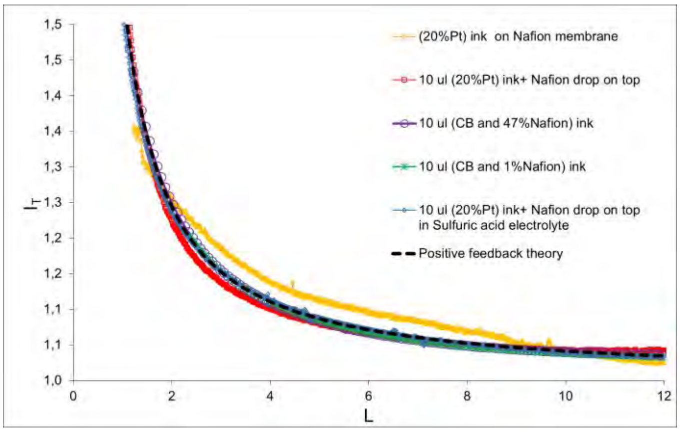

Figure 1. Theoretical Positive feedback curve and approach curves of different catalyst layers, in KOH and H_2SO_4 electrolytes.

Reducing the anode catalyst loading of proton exchange membrane water electrolyzers (PEMWE) is one of the major challenges for their mass commercialization[1,2]. In recent studies, the role of in-plane conductivity in low-loaded catalyst layers (CLs) has been studied intensively, suggesting that electrically isolated portions in the CL [2] and ionomer swelling during operation [3], result in higher resistances and hence lower catalyst utilization. We present a novel approach to reduce the CL in-plane resistivity by blending the proton conductive ionomer (Nafion) in the CL with an electrically conductive polymer (PEDOT:PSS). With this blend of ionomer and electrically conductive polymer we are able to increase the in-plane conductivity and reduce the contact resistances of a CL with an Ir-loading of 0.22 mg cm^{-2}. This results in a significant performance increase of a 120 mV lower overpotential at 3 A cm^{-2} compared to a conventional CL with ionomer only as binder and identical Ir-loading.

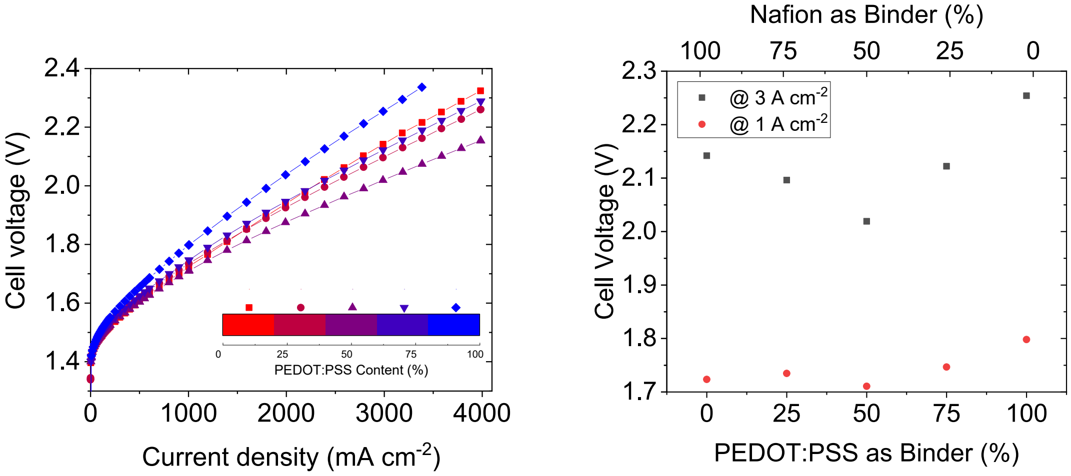

Figure 1 Blending of Nafion and PEDOT:PSS as a bi-functional binder in the CL resulted in lower overpotentials (left). The highest improvement was observed with a 50 % Nafion 50 % PEDOT:PSS blend (right). Operating conditions were: 80 °C, cathode and anode flowrate 40 ml min^{-1}, at ambient pressure, N115 membrane, anode loading of 0.22 mg cm^{-2} Ir and a cathode loading of 0.5 mg cm^{-2} Pt

Perfluorinated sulfonic acid-based ionomers (PFSAs) are the state-of-the-art proton conducting material in polymer electrolyte fuel cells nowadays. PFSAs, however, feature several drawbacks including the high cost, restricted operating temperature range, insufficient chemical stability and environmental hazard due to the use of fluorine-based chemistry[1]. Under these circumstances, several non-fluorinated hydrocarbon-based ionomers were introduced in recent years to replace PFSAs. A very promising candidate is a sulfonated phenylated polyphenylenes-based (sPPP) ionomer introduced by Skalski et al.[2]. The authors reported competitive MEA performance in comparison to a Nafion^{TM} membrane. In this work, we present different approaches to improve and engineer the electrode structure employing a sPPP-based ionomer (Pemion^{TM}) resulting in strongly improved performance of the all-hydrocarbon fuel cell[2]. This includes an adjustment of ionomer contents in the catalyst layers, as well as improved processing conditions of the CCM fabrication. This work reports electrochemical performance from all-hydrocarbon MEAs at different operating conditions, as well as ex-situ characterization via electron microscopy and dynamic light scattering.

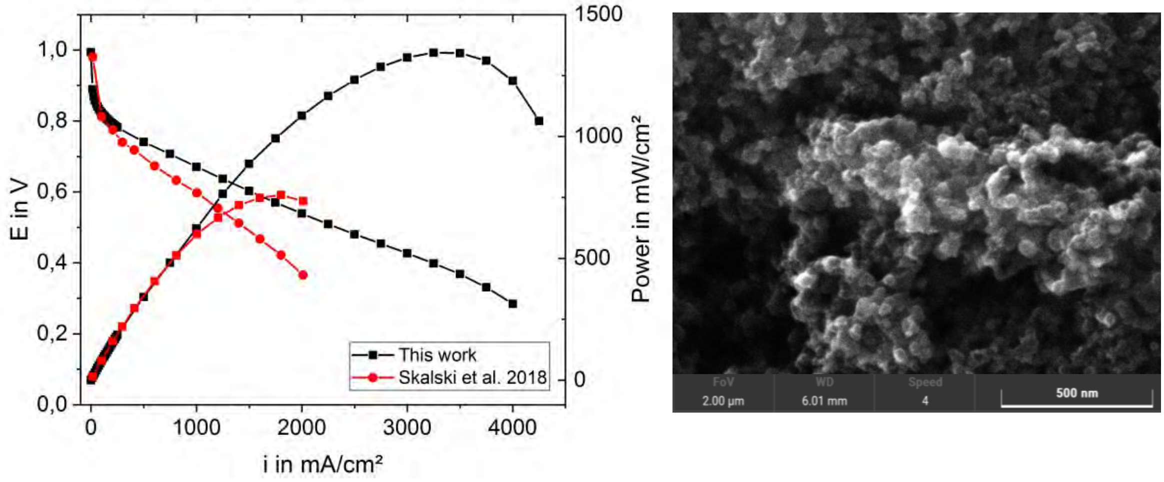

Figure 1 Elevated performance of PEMFCs (Pt-loading anode/cathode = 0.1/0.4 mg/cm²) with Pemion^{TM} (15 µm membrane thickness) in H_2/O_2 with a fixed flow of 0.25/1 l/min, 80°C, 95% r.H. and 1 atm (left) in comparison to literature (37 µm membrane thickness) and SEM micrograph of a CL with Pemion ionomer (right).

This study aimed to examine the influence of the morphological characteristics of green algal cells on the adhesion process and their mobility. The used model organisms were *Tetraselmis suecica* and (Chlorophyceae), motile microalgae of micrometer size, with different morphological characteristics of the cell envelope. The *D. tertiolecta* cell consists cell membrane [1,2] enveloped by a glycoprotein cover (glycocalyx), while *T. suecica* cell consists of a cell membrane with complex theca made of scales, encrusted with calcium carbonate. *D. tertiolecta* cells have two flagella of equal length emerging from one basal body, whereas *T. suecica* cells have four flagella that pair out of two basal bodies.

Using the electrochemical method of polarography and chronoamperometry on a dropping mercury electrode, *D. tertiolecta* cells were characterized based on characteristic adhesion signals occurring over a wide potential range. *T. suecica* cells do not adhere to the charged electrode, which is a consequence of the compact cell envelope.

Using computer-assisted video microscopy and an Open Source Image Processing Software Icy (http://icy.bioimageanalysis.org/) cell swimming speed, the displacement length, and shape of their trajectories were quantified on 500 individual cells. Results showed that the speed of *T. suecica* cells is up to 4 times higher than that of *D. tertiolecta*, which is a consequence of a complex flagellar system.

Based on algal cell adhesion and motility characterization, the obtained results could contribute to a better understanding of the spatial distribution of green algal cells in the aquatic environment under stress.

Self-standing nanowires arrays have shown great potential in a variety of important applications, including supercapacitors because of the high volume to weight ratio. They act as a current collector and as a substrate on which the active materials can be grown. Usually, controllable arrays of nanowires are obtained involving template assisted electrochemical deposition where nanoporous ordered aluminum anodic oxide (AAO) architectures represent the host matrix. Conventionally AAO patterns are produced through aluminum anodization in oxalic acid based electrolytes at low operating temperatures and relatively low anodic film growth rates. Low temperatures are preferred because the heat generated during anodization at high temperatures causes inhomogeneous growth of the porous AAO. In order to optimize the anodization process to form ordered AAOs, a quite novel approach involves the use of ionic liquids (ILs) as potential environmentally benign solvents and widespread application in materials chemistry and electrochemistry in a green synthetic strategy [1].

In this study, we aimed to bring insight to the synthesis of AAO architectures involving novel formulations of deep eutectic solvents based on eutectic mixtures of cholinium compounds, respectively of choline dihydrogencitrate/oxalic acid/ethylene glycol systems and comparing them with the anodic oxides formed in traditional aqueous electrolytes. The structural-morphological characteristics of the obtained AAO films formed under various operating parameters (i.e. anodization voltage, electrolyte temperature, anodization duration) were studied. The formed AAO architectures involving ILs were then used as patterns to electrodeposit Ni nanowires (Ni NWs) from aqueous solution at constant potential conditions. Afterwards, the surface of the Ni NWs was converted directly into $Ni(OH)_2$ involving the hydrothermal method [2]. The structure, composition and morphology of the obtained AAO, Ni NWs and $Ni(OH)_2$ were investigated by XRD, Raman and SEM techniques. The electrochemical performance of $Ni(OH)_2$ was studied by cyclic voltammetry and electrochemical impedance spectroscopy.
The influence of the AAO structural characteristics on the final self-standing Ni NWs and their electrochemical characteristics is also discussed.

Cathodic Corrosion of Polycrystalline Au Electrodes: Applications in Electrocatalysis and Surface Spectroscopy

Ludwig A. Kibler, Mohamed M. Elnagar, Johannes M. Hermann, Timo Jacob
Institute of Electrochemistry, Ulm University
Albert-Einstein-Allee 47, 89081 Ulm, Germany
ludwig.kibler@uni-ulm.de

Faceting and nanostructuring of polycrystalline Au electrodes by cathodic corrosion in concentrated aqueous alkali metal hydroxide electrolytes have been studied systematically. Scanning electron micrographs show the formation of octahedral Au nanocrystals and triangular pits by using NaOH and KOH solutions, respectively. These Au surfaces with preferential (111)-texture and a unique nanostructure are of special interest for new developments and applications in electrocatalysis and surface-enhanced Raman spectroscopy (SERS) [1,2].

Cathodic corrosion of Au leads to a single-crystal-like electrochemical behavior with characteristic features of Au(111) electrodes [3,4]. The electrocatalytic behavior of this new type of nanostructures will be presented for the hydrogen evolution reaction (HER) and for the formic acid oxidation reaction (FAOR).

The Raman activity of adsorbed pyridine on the nanostructured Au electrodes was studied with SERS. While untreated polycrystalline Au is not SERS-active, the use of cathodic corrosion opens up a way for *in-situ* applications of SERS in electrochemistry.

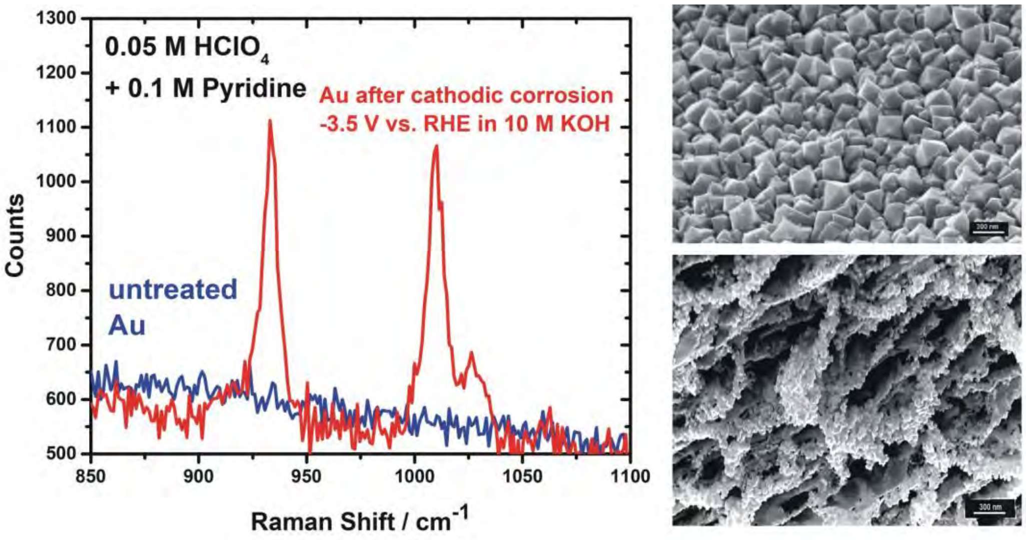

Figure 1: (left) Raman spectra of Au in 0.1 M pyridine + 0.05 M $HClO_4$ before and after cathodic corrosion in 10 M KOH with application of 3.5 V for 60 seconds. (right) Selected SEM micrographs of gold surfaces after cathodic corrosion.

Graphene is a two dimensional material characterised by a honeycomb structure and sp2 hybridization that provides outstanding properties of this material. It can be prepared as a powder or as a porous monolithic structure (hydrogel or graphene paper). Graphene paper is characterized by high surface area, low weight, high electrical conductivity and furthermore it is a flexible and free-standing material, which makes it a perfect candidate for energy storage applications.

The objective of this research was electrochemical synthesis of graphene paper (ErGO) and its application in the flexible supercapacitor as freestanding active material. In order to obtain ErGO, graphene oxide (GO) paper was prepared by vacuum filtration or drop-casting while electrochemical reduction of GO paper was carried out by chromoamperometry method. During the reduction process GO paper was connected as working electrode by pressing a titanium road onto the paper. By using a number of techniques, including Fouirer-transformed infrared spectroscopy (FTIR), Raman spectroscopy, X-ray diffraction analysis (XRD) and conductivity measurement, it was shown that the reduction process was carried out successfully. The obtained ErGO papers were used for assembling supercapacitors with nickel current collector or supercapacitor with freestanding flexibile ErGO paper. The prepared supercapacitors were tested by cycling voltammetry and electrochemical impedance spectroscopy methods. The obtained results indicated good reversibility with specific capacitance of 44 F g^{-1}

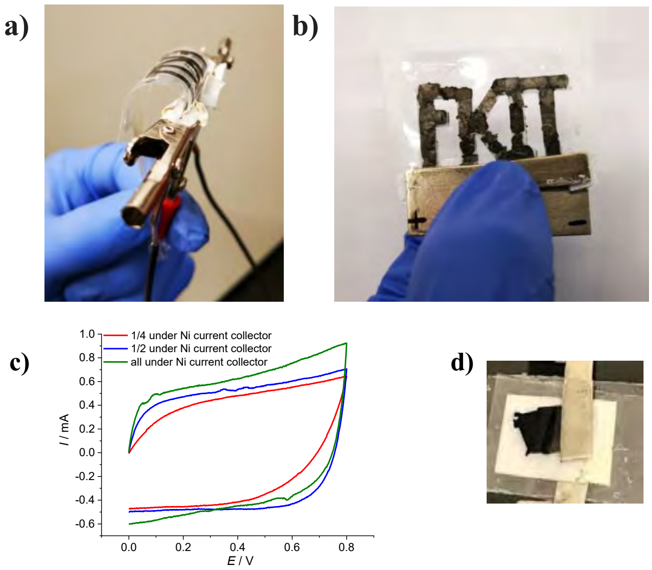

Fig. 1. Different forms of supercapacitors (a, b, d) and cyclic voltammetry response of freestanding ErGO paper or ErGO paper covered by Ni current collector (c).

Photoelectrochemical Degradation of Pharmaceutical Compounds at TiO_2/SnS_2 Electrode

Pharmaceuticals are known to have a significant impact on aquatic environment causing ecological risk and human health damage. Accordingly, it is important to develop an innovative and practical water treatment technique, which will be able to remove them. Photoelectrochemical oxidation is one of the promising techniques due to its simplicity and combination of photocatalytic and electrochemical process. Additionally, recombination of photogenerated electron/hole pairs that occurs decreases by applying external potential, leading to enhancement in pharmaceutical degradation efficiency. One of the most important photocatalytic candidates is TiO_2. Since it is limited to UV-irradiation, significant efforts have been done to extend its absorption into the visible light region through TiO_2 doping or TiO_2 composite formation. Therefore, the aim of this work was to investigate photoelectrochemical activities of TiO_2/SnS_2 nano-composite. The examination was performed using photoelectrochemical techniques in 0.1 mol dm^{-3} NaCl solution, for degradation of pharmaceuticals such as diclophenac, salicylic acid and memantine hydrochloride. For this purpose, TiO_2/SnS_2 nano-composite was immobilised on FTO electrodes.

Good sensitivity of photocatalyst was shown by monitoring OCP in chopped light irradiation and by comparing EIS response in dark to the one under light irradiation. Electrochemical and photoelectrochemical degradation of pharmaceutical was monitored by linear polarisation. The experiments showed that it is possible to degrade pharmaceutical using electrochemical process and to improve degradation using solar irradiation for TiO_2/SnS_2 nano-composite electrode (Fig. 1). The obtained response is dependent on the on the type of pharmaceutical and its affinity towards the adsorption at TiO2-SnS2 surface [1].

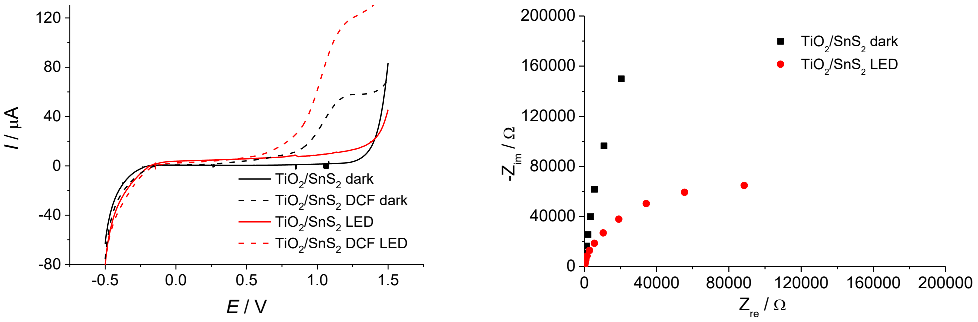

Fig 1. a) Linear sweep voltametry photocurrent response of TiO_2/SnS_2 in the presence and absence of diclofenac (DCF) and b) the Nyquist plot of TiO_2/SnS_2 composite in dark and under LED irradiation.

Since the first reported magnesium-sulfur (Mg-S) cell by Kim et al. in 2011 [1] interest in this post-lithium battery system has steadily increased due to its promising properties in regards of volumetric energy density, safety and costs. In recent years many research groups have attempted to unveil the underlying electrochemical mechanisms by sophisticated structure analysis of the solid product (MgS) [2] as well as spectroscopic investigations of the soluble intermediates (magnesium polysulfides, MgS_x) [3]. Analogous to lithium-sulfur (Li-S) batteries, the solubility of the latter causes the loss of active material and charge compensation through the polysulfide shuttle. Furthermore, the sulfur species contribute to the formation of an anodic SEI, which – in the case of magnesium metal – exhibits a rather passivating nature. This is supposed to be one of the origins for the fast capacity decay and the short cycle life of magnesium-sulfur battery cells.

Benefitting from previous Li-S research to retain sulfur species within the cathode and prevent the polysulfide shuttle, several retention approaches can be considered for the Mg-S system. Among the different strategies, the most promising ones are the sulfur incorporation in micropores, separator coatings with ionomers or carbons, covalently bound sulfur or the use of polar cathode additives as adsorption sites. In this study, the capability of selected attempts on magnesium polysulfide retention was investigated via *operando* UV/Vis spectroscopy and *operando* microscopy in optical cells. Besides the analysis of the separator coloration during galvanostatic cycling, the self-discharge during OCV was surveyed. In addition, significant influence of the electrolyte solvent and the polysulfide diffusion length on the reoxidation of the sulfur species was observed.

Functionalization of metal surfaces with organic molecules play key roles in biosensor fabrication, hybrid nanomaterials design, and controlled growth of nanostructures. Detailed understanding of the chemistry and dynamics involved can therefore lead to increased surface performance and control. Gold surfaces are widely used in catalysis and in molecular and biomolecular electrochemistry, where catalyst functionalization frequently relies on gold-sulfur chemistry.

We have explored monolayer formation and structure of cysteine (Cys), a natural amino acid that holds $-NH_3^+$, $-COO^-$ and –SH functionalities, on Au(100), which is much less studied than the other low-index Au-surfaces.[1] We have mapped the dynamics of Cys self-assembled monolayer (SAM) formation by a combination of open circuit potential evolution and kinetic Monte Carlo simulations. The structure of the SAMs is imaged using *in situ* scanning tunneling microscopy (STM) with single-molecule resolution supported by DFT calculations and STM contrast simulations (Figure 1). Unusual one-dimensional features were disclosed by the *in situ* STM images, unique to Au(100) and closely correlating with unique reductive desorption behavior (Figure 1b). Based on detailed analysis of *in situ* STM images and DFT calculation of Cys monomer and dimer adsorbates, we propose that the bright two-dimensional STM structures and high-energy reductive desorption peak represent Cys dimers. The dimers associate via two-prong electrostatic interaction between ammonium and carboxylate functional groups and bind vertically to Au(100) via a single Au–S bond leaving the other –SH group pointing away from the surface.

This level of molecular understanding of the chemistry involved in Cys SAM formation and structure is achieved by the combination of electrochemistry, microscopy and theoretical efforts, and can help to guide future electrochemical device design and gold nanomaterial functionalization protocols.

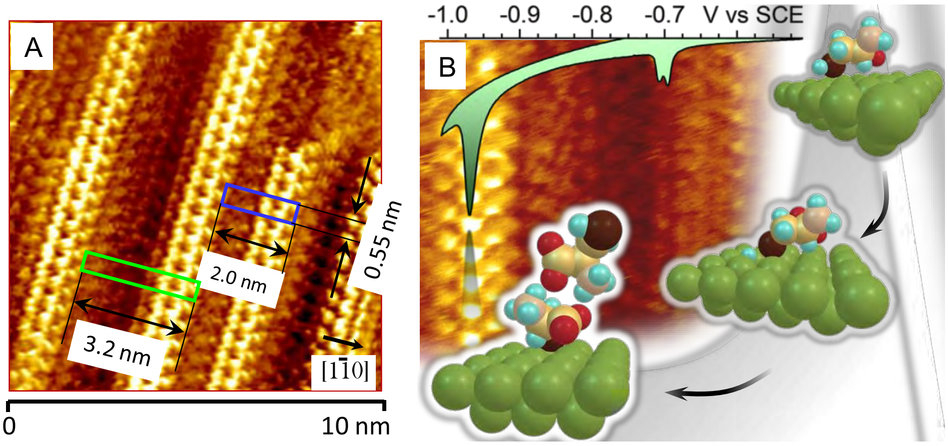

Figure 1. (A) *In situ* STM micrograph of L-Cys SAM on Au(100). Two distinct unit cells are observed highlighted with the green and blue squares. (B) CV of reductive desorption along with DFT simulations of L-Cys dimer formation.

florescum@unitbv.ro

Folic acid (FA) is a bioactive food component whose deficiency can lead to a variety of health problems, while a high intake can reduce the cytotoxicity of natural killer cells. One of the most commonly used proteins in small molecules transport is bovine serum albumin (BSA). BSA interacts with these ligands at one or more of its sites, located in hydrophobic cavities. Herewith, the development of a BSA based biosensor for small molecule detection can be of great importance.

The binding mechanism of FA to free BSA was studied using fluorescence, while cyclic voltammetry and electrochemical impedance spectroscopy offer an insight on both the overall characteristics on the phenomena at the gold electrode surface (BSA binding to the electrode surface) and the detection of FA [1].

The fluorescence quenching mechanism of BSA by FA shows that there occurs a FA-BSA complex formation where one molecule of FA binds per one molecule of BSA, and the binding process is characterized by a moderate interaction with a binding constant of $K_b = 8.72 \times 10^4\ \mathrm{M}^{-1}$ at 25 °C. Knowing this, a BSA biosensor was used for electrochemical FA detection. Confinement of BSA to gold surfaces occurred through drop casting, inducing conformational changes, which influenced the orientation of BSA molecules binding sites towards free FA. Thus, the apparent binding constant calculated using electrochemical methods was 5 times higher, proving a stronger binding. Preliminary results show a sensitivity of 67 nA cm^{-2} $\mu\mathrm{M}^{-1}$, with a linear range up to 20 µM FA. These results enable further studies towards BSA-biosensor development for the detection of small molecules such as FA.

The Impact of Bronze Composition on Properties of Self-Assembled Monolayers of Phosphonic Acids

Dajana Mikić, Magdalena Osrečak, Helena Otmačić Ćurković
Faculty of Chemical Engineering and Technology, University of Zagreb
Savska cesta 16, Zagreb, Croatia
dajana.mikic@fkit.hr, helena.otmacic@fkit.hr

Self-assembled monolayers (SAMs) of long-chain organic acids are formed by adsorption of acid on the surface of oxide-covered metal, resulting in acid-base reaction between metal oxide and acid. This reaction is followed by the self-organization of alkyl chains which creates a very thin and compact film. Due to their unique properties, they are used in many fields, from nano fabrications, sensorics, electrocatalysis to microelectronics. In addition to the listed fields, they have also proven to be good corrosion inhibitors on various metal substrates. Given that corrosion is a significant problem globally, SAMs are emerging as a potential solution to this global problem.

There are many parameters in the preparation of SAMs that can influence the quality of the formed film, but in this work we will deal with the influence of the composition of the bronze substrate on their formation. More specifically, we will form films on pure copper and several bronzes of varying composition so that we can see how and to what extent individual alloying element affect the quality and arrangement of the SAMs. This information is important given that better arranged films provide stronger and longer lasting protection.

In order to obtain a compact well-ordered film which will provide long term protection, SAMs preparation procedures consist of bronze pretreatment and phosphonic acid adsorption by dip-coating followed with drying period. Protective properties of phosphonic acid SAMs are examined by linear polarization measurements and electrochemical impedance spectroscopy. These measurements are carried out in simulated acid rain (0.2 g/L $NaNO_3$ + 0.2 g/L Na_2SO_4 + 0.2 g/L $NaHCO_3$ at pH 5) which simulates the rain in urban atmosphere. The surface of modified samples is also examined by scanning electron microscopy and Fourier transform infrared spectroscopy in order to verify adsorption of phosphonic acid on metal and formation of an ordered organic layer.

Calculation of mechanistic parameters of the oxygen evolution reaction

Denis Antipin, Marcel Risch
Nachwuchsgruppe Gestaltung des Sauerstoffentwicklungsmechanismus,
Helmholtz-Zentrum Berlin für Materialien und Energie GmbH
Hahn-Meitner Platz 1, 14109 Berlin, Germany
denis.antipin@helmholtz-berlin.de

Energy is the most important issue of the 21st century. With the increase of worldwide energy demands, sustainable energy resources are in focus more than ever. In addition to currently existing intermittent energy sources, efficient energy conversion and storage systems are required. Electrochemical water splitting is one of the promising approaches to contain excess of energy in form of hydrogen. However, the efficiency is limited by the sluggish kinetics of anodic half-cell reaction, viz., oxygen evolution reaction (OER, $4OH^- \rightarrow O_2 + 2H_2O + 4e^-$). To overcome this limitation, researchers have examined a number of strategies to develop more active OER catalysts. However, despite numerous studies devoted to OER, the mechanism of OER on transition metal oxides remains controversial.

There are several mechanistic schemes proposed by different scientific groups since the 1960's. We classified them into three prototypical mechanism recently [1]. First, the most commonly discussed mechanisms emphasize the acid-base chemistry of the adsorbates with little change of the metal valence. Second, mechanisms have been proposed where a high metal valence must be achieved for breaking of the oxygen bond, which is known for oxygen evolution by natural photosynthesis. We have previously compared the mechanism of $LiMn_2O_4$ to that of photosystem II (PSII) under the assumption that the latter was an electrocatalytic surface [2], which provides a link to commonly studies oxides. Thirdly, mechanisms gained renewed interest recently where oxygen comes from the crystal lattice rather than adsorbed water/hydroxide. It is currently unknown how these prototypical mechanisms can be distinguished best. We calculated the Tafel slopes for these cases based on microkinetic analysis. We assumed OH-covered metal sites as resting state, which is more likely in alkaline solution. This contrasts previous similar analyses [3] based on bare metal sites. This information will guide the design of in situ experiments to experimentally identify one of the prototypical mechanisms on an oxide catalyst. A deeper understanding of the mechanism is desperately needed as it opens the ability to improve the mechanism and thereby enhance the activity beyond the present limitations.

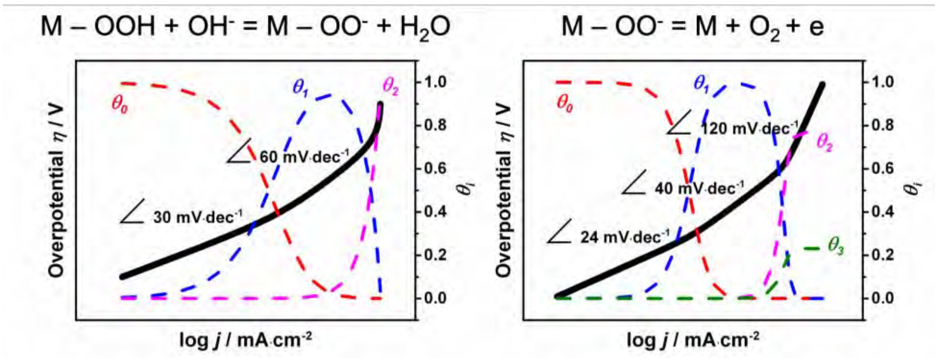

Fig.1.Tafel slope simulations of the two mainly discussed rate-limiting steps of the adsorption mechanism.

Development and upscaling of gas diffusion electrodes for CO_2 reduction and electrosynthesis of chemicals

Deepak Pant, Yuvraj Birdja, Metin Bulut, Jan Vaes
Separation & Conversion Technology, Flemish Institute for Technological Research (VITO), Boeretang 200, 2400 Mol, Belgium
Deepak.pant@vito.be

Technologies related to gas diffusion electrodes (GDEs) offer solutions for gaseous reagents taking part in electrochemical reactions. (Bio)electrochemical processes suffer from challenges like high costs of platinized electrodes[1]; rapid catalyst degradation and low performance due to non-uniform electrode quality[2]; difficulties in upscaling. Scaling up microbial fuel cells (MFCs) requires use of large electrodes which are often difficult to fabricate without loss in quality. VITO has developed GDEs tailored for systems with aqueous electrolytes and a gas-water interface, which are characterized by controllable pore diameters in the polymer-bound active layer, mechanical robustness and low water permeability[2]. These cold-rolled (VITOCORE®) and phase-inversion based (VITO CASE®) electrodes enable reproducible quality in sizes from 10 cm^2 to 1 m^2. Large-scale VITOCORE® air cathodes were recently developed and tested in 85 L and 255 L MFCs to evaluate the impact of the cathode size on MFC performance[4,5]. For CO_2 electroreduction, GDEs based on Sn, Cu and Pd were developed and evaluated for production of formic acid and oxalic acid.

Search for Organic Molecules for Use in Redox Flow Batteries

Mahsa Shahsavan, Rasmus Rönkä, Pekka Peljo
Research group of Physical Electrochemistry and Electrochemical Physics, Aalto University
P.O. Box 16100, 00076, Finland
mahsa.shahsavan@aalto.fi

Nowadays, large fraction of energy generation is from renewable sources; however, due to their intermittent behavior, it is impossible to make use of them whenever more energy is needed. Therefore, it is important to store large amount of the produced energy for use when the demand for energy is high. Redox flow batteries (RFBs) are a well-suitable choice to store energy but their current cost is too high, and commercialized systems require critical raw materials such as vanadium [1-3]. Our aim is to look for alternative materials for flow batteries. For this purpose, in our research we are looking for new organic molecules that can be used in aqueous RFBs. Although molecule screenings like this has been done before, in our work we evaluated over 20 commercially available organic molecules for flow battery applications that most of them were not studied before for the purpose of using in RFBs. These compounds were selected based on their commercial availability and based on their chemical structures that indicate redox activity because of their functional groups. The best possible candidates for use in RFBs were chosen according to their redox behavior, solubility and stability. Carminic acid, Gallocyanine, Indigo Carmine, Methylene Blue, Neutral Red, O-Dianisidine, Promethazine hydrochloride, Safranin O, Toluidine Blue O, H_2TauNDI (N, N'-di(ethanesulfonic acid)-1,4,5,8-naphthalenediimide) were the ones with promising results so that they can be tested for use in RFBs. Cyclic voltammetry (CV) measurements were done to determine redox behavior and stability of compounds. Concentration of 1mM of the solute and three different solvents such as 0.5M Sulfuric acid, 0.5M Potassium Sulfate and 100mM Sodium Hydroxide was used for pH 1,7 and 13 respectively. During the first scans, the full potential range was examined, and appropriate parameters were selected based on the redox peaks present, then scanning was repeated with different scan rates. According to the results, aforementioned molecules shows reversible reaction peak in acidic solution expect Carminic acid and H_2TauNDI. Standard redox potential of these molecules based on their CV result at scan rate 10mV/s, is shown in Figure 1.

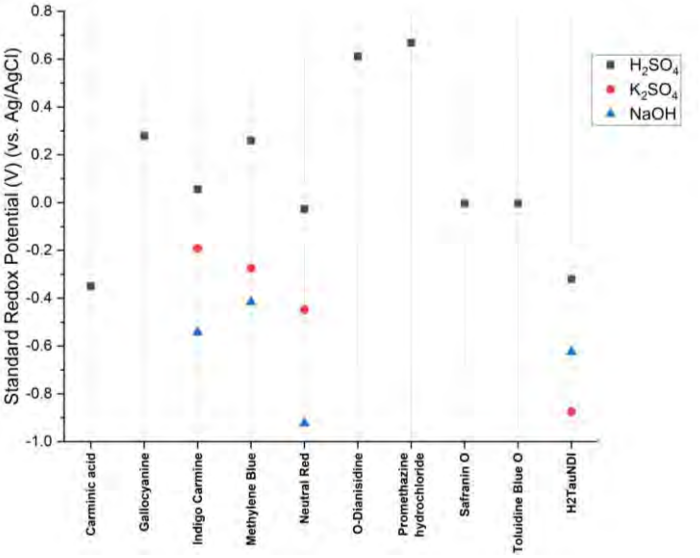

Figure 1- Standard redox potential of promising candidates, sweep rate 10mV/s

Fermented whey as natural descaling agent: Electrochemical and microscopical analysis

Aisholpan Kaziullayeva, Kayode Olaifa, Enrico Marsili
School of Engineering and Digital Sciences, Nazarbayev University
53 Kabanbay Batyr Avenue, 010000 Nur-Sultan, Kazakhstan
aisholpan.kaziullayeva@nu.edu.kz

The characterization of fouling and corrosion of steel is relevant to many industries including oil and gas, automotive, construction and home appliances. Electrochemical characterization of fouling and corrosion is rapid and effective, allowing routine analysis under a broad range of environmental conditions. Tap water in Nur-Sultan, Kazakhstan, is rich in carbonate due to contamination of surface water and insufficient drinking water treatment. This leads to strong fouling and corrosion-related problems in both home appliances and water transportation infrastructure. A broad range of de-scaling agents is available for industrial applications. However, access to chemical and services is still a major problem in rural Kazakhstan community, thus traditional methods are still used, which employ locally available materials. In the rural communities of the south-west regions, de-scaling of cooking equipment is carried out by fermented whey, which is widely available as by product of small-scale faming activities, and is rich in lactic acid, with a low pH ~ 2.8. The de-scaling properties of lactic acid are well-known, thus it is possible to formulate a low-cost, environmental friendly de-scaling agent for use in rural communities.

In this work, the scaling process of mild steel coupons was carried out through carbonate precipitation, which were then cleaned with water, fermented whey and food-grade vinegar as control (pH ~ 3). The scaling and de-scaling process were characterized through electrochemical methods and scanning electron microscopy (SEM). While the traditional cleaning time was ~ 15 h, it was observed that 3 h of treatment are sufficient for the de-scaling process. The corrosion potential and the corrosion current decrease after formation of the carbonate deposit (Figure 1). While both application of fermented whey and vinegar remove the fouling layer, they cause substantial pitting corrosion (Figure 1). A corrosion inhibitor should be added to prevent this effect. Overall, these results show that fermented whey can be used as environmentally friendly de-scaling agent. However, the traditional method of application causes damage to the steel surface and must be optimized, decreasing the exposure time and adding an inorganic corrosion inhibitor.

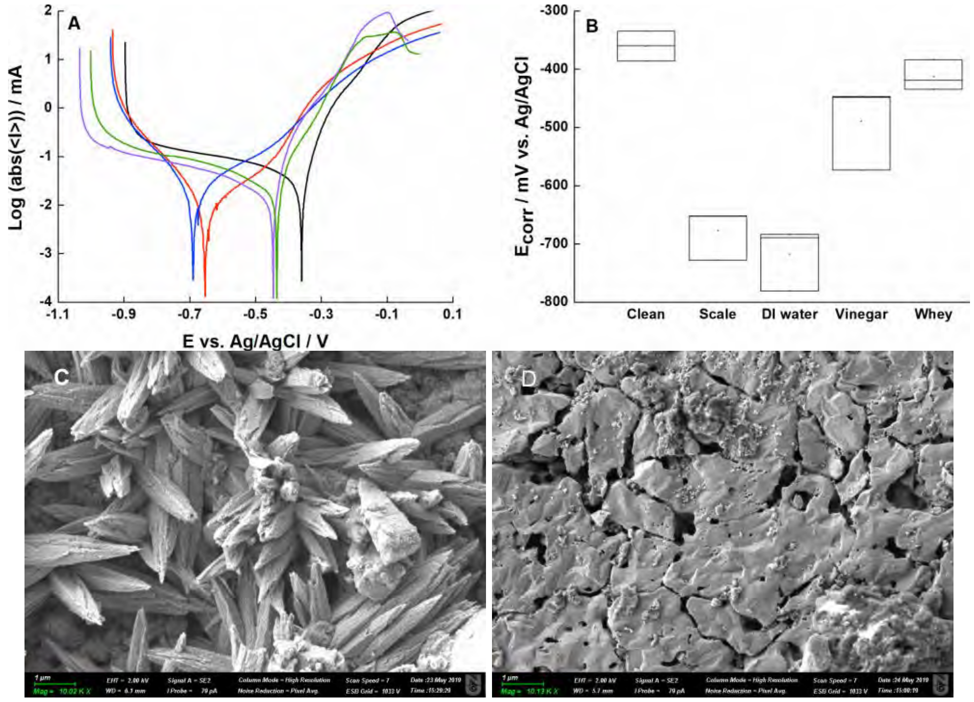

Figure 1: (A) Linear Sweep Voltammetry of mild steel coupons before (black) and after carbonate fouling (red), after cleaning with distilled water (blue), vinegar (magenta) and fermented whey (green); (B) Corrosion potential; SEM of (C) Scaled mild steel coupon; (D) whey cleaned.

Recurrence Quantification Analysis as a Tool to Investigate Current Oscillations Observed During the Mass-Transport Controlled Electrodissolution of Fe in Sulfuric Acid Solutions

Chrysanthi Gkili, Dimitrios Valavanis, Dimitra Sazou
Department of Chemistry, Aristotle University of Thessaloniki
Thessaloniki, T.K. 54124, Thessaloniki, Greece
e-mail address: chrysagkili@gmail.com

Recurrence is a fundamental property of nonlinear dynamical systems, which can be utilized in order to characterize the system dynamics in phase space. A visual tool for exploiting the recurrence behavior of phase space trajectories is the recurrence plot (RP) introduced in 1987 by Eckman et al [1]. On the basis of the RP, recurrence quantification analysis (RQA) can be carried out to identify different dynamical regimes and characterize transitions between them. Recurrence plots (RPs) and recurrence quantification analysis have been widely used in many scientific fields from chemistry, physics and engineering to life sciences, ecology and economy [2, 3]. RQA was also turned out to be a key issue revealing complex dynamics, phase and generalized synchronization in non-phase-coherent and even non-stationary time series of electrochemical systems and characterizing different corrosion states of metals and alloys [4-6]. This study aims in exploring non-linear quantifiers based on RPs and RQA in order to investigate complex current oscillations observed during the mass-transport controlled electrodissolution of iron in sulfuric acid solutions (Fe|0.75 M H_2SO_4 interfacial system). Under the potentiodynamic operation mode, Fe|0.75 M H_2SO_4 is a well-known electrochemical system exhibiting multiple oscillatory potential regimes depending on various control parameters [7]. Our focus here is on oscillations appeared in the limiting current region beyond a critical value of the ohmic potential drop and when proper hydrodynamic conditions are established across the interfacial region [8]. By applying two system configurations comprising an upward and a downward-facing Fe-disc electrode, visual changes in RPs plots and RQA measures, such as the average diagonal line (ADL), the trapping time (TT) and the longest vertical line (LVL) along with a new entropy quantifier, reveal different nonlinear correlations. The new entropy quantifier was based on recurrence matrix microstates that represent more general properties of the recurrence space as compared with the entropy quantifier based on just diagonal or horizontal lines of the recurrence space [9]. Indeed, the microstate-based entropy quantifier reflects correctly the system complexity in agreement with ADL, TT and LVL. All RQA measures indicate that the enhancement of the mass transfer affects the complexity and the transitions between different nonlinear dynamical regimes.

Due to the remarkably high theoretical energy and light weight, metal-air batteries represent one class of promising power sources for applications in next-generation electronics, electrified transportation and energy storage of smart grids [1]. The most prominent feature of a metal-air battery is the combination of a metal anode with high energy density and an air electrode with open structure to draw cathode active materials (*i.e.* oxygen) from air [1]. Gas Diffusion Electrodes (GDEs), made of a two-layer or a three-layer structure, are widely used as cathode in metal-air devices [3]. However, one of the main drawbacks related to the cathodic reaction (ORR) is the overpotential loss (about 0.3-0.4 V) under operation condition. Thus, lots of efforts were spent to inhibit the voltage loss requiring an effective ORR catalyst [1,4]. One of the most promising materials, in terms of both performances and costs, seems to be manganese dioxide. According to the recent literature, MnO_2 would ensure capacities comparable to those of platinum, letting higher capacity retention to be reached in non-aqueous electrolytes to prevent Li decomposition [5,6].

In the present work, the electrochemical performances of either bare or Fe/Co-doped (at both 2% and 5%) MnO_2 nano-electrocatalysts are evaluated by Linear Sweep Voltammetries (LSVs). The crystal structure and the surface properties of the present materials are examined by means of XRPD, BET-BJH, TEM, SEM/EDX and XPS analyses. Correlations between their physico-chemical features and the final electrocatalytic performances are drawn. Experimental results reveal that the as-synthesized powders have excellent electrochemical properties in organic electrolytes (0.15 M $LiNO_3$ in propylene carbonate, PC) showing a shift of the onset potential of about 150 mV with 2% Co-doped MnO_2 (Figure 1), thus resulting very promising candidates to be used in lithium-air batteries.

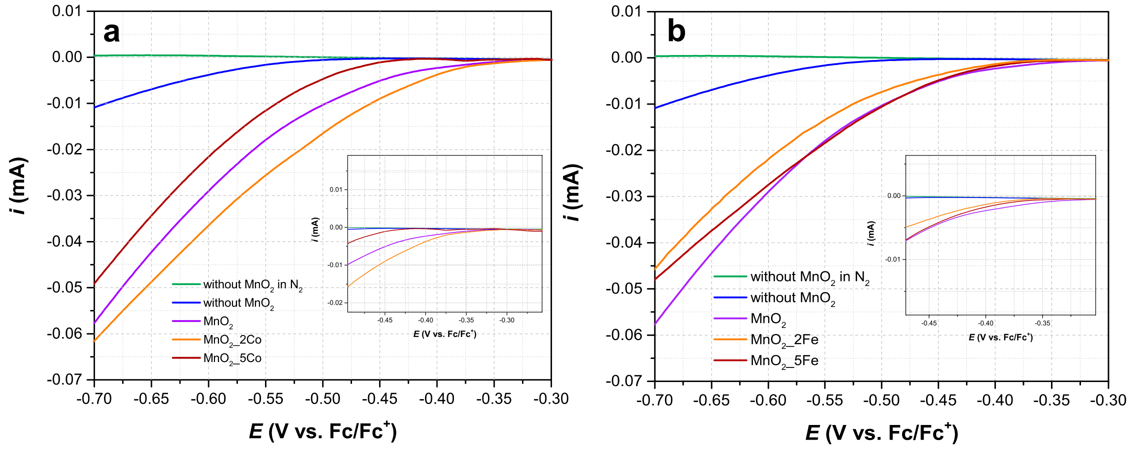

Figure 1. Comparison of ORR onset potentials obtained with (a) Co-doped and (b) Fe-doped MnO_2 nano-electrocatalysts modified glassy carbon electrodes through LSVs tests (in 0.15 M $LiNO_3$/PC).

andreas.hellmann@uni-ulm.de

Next to the free radical superoxide ($O_2^{-}\cdot$) and hydroxyl radical ($OH\cdot$), the stable and non-radical hydrogen peroxide (H_2O_2) is one of the most extensively studied reactive oxygen species (ROS). This group of destructive molecules can lead to protein oxidation, lipid peroxidation, and DNA damage and elevated ROS production leads to oxidative stress. Therefore, its detection is of particular interest since the involvement and concentration levels of H_2O_2 at the cellular level are not fully understood yet. H_2O_2 is frequently determined via electrochemical measurements. However, the relatively high oxidation potential (+0.6 V vs. Ag/AgCl) of H_2O_2 may lead to false positive results due to co-oxidizable compounds such as ascorbic acid, catecholamines etc., present in biomedically relevant samples [1].

To overcome these challenges, strategies for electrochemical H_2O_2 detection at low potential will be presented avoiding such interference problems based on electrocatalytically modified microelectrodes. As these studies are targeted towards cell measurements (granulocytes and peripheral blood mononuclear cells from pigs, which are subjected to an acute subdural hematoma) at low sample volumes, microelectrodes will be used. To enhance sensitivity for H_2O_2 detection, microelectrodes are modified with Platinum black (H_2O_2 detection at +0.3 V vs. Ag/AgCl) [2] or Prussian Blue (PB) (H_2O_2 detection at +0.05 V vs. Ag/AgCl) [3,4]. As catecholamines are administered during the recovery phase of pigs, a two-electrode approach is pursued using Platinum black modified electrode for H_2O_2 detection and for example, a carbon fiber electrode (+0.4 V vs. Ag/AgCl) for the detection of catecholamines. Carbon based electrodes are suitable for the detection of catecholamines such as norepinephrine and epinephrine [5] but show no significant signal for H_2O_2 at the detection potential. Next to the thorough characterization of the microsensors, measurements alongside control experiments at granulocytes and peripheral blood mononuclear cells from pigs, which are subjected to an acute subdural hematoma, will be presented.

Electrochemical impedance time variation of electrodialysis using lithium ion electrolyte $La_{0.57}Li_{0.29}TiO_3$

Kiyoto Shin-mura[1], Yuma Hachinohe[2], Sogo Shinohara[2], Kazuya Sasaki[1,2]
[1] Graduate School of Science and Technology, Hirosaki University,
[2] Department of Science and Technology, Hirosaki University
[1,2]3 Bunkyo-cho, Hirosaki, Aomori 036-8561, Japan
k_sasaki@hirosaki-u.ac.jp

There is a need for a better recovery technology for supplying a large amount of high-purity lithium for a lithium-ion battery at low cost. Electrodialysis using a lithium-ion electrolyte is a promising candidate technology. When electrodialysis was performed using a lithium ion electrolyte $La_{0.57}Li_{0.29}TiO_3$ (LLTO) plate, despite the constant applied voltage, as shown in Figure 1, the lithium transfer rate increased with the dialysis time to a certain value. In this research, we clarify the cause of this peculiar phenomenon.

An anode (primary solution side) and a cathode (secondary solution side) electrodes were formed on both sides of the LLTO. Reference electrodes were formed on the LLTO surfaces away from the anode and cathode. The reference electrodes were placed inside or outside the solution, depending on the experimental purpose. A DC voltage was applied between the anode and the cathode. The electrochemical impedances between the reference electrode on the primary solution side and the anode and between the reference electrode on the secondary solution side and the cathode during the application of this voltage were measured by AC impedance method. The measured electrochemical impedances correspond to the ionic conduction resistance and electrode reaction resistance of the electrolyte near both surfaces of the LLTO.

As shown in Figure 2, all these resistances were stable on the primary side regardless of time, but on the secondary side, they decreased toward constant values during voltage application. The values on the secondary side were greater than those on the primary side.

It is considered that these phenomena are caused by uneven distribution of Li^+ concentration generated in the LLTO plate during electrodialysis. That is, the Li^+ elution reaction into the solution that occurs on the secondary surface of LLTO is slow, and the Li^+ concentration increases near the secondary surface of LLTO during voltage application. At this time, titanium ions are reduced from tetravalent to trivalent for charge compensation. This reduction causes the crystal lattice to expand. As a result, the bottleneck of Li^+ migration widens, and the electrode reaction resistance on the secondary solution side of LLTO and the electrolyte resistance near the surface decrease. These changes stop when equilibrium is reached. The phenomenon shown in Figure 1 may be the result of these series of changes due to the uneven distribution of Li^+.

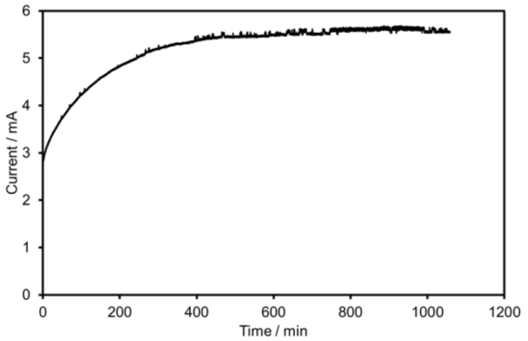

Figure 1 Current change with electrodialysis time.

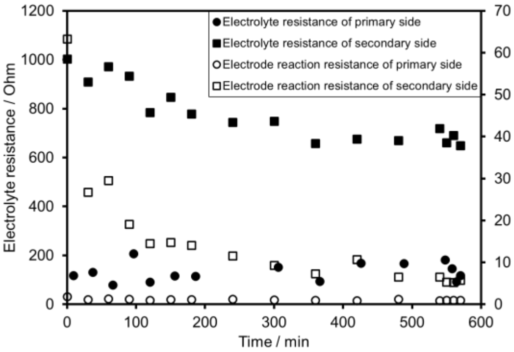

Figure 2 Changes in electrolyte resistance and electrode reaction resistance with electrodialysis time.

n-doped GaP nanowires: Potential Photocatalytic cathodes for Carbon (IV) oxide reduction

O.O. Fashedemi .[a,b*] K. Krischer,[a]

Increasing CO_2 concentration in the atmosphere is believed to have a profound impact on the global climate. One of the ways to reverse this negative impact is developing effective strategies to capture and utilize CO_2 from the atmosphere. Among several available strategies, CO_2 reduction via the electrochemical or photochemical approach is particularly attractive since the required energy input can be potentially supplied from renewable sources such as solar energy [1]

Compared to other available semiconductors, gallium phosphide (GaP) is considered a highly promising photocathode material for solar-fuel conversion. Its high conduction band edge allows it to reduce not only water into hydrogen but also CO_2 into chemical fuels [3]

However, the conventional planar geometry from a single crystalline wafer poses an obstacle to exploring the potential of GaP fully, since in the planar geometry most of the photons absorbed by GaP do not fall within the charge collection layer, as is required for an efficient photo electrode. [3] Recent progress indicates that this issue could be solved when the photo electrode is composed of semiconductor micro wires [4]

We have synthesized GaP nanowires by the reaction between gallium vapor and phosphorus vapor inside a tube furnace system. The as synthesized nanowire Gap were also deposited on carbon nanotubes (CNTs). The nanowires were characterized by Field emission scanning electron microscopy (FESEM) and X-ray diffraction (XRD). We present some of our findings on the exploration of these nanowires deposited on glassy carbon surfaces and GaP wafers as effective photocathodes for CO_2 reduction.

Faceting and Nanostructuring of Au through Cathodic Corrosion: Role of Cationic Electrolyte Species and Water

Mohamed M. Elnagar, Johannes M. Hermann, Timo Jacob, Ludwig A. Kibler
Institute of Electrochemistry, Ulm University
Albert-Einstein-Allee 47, 89081 Ulm, Germany
mohamed.elnagar@uni-ulm.de

Gold is one of the most frequently employed electrode materials in electrochemistry due to its exceptional properties such as chemical inertness and high resistance to oxidation and dissolution [1]. According to Pourbaix diagrams, gold is considered stable against degradation under cathodic polarization [2]. In contrast, applying relatively high negative potentials in the presence of alkali metal cations induce notable changes on Au electrode surfaces [3]. In this study, cathodic corrosion of polycrystalline gold in different electrolytes of alkali metal hydroxides has been systemically investigated. In comparison to the recent work [3], this study provides new findings as a function of the applied parameters for the nanostructuring of gold surfaces. Cell design and the distance between the electrodes have carefully been controlled and optimized. The progression of surface restructuring and corrosion features was investigated using cyclic voltammetry (CV) and scanning electron microscopy (SEM). The results show different corrosion features depending on the nature and the concentration of alkali metal hydroxides, on the applied voltage, and on time. Current-potential curves for the modified electrodes in 0.1 M H_2SO_4 show characteristic features in the double-layer and oxidation regions. Cyclic voltamogramms of the corroded electrodes provide evidence about the preferential orientation of facets and the electrochemical active surface area as a function of the applied parameters. SEM micrographs show that polarizing the gold surfaces at relatively high negative potentials generates different size and orientation of octahedral nanocrystals using NaOH, spherical nanoparticles and triangular pits using KOH and triangular pits using LiOH. Besides the alkali metal cations, the electrolyte concentration and the applied voltage are important parameters.

Furthermore, the role of water in cathodic corrosion of gold has been investigated using mixtures of different mole fraction of water and non-aqueous electrolytes. The absence of corrosion features using water-free non-aqueous electrolytes reveal that water plays a key role in the cathodic corrosion process.

In addition, various aqueous mixed electrolytes have been systemically investigated. The results show combined corrosion features according to the mole fraction of different cations. For example, a 1:1 NaOH + LiOH mixture leads to the formation of rectangular pits which are attributed to (100)-facets compared to a 1:1 KOH + LiOH mixture which leads to triangular pits revealing the formation of (111)-facets.

Electrochemical Evaluation of Various Nanoparticles-based Sensors for Levothyroxine Detection

Melinda David, Adrian Şerban, Monica Florescu
Faculty of Medicine, Transilvania University of Braşov, Bulevardul Eroilor 29, Braşov 500036, Romania
melinda.david@unitbv.ro

Carbon-based nanoparticles, such as graphene and carbon nanotubes or gold nanoparticles are widely used since they are good conducting materials, assure an enhanced effective surface area and biocompatibility or are able to catalyze specific reactions.

Levothyroxine (LT4) is used as medication in a large variety of medical conditions, like hypothyroidism, where the best therapy is the hormone replacement. LT4 replaces the thyroxine hormone normally produced by the thyroid gland which regulates the body's energy and metabolism. Since the effect of administration of LT4 can be monitored mainly through clinical observations, monitoring of LT4 levels requires a simple, reliable tool, such as label-free nanoparticle based sensors. Analyzed carbon nanotubes in this work can act similar to enzymes, and thus they have been used for label-free sensors development as rapid screening tools for LT4 with a sensitivity of 4 μA cm^{-2} μM^{-1} and a limit of detection in nanomolar range.

Electrochemistry was used for the characterization, comparison and optimization of the most suitable nanoparticle-based sensors for LT4 detection (Fig. 1). The oxidation mechanisms of LT4 together with the interfacial changes, which occur due to their electrochemical properties at sensor surfaces, were studied by electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV). The analytical performance of the sensors was evaluated by differential pulse voltammetry (DPV).

The abuse of illicit drugs has become a global concern considering its close relationship with the increasing incidents of crimes and severe social problems. The widespread use of illicit drugs and the consequences of drug abuse on individuals and societies has led to increasing efforts to quickly and accurately detect drugs on-site. The current methods used to quickly detect drugs on-site are presumptive tests, such as color-tests. However, they lack selectivity, giving a high number of false negative and false positive results, due to the presence of adulterants and cutting agents.

Electrochemical methods proved to be excellent techniques for the fast determination of drugs with high sensitivity and specificity, suitable for the development of miniaturized portable devices to be used in-field.

Drugs are usually adulterated with adulterants (added to modify the properties of the drugs or to mimic the drugs' effects, e.g. procaine has local anesthetic effect similar to cocaine) or diluted with cutting agents (used to 'cut' or 'dilute' the sample). The characterization of cutting agents and adulterants in seized cocaine samples is important from a forensic point of view in order to link different seizures to one original batch, as well as for the health implications some of them might have. For instance, levamisole used as adulterant in cocaine samples was linked to serious adverse effects such as leukoencephalopathy.

We used nanomaterials-modified electrodes to detect cathinones and adulterants/cutting agents by means of square wave voltammetry. We tested several nanomaterials-based platforms and depending on the obtained signal for the oxidation of drugs we chose graphene and carbon-nanotubes based platform to further test cathinones. We investigated several cathinones (such as methcatynone, chloroetcathinone) and adulterants/cutting agents such as mannitol, sorbitol, procaine, benzocaine, creatine. The effectiveness of the developed method was tested for the detection of drugs in simulated drugs samples.

1D nanostructures exhibit a very high surface to volume ratio as well as unique electrical properties which make them ideal candidates to build high performance electrochemical sensors and bio-sensors [1]. Bismuth nanostructures are considered as “green” electrode materials since 2000 and gained an increased interest for detecting various analytes [2]. Usually, size- and shape-controlled Bi nanowires (Bi NWs) are electrochemically synthesized involving aqueous electrolytes and template-assisted method. Other 1D Bi nanostructures may be prepared using the hydrogen bubble template electrodeposition method [3].

Herein, the electrochemical synthesis of Bi NWs is reported, involving electrolytes based on eutectic mixtures of choline chloride with oxalic acid or malonic acid (the so-called “deep eutectic solvents” – DES). The”soft template” electrodeposition based on a proper selection of the surfactant/stabilizer, as well as the classical template-assisted method using porous membranes have been applied (see Fig.1).

The electrochemically synthesized nanowires have been characterized using SEM, STEM and XRD investigations. Cyclic voltammetry has been selected as electrochemical technique in order to get more information on the Bi NWs deposition process and on the influence of the main operation parameters, mainly the applied current density/deposition potential, and the electrolyte composition. A comparative analysis of the structural features of the obtained Bi NWs using the soft template method and the traditional template-assisted technique is provided, too.

In addition, preliminary results related to their electrochemical sensing performance for folic acid and hydrogen peroxide are also discussed.

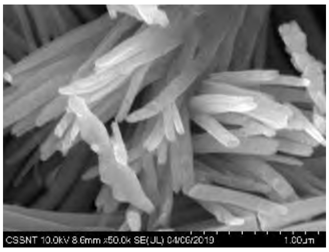

Figure 1. SEM micrograph of Bi NWs using „soft” template

Illicit drugs use and abuse remains an increasing challenge for worldwide authorities and, therefore, it is important to have accurate methods to detect them in seized samples, biological fluids and wastewaters. They are recently classified as the latest group of emerging pollutants as their consumption increased tremendously in recent years.

Nanomaterials have gained much attention over the last decade in the development of sensors for a myriad of applications. The applicability of these nanomaterials, functionalized or not, significantly increases and are therefore highly suitable for use in the detection of drugs of abuse.

We have assessed the suitability of various nanoplatforms for the electrochemical detection of illicit drugs, such as graphene, singled-walled carbon nanotubes, multi-walled carbon nanotubes functionalized with platinum nanoparticles, gold nanoparticles and platinum nanoparticles. Graphene and singled-walled carbon nanotubes were drop-casted onto graphite screen printed electrodes and left to dry at room temperature. Multi-walled carbon nanotubes were functionalized with platinum nanoparticles using a simple and efficient chemical process, in which carboxylic acid-functionalized multi-walled carbon nanotubes were mixed with chloroplatinic acid in a mixture of ethylene glycol and water to result in platinum-functionalized multi-walled carbon nanotubes. The functionalized multiwalled carbon nanotubes were drop-casted onto graphite screen printed electrodes. Gold and platinum nanoparticles were deposited by electrodeposition from a solution of chloroauric acid and chloroplatinic acid, respectively, by cyclic voltammetry.

The electrochemical fingerprints of cocaine and cathinones (such as mephedrone, alpha-polyvinylpirolidone, methylmethcatinone, chloroethcatinone, chloromethcathinone, etylone) were elucidated on the above-mentioned nanoplatforms. Square wave voltammetry was performed as a high-performance electrochemical method. This allowed for the sensitive and selective (class selectivity) of the investigated illicit drugs.

Ceramic Nanofibers: A versatile material class to improve Electrochemical Energy Applications

Florian Lombeck[a], Friedemann Hegge[b], Miriam von Holst[a] , Severin Vierrath[a,b], Matthias Breitwieser[a,b]

Nanofibers exhibit a large surface-to-volume ratio as well as high porosity. Ceramic materials have excellent thermal stability and are largely chemically inert.[1] In electrochemical energy devices, such as fuel cells, electrolyzers and batteries, (electro-) chemical reactions take place at the interface of an electrode with gas (H_2/O_2), a liquid or an electrolyte, respectively. In these devices, the combination of a high active surface area for improved reaction rates, large porosity for a substantial material flux, thermal and chemical stability for long term operation as well as conductivity for electron transport processes are of vital interest. Nanofibers are usually fabricated by the electrospinning technique. The liaison of appropriate material combinations, spinning parameters and post-treatment procedures gives rise to a vast spectrum of tailored nanofibers with fine-tuned properties such as catalytic activity, electrical conductivity, radical scavenging activity or chemical resistance.[2]

In our work, we demonstrate with two recent examples, that the integration of ceramic nanofibers into electrochemical energy systems enables significant improvement of the properties of electrochemical enery systems: In Fig. 1 (left) CeO_2 nanofibers are shown, which can be used as radical scavenging membrane additive. Secondly, IrOx nanofibers enable a significant reduction of - usually expensive - catalytic material *via* providing electrically conductive pathways (Fig. 1, right). Upon reducing the amount of catalytic material, islands of non-connected catalyst are formed. Conductive ceramic nanofibers electrically link these islands, thus utilizing more catalytically active surface area. By this approach, we showed a reduction of 80% Iridium oxide at the anode of a proton exchange membrane (PEM) water electrolyzer cell while maintaining its high performance.[3]

Stabilization effect of Pt on FeNC: A gateway to elucidation of degradation mechanism of FeNC in PEMFC

Hydrogen fuel cells (such as PEMFC) could reduce or possibly replace the fossil fuel dependency if the high cost and low durability issues of the fuel cells are resolved. Non-precious metal-based materials (such as FeNC) are promising candidates to replace expensive Pt-based catalysts and thereby reducing the cost of the fuel cells. Although these catalysts show a decent activity, their poor stability, especially at high potentials, limits their applicability.[1,2]

Among the various approaches to stabilize FeNC catalyst, our recent approach of adding minute amount (0.5-2 wt%) of Pt was successful in stabilizing FeNC. Pt itself remains in an ORR-inactive state throughout the measurement.[3] Although stabilization with the addition of Pt, which itself is an expensive metal, may not be a better option, a proper illustration of how Pt stabilizes FeNC during ORR in fuel cell would give us a better insight into the degradation mechanism of FeNC.

Here, we elucidate the nature of this Pt-species and its role in the stabilization of the Fe-N-C to understand FeNC degradation mechanism and possible ways to prevent them. Structural analysis with high-resolution TEM of the hybrid Pt/Fe-N-C catalyst, indicate a protective Fe-shell is formed around the Pt-particles, making them ORR-inactive. Nevertheless, electrochemical analysis proves that the hybrid catalyst reduces H_2O_2 formation (an undesirable side product of ORR) as well as reduced catalyst degradation. Besides, electron paramagnetic resonance (EPR) spectroscopy on hybrid Pt/Fe-N-C shows the formation of less radical oxygen species (ROS), which are potentially harmful to the catalyst (Figure 1). These results prove the ability of the deposited Pt-species to significantly reduce the amount of ROS, ultimately increasing the stability of hybrid Pt/Fe-N-C in PEMFC.

In order to tackle the environmental issues, caused by our excessive reliance on fossil fuels, one of the things we need to develop are efficient alternatives to internal combustion engines for transportation. One alternative are low-temperature proton exchange membrane (PEM) fuel cells. To produce clean electricity, PEM fuel cells require an electrocatalyst that is usually based on Pt or Pt-alloy nanoparticles supported on high surface area carbons.

In order to study the structure-activity and structure-stability relations of such materials, transmission electron microscope (TEM) is one of the essential tools commonly used to do so. As part of TEM analysis, numerous microscopic images (in other words large amounts of data) of the studied materials must be taken and analyzed.

To quantify the data within the TEM images, different software options are available [1]. However, most software solutions cannot reliably recognize all the relevant features in an image, such as overlapping and out-of-focus features. For a given type of material, it often turns out that researchers write their own software which is more reliable than the one-size-fits-all commercial options, but the exact code is commonly not made available to the public [2].

In this contribution, we will present new image-analyzing algorithms, which have the potential to be more efficient and reliable than the classical ways of analyzing STEM images. Here, various machine learning methods are included, where the goal is to analyze large amounts of information in a short time and care is taken that the user interaction is kept to a minimum, which will ensure less biased output information [3].

As the studied system, a series of HAADF-STEM images of a platinum-based electrocatalyst were selected, which are in the form of platinum-copper alloy nanoparticles, embedded in a carbon support [4]. The output information includes all the quantifiable data that can be extracted from the images, such as the histograms of size distribution, information about homogeneous surface coverage, spatial information and more. As part of this work, we will discuss how to prepare the input data for analysis, how to obtain output data with novel computational methods and how to deal with challenges such as resolving overlapping particles.

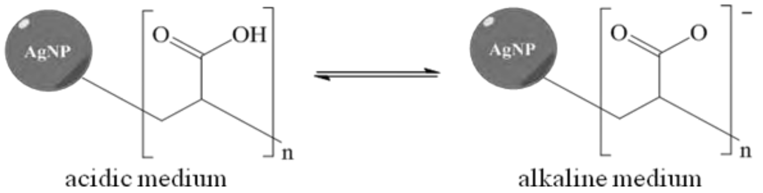
ivaniseivc@fkit.hr

In recent years, silver nanoparticles (AgNPs) have received great attention due to their unique optoelectronic and physicochemical properties resulting in various applications [1, 2]. This study reports a wet chemical synthesis of AgNPs, using hydrazine monohydrate as a reducing agent and poly(acrylic acid) (PAA) as a capping agent [3]. PAA-coated silver nanopowders, precipitated with inorganic acids (perchloric, phosphorous and sulfuric), were used for nano-ink formulations. Characterization of the reaction mixture, as well as of the prepared conductive inks, was performed by cyclic voltammetry and UV-Vis spectroscopy, respectively.



Schematic presentation of PAA-encapsulated AgNPs in acidic and alkaline medium.

PAA adsorbed on the nanoparticle surface behaves as a weak acid. In alkaline media, negative surface charge generated due to the dissociated PAA engenders repulsion forces between nanoparticles. Thus, efficiency of electrostatic stabilization of the prepared suspension depends on the acid dissociation rate. The stability of the formulated nano-inks was tested in a wide range of Britton-Robinson buffer solutions. The highest anodic current responses and maximum absorbance (λ = 419 nm) were plotted versus pH to determine the quantity of surface bound PAA.

Folded V_2O_5 Scaffolds for High Energy Density Aluminum-Ion Batteries

Zaklina Burghard, Achim M Diem, Joachim Bill
Institute for Materials Science, University of Stuttgart, Germany
Heisenbergstarsse 3, 70569 Stuttgart
zaklina.burghard@imw.uni-stuttgart.de

Unidirectional ice-templating of aqueous V_2O_5 nanofiber dispersions yielded scaffolds with an anisotropic structure, wherein well-aligned lamellas form ordered channels (**Figure 1a**). The latter are optimally suited to facilitate ion diffusion throughout the entire scaffold architecture. The micrometer-sized pores in the form of cavities as well as the mesoporosity (~5 nm pore size) of the lamellas and pillars lead to an exceptionally high porosity of 99.9% and a high specific surface area of 211 m²/g. By compressing the scaffolds, compact electrodes were obtained. To ensure their mechanical stability, the scaffolds were tested under compression and the microstructure of the resulting compact electrodes was investigated. From the compressive stress-strain curves we concluded that above 50% strain the scaffolds start to densify forming a densely packed disc at 80% strain. The latter shows a two-fold enhancement of the electrical conductivity vs. the pristine sample. Microstructural analysis of the densely packed disc evidenced the presence of an open surface porosity, as well as a corrugated lamella structure that comprises new contact points (**Figure 1b)**. The preservation of a high porosity (99.6%) and the transformation into a folded lamella structure without any appreciable damage represent exceptional features of these scaffolds, appointing them as outstanding in respect to other cathode materials. The extraordinary anisotropic porosity of the electrodes, combined with their large surface area, effectively compensate for the restricted diffusion of the ions, thus allowing for the discharging of the cathodes at higher current densities (500 mA/g, 105 mAh/g vs. 2000 mA/g, 58 mAh/g) [1]. Moreover, in comparison to the dense paper-like cathode materials, higher capacities at the same current density were achieved, which further highlights the importance of the unique porous structure. The increased area of the electrode/electrolyte interface and the channel-like structure along the ion diffusion paths (**Figure 1c**) synergistically enable the increase of the applied current densities, while largely preserving the capacity. Remarkably, the porous scaffolds feature significantly increased energy densities up to 52 Wh kg^{-1}, which outperform not only the paper-like cathodes[2], but also the state-of-the-art V_2O_5-based electrodes for aluminum-ion batteries (**Figure 1d**). The developed nanostructured cathodes are promising for application as binder-free electrodes in metal-ion batteries, featuring enhanced capacity and energy density at high current densities.

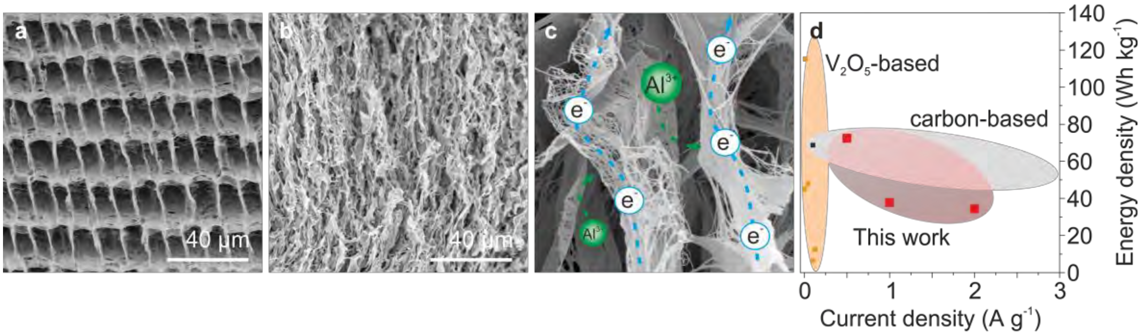

Figure 1. SEM images of the V_2O_5 scaffold microstructure, showing the cross-section and surface (a) before and (b) after compression at 80% strain, respectively. (c) Higher magnification SEM image of the microstructure with characteristic folded lamellas. Overlaid is a schematic illustration of the electron and ion paths during electrochemical cycling. (d) Comparison of the electrochemical performance to state-of-the-art V_2O_5- and carbon-based cathodes.

CNF-AG as highly flexible, high performance separator for shape-conformable metal ion batteries.

Flexible separators with minimal impact on the battery cell performance, are nowadays important due to the rapidly developing flexible electronics. In this context, a novel bio-degradable and highly flexible cellulose-nanofiber aerogel (CNF-AG) separator is developed, fabricated by ice-templating. [1], [2] The tailored channel-like structure provides a network of meso- and macropores, yielding a high porosity of 99.5%. The synergy of the high structured porosity, affinity of the cellulose to the electrolytes and mechanical stability greatly improves the separator performance, compared to the state-of-the-art glass fiber (GF) membranes. An enhanced electrolyte uptake capability is obtained, one order of magnitude higher than that for the GF. In addition, the thermal characteristics analysis revealed a high stability up to 200°C, ensuring the separator's suitability for batteries working under harsh conditions. Furthermore, an enhanced ionic conductivity of 2.4 mS cm^{-1} and 8.4 mS cm^{-1} is achieved for Li- and Al-based electrolytes, respectively. The comparison of the Li^+ diffusion coefficient in GF and CNF-AG, revealed 60% faster diffusion in the CNF-AG. Compared to GF, an improved electrochemical performance is obtained, in regards of a decreased interfacial resistance of 300 Ω, and the significantly stable cell cycling ability reaching high specific capacities. The good mechanical stability as well as the low impact on the battery cell performance revealed the suitability of the CNF-AG as separators for metal ion batteries.

sara.grecchi@unimi.it

Chiral membranes are important tools for enantiomer discrimination or/and separation in a broad range of applications, especially concerning preparative separations in the pharmaceutic field. Many chiral membranes are of natural origin (*e.g.* polysaccharides, polyaminoacid derivatives), or based on natural chiral components while less common so far are membranes based on synthetic chiral components (*e.g.* calixarenes or crown ethers). However, synthetic chiral membranes have interesting intrinsic features, like wide range of molecular designs and functional properties, equal availability of both enantiomers, and easy synthesis scalability. Among analytical applications of chiral membranes, a potentially interesting one concerns implementation as key components in chiral potentiometric sensors. Concerning design of synthetic membranes, different stereogenic elements can be considered to endow them with chirality, the most common ones being localized stereocenters, but it was observed that much better enantioselection performances can be obtained by implementation of the "inherent chirality" strategy. [1-2] In this frame we have discovered that the electrooligomerization, in acetonitrile as solvent, for 108 deposition cycles, on an ITO electrode support, of our "inherently chiral" benchmark monomer, leads to self-standing racemic or enantiopure membranes. These ones were obtained by simply peeling off the solid deposit from the ITO immersed in water after the electrodeposition in acetonitrile. We have then characterized inherently chiral membranes with different techniques (*e.g* FTIR, HR LDI, scanning electron microscopy, BET for surface area and pore size distribution, CD spectra to check that chirality was fully transferred from the monomer to the oligomer films, and atomic force microscopy) comparing the racemic *vs* enantiopure deposit properties. We have decided to implement enantiopure inherently chiral membranes in a "ion-selective like" set-up in order to study their enantiorecognition capability (as depicted in the Figure). First of all we have verified the potential difference was read correctly through the membrane to allow correct determinations of transmembrane potentials. After that we have tested enantiopure membranes in the presence of chiral charged species (in all configurations for both membranes and internal/external electrode solutions) for determining their enantioselective capability [3]. Preliminary results are very promising and encourage us to perform the scaling up of the membrane electrosynthesis to be used for industrial scopes and to extend the study to other probe useful in the analytical and pharmaceutical field.

oriol.gutierrez@uantwerpen.be

Typical CO_2 electrolyzers require gas feeding or to prior saturate the electrolyte to be able to electrocatalytically convert CO_2 to carbon products. If CO_2 is captured and stored in aqueous alkali solution as a carbon pool, then it can be used as a feedstock for a CO_2 electrolyzer. In weak alkali media, CO_2 is present as bicarbonate (HCO_3^-) and, since it requires high thermal energy to extract the CO_2 back, it is convenient to find an active catalyst and an optimal electrochemical cell able to electrocatalytically convert bicarbonate directly to carbon products. Firsts electrolysis experiments using different concentrations of bicarbonate as carbon source showed faradaic efficiencies around 10% towards formate ($HCOO^-$) at -0,7 V vs RHE using bulk Sn as cathode. The faradaic efficiency variations were negligible when increasing the concentration of bicarbonate and, by comparing the results to analogous experiments using saturated CO_2 solutions, where the faradaic efficiency raised up to more than 70%, it is concluded that, even though there is conversion from bicarbonate solutions, the efficiency is very low compared to typical CO_2 saturated electrolytes. A model is proposed (figure 1) in order to increase the faradaic efficiency of the reduction of bicarbonate by approaching the inhibition of the main co-reaction undergoing at the same time, which is consuming most of the current, the hydrogen evolution reaction (HER). HER is inhibited by forming an hydrophobic non-polar layer close to the surface of the working electrode with the addition of cationic surfactants to the electrolyte. The model is tested by measuring the response of the current within a certain potential range in electrolytes with surfactants of different nature. Cetrimonium bromide (CTAB) is chosen as a potential inhibitor obtaining an increase in the faradaic efficiency from 10 to 50% at -0,7 V vs RHE in 2 M bicarbonate and 2.5 mM CTAB electrolyte. After that, the cationic surfactant is optimized in order to not only inhibit HER, but also promote HCO_3^- reduction. A benzyl-functionalized surfactant, cetalkonium chloride (CKC), is used as HER inhibitor and CO_2R promotor obtaining conversion efficiencies up to 80% in the same conditions, higher than CO_2 saturated electrolytes. It is proven that, by increasing the hydrophobicity of the cathode surface, polar molecules, like water, are repelled while non-polar molecules, like CO_2 (derived from the HCO_3^- aqueous equilibrium), are promoted to cross the hydrophobic layer, approach the surface of the electrode and reduce.

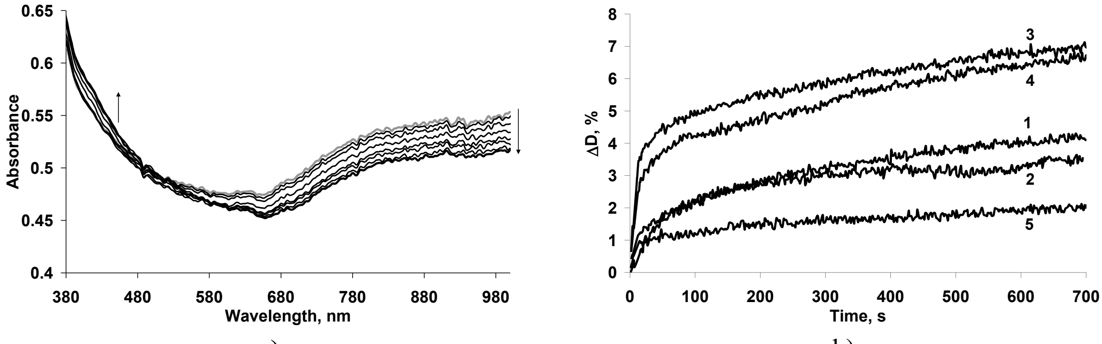
e-mail: oxgribkova@gmail.com

We present a comparative study of pyrrole electrochemical polymerization in aqueous solutions of sulfonated polyelectrolytes with different structure and flexibility of the polymer backbone. Polypyrrole (PPy) synthesis was carried out in the presence of the following polyelectrolytes: flexible-chain poly(styrene-4-sulfonic acid) (PSSA) and poly-2-acrylamido-2-methyl-1-propanesulfonic acid (PAMPSA), semi-rigid-chain poly-(4,4’-(2,2’-disulfoacid)-diphenylen-iso-phthalamide) (i-PASA), rigid-chain poly-(4,4’-(2,2’-disulfoacid)-diphenylen-tere-phthalamide) (t-PASA) and their sodium salts. The processes of PPy electrodeposition in potentiodynamic, potentiostatic and galvanostatic regimes was studied by in situ spectroscopy in the UV-Vis-NIR spectral regions and Raman spectroscopy with simultaneous monitoring of the electrochemical parameters of the synthesis. For comparison, the electrosynthesis of PPy was also carried out in common aqueous solutions of H2SO4 and Na2SO4. The obtained films were characterized by cyclic voltammetry, UV-Vis-NIR spectroelectrochemistry.

It was shown that the course of synthesis and the electronic structure of PPy/polyelectrolyte complexes depended strictly on the structure of polyelectrolyte and the nature of its cation. In the presence of the acid forms of flexible-chain polyelectrolytes the films are formed with higher absorbance in the NIR range (higher degree of charge carriers’ delocalization), with more rough surface and spectroelectrochemical properties similar to those of PPy films obtained in inorganic electrolytes. Contrarily, PPy films obtained in the presence of the acid form of semi-rigid-chain i-PASA are characterized by lesser roughness and lesser degree of charge carriers’ delocalization.

PPy films were successfully tested as sensitive layers in optical ammonia sensors (Fig.1a). The optical responses of these sensors in Vis-NIR spectral range were dependent on the polyelectrolyte structure (Fig.1b). It was shown that optical sensors based on films of PPy complexes with salt forms of all polyelectrolytes and rigid-chain polyelectrolytes in the acid form can detect 25 ppm ammonia with response time about 6 min.



a) b)

Fig.1. Evolution of UV-Vis-NIR absorption spectra of PPy-t-PASA film (a) and responses of PPy films (b) obtained in the presence of PSSA (1), PAMPSA (2), i-PASA (3), t-PASA (4) and H_2SO_4 (5) exposed to 529 ppm NH_3.

The Anode Behavior in Novel Polymer Gel Electrolytes for Secondary Aluminium Batteries

The production of cheap and sustainable batteries with long lifetime that can compete with Li-ion batteries has been of great interest in recent years. A promising alternative are aluminium batteries, which promise high energy density and low prices.[1] Similar to Li, however, aluminium is prone to dendritic growth ultimately leading to device failure.[2] A promising strategy to circumvent dendritic metal deposition and to enhance battery safety is the use of polymer gel electrolytes. Polyethylene oxide (PEO) as a matrix material has already been studied extensively in Li-ion batteries because it is cheap and shows good electrochemical and thermal stability while maintaining its shape and flexibility.[3,4,5] They can further act as spacer between electrodes without the need of an additional separator.[4] The preparation of polymer gel electrolytes can be done by adding specific amounts of the polymer to the ionic liquid and heating the mixture until the polymer is dissolved. However, it is also possible to add the required monomers directly in the ionic liquid using it as the solvent for polymer synthesis.[6] The presence of a strong native oxide layer present on the aluminium anode also provides a challenge. It is, however, reported in literature that leaving the aluminium anode to soak for a certain amount of time in the electrolyte has a positive effect on the electrochemical performance of the electrode.[7]

We measured the conductivities of the DES and the polymer electrolytes with electrochemical impedance spectroscopy. The deposition/dissolution characteristics of the aluminium anode was tested by galvanostatic cycling in PEO based gel electrolytes with a $AlCl_3$:urea deep eutectic solvent (DES).[8] The mere DES was tested as well as mixtures with different ratios of PEO (1-5 wt%). The experiments were carried out in symmetrical aluminium half-cells and the surface morphologies of the aluminium anodes were studied with SEM/EDS. The soaking time of the aluminium anode in $AlCl_3$:urea DES was optimized to improve the morphology of the deposited aluminium during galvanostatic cycling. The soaking tests were also performed with the polymer electrolytes after finding the optimum with the pure $AlCl_3$:urea deep eutectic. Since the loading of the cells with the viscous polymer electrolytes introduced gas bubbles, a method to remove those and improve the electrode/electrolyte contact was sought. This could be achieved by heating the assembled cells with the PEO based electrolytes to 60°C (melting point of polymer).[9] Further, the impact of this heating step on the overpotentials and the final anode morphology was examined showing good correlations.

The tolerance of hydrogen oxidation electrocatalysts towards fuel contaminants such as carbon monoxide is an important figure of merit in assessing their viability for use in proton exchange membrane fuel cells (PEMFCs). Significant cost reductions could be realized if PEMFCs were engineered to run on low-purity hydrogen, so efforts are underway to develop electrocatalysts with improved tolerance to CO poisoning. The CO tolerance of Pt electrocatalysts is well-known to be improved by alloying with Ru, but this is a relatively expensive raw material and further lowering of the potential of CO oxidation is sought. One alternative approach is to use tungsten oxide (WO_3) as a support or co-catalyst for Pt-based electrocatalysts, which has been shown to facilitate CO oxidation on Pt at potentials below that achieved by Ru. However, the detailed mechanism of improved tolerance is not fully understood, which is a bottleneck to fully exploiting this phenomenon.

In this work we use the combination of electrochemistry with *in situ* Raman spectroscopy and *in situ* attenuated total reflection infrared (ATR-IR) spectroscopy to probe the mechanism of improved CO tolerance observed by physically mixing a commercial Pt/C electrocatalyst with WO_3. We conclude that the WO_3-assisted CO tolerance is imparted through a bifunctional mechanism, with the WO_3 itself mediating oxidation of Pt-adsorbed CO at potentials lower than in the absence of WO_3, as well as providing surface oxygen species. We also rule out an electronic mechanism (where the additive weakens the Pt-CO bond thus facilitating its oxidation) since our data in fact suggest a slight strengthening of the Pt-CO bond in the presence of WO_3. We discuss the implications of these insights on the potential application of WO_3 as a fuel cell catalyst additive, as well as providing a framework for distinguishing between the above mechanisms using complementary *in situ* spectroscopic techniques to characterize the roles of multiple components as a function of potential.

Towards Holistic Understanding of Electrochemical Energy Conversion and Storage Systems Using High Energy X-rays.

Complete physico-chemical operando characterization of electrochemical devices in whole, or it's constituent materials separately, is necessary to guide the development and to improve the performance. High brilliance synchrotron X-ray sources play a crucial role in this respect as they act as a probe with relatively high penetration power and low damage potential. Synchrotron sources will undergo major upgrades in next decade and will provide even higher brilliance and, more importantly, coherence. These upgrades will be particularly advantageous for beamlines providing high energy X-rays as they will allow use of advanced scattering techniques with highly penetrating probe. Therefore, the techniques typically used for ex-situ measurements or at lower X-ray energies could be used on materials in liquid half-cells and operating electrochemical devices. In this contribution the new possibilities of using high energy, high intensity, coherent X-rays to probe model systems and whole electrochemical devices will be presented. The focus will be on defects tracking, local structure determination and correlative multimodal characterization using advanced WAXS, SAXS and surface scattering techniques.

To study fuel cells or batteries as a whole, elastic scattering techniques such as wide angle and small angle scattering are typically employed, as they can provide important complementary information to more standard X-ray imaging and tomography. The advantage is that the chemical contrast and sensitivity at atomic and nm scales is superior. Coupling these technique with the tomographic reconstruction (XRD-CT and SAXS-CT) is much less common as it requires bright synchrotron sources, fast 2D detectors and advanced instrumentation [1]. However, such combination allows spatial reconstruction of materials important atomic parameters in operando conditions. This will be demonstrated on imaging of standard 5 cm^2 PEM fuel cell during operation and Li-ion battery Si/C composite anode during charge and discharge.

Furthermore, local atomic and mesoscale structure, together with defect content, can also be determined by using Rietveld fitting, Pair Distribution Function (PDF) analysis and advanced SAXS theory. This in principle allows holistic investigations of interfaces at the device level, specification of defects' role in catalysis and determination of interplay between different phases during operation. These are critical questions needed to be answered in order to incorporate novel materials into the electrochemical devices. Examples will be given on studies of the defectous ORR catalysts [2,3] and amorphous Li-ion anodes.

HESXRD (High Energy Surface X-ray Diffraction) [4] and TDS (Transmission Surface Diffraction) [5] provide ideal tools to study structural changes during reaction conditions on single crystal model electrodes. The main advantage of both techniques is the possibility to follow the surface structural changes precisely with atomic resolution. While HESXRD is ideally used to determine exact atomic position, the TSD is easier from experimental perspective and allows studies with high spatial resolution. Advantages and disadvantages of both approaches will be discussed and examples of measurements on ORR and OER catalysts will be given. The future possibility to use high energy coherent beams will open new opportunities for both techniques to study single defects and surface dynamics in operando conditions.

Karlsruhe Institute of Technology (KIT), 76021 Karlsruhe, Germany

tobias.eisenmann@kit.edu

The transportation sector is continuously transitioning from combustion engines towards fully electric vehicles, and lithium-ion batteries (LIBs) are the energy storage device of choice due to their high volumetric and gravimetric energy density.[1] However, to meet future targets in terms of driving range and re-/charging times, the state-of-the-art graphite anode needs to be replaced with materials offering even higher energy densities and, especially, better power capabilities. Alloying metal-oxides such as ZnO and SnO_2 have been widely studied so far since they offer high theoretical specific capacities (966 mAh g^{-1} and 1494 mAh g^{-1}, respectively) at relatively low cost. Furthermore, such alloying metal oxides have high densities, which leads to substantially higher volumetric capacities compared to graphite. However, these high densities, in combination with the high overall Li^+ uptake, lead to pronounced volume expansion upon cycling. Furthermore, the eventually irreversible Li_2O formation limits the practically achievable specific capacity to the alloying contribution only. It has been shown that these detrimental effects can be overcome by introducing a transition metal (e.g., Fe, Co) into the lattice, leading to a reversible Li_2O formation and less pronounced volume expansion and, consequently, to capacities which are close to the theoretical values.[2,3] This concept of transition metal doping has also been transferred to germanium oxide – an example for an Li^+ alloying oxide with even higher theoretical specific capacity (i.e., 2152 mAh g^{-1}) – and was shown to partially enable re-oxidation of the germanium to germanium oxide, though (so far) only in the initial cycles.[4]

Within this study, we tackled the problem from a different perspective and elaborate on the effect of Fe in GeO_2 on the structural stability of different germanium oxide phases and, as a result, its electrochemical performance. The techniques employed include, amongst others, highly complementary *in situ/operando* characterization such as *in situ* high temperature XRD, *operando* XRD and *operando* dilatometry. The results on germanium oxide as a model compound shed light on a commonly overlooked impact factor for the electrochemical performance of such materials and, in fact, metal oxides in general.

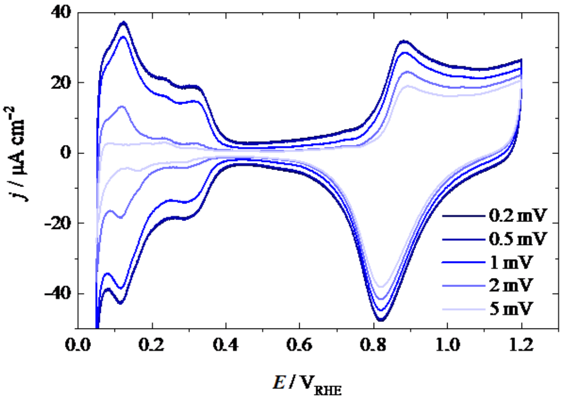
Staircase Voltammetry: The Effect of the Applied Potential Ramp on the HUPD in Cyclic Voltammograms of Platinum

Urša Petek, Nejc Hodnik, Miran Gaberšček
Department of Materials Chemistry, National Institute of Chemistry
Hajdrihova 19, SI-1000 Ljubljana, Slovenia
ursa.petek@ki.si

Although cyclic voltammetry (CV) is widely relied upon to interpret the behaviour of electrochemical systems, it is often overlooked that the measured responses depend not only on the studied system, but also on the applied settings and technical capabilities of the potentiostat. The main device-dependent variable is the type of the applied potential ramp, which can be either a truly linear or a stepwise function of time. While a linear change of potential is typically assumed for interpreting the results, most potentiostats operate with a digital ramp by default and a true analog ramp generator is only offered as an optional feature.

The analog ramp is defined by only one parameter – the scan rate – but a staircase function is also determined by the size of the potential step ΔE or the step duration Δt. Additionally, the delay time of a current measurement within the step duration ($\alpha \cdot \Delta t$) strongly affects the measured current response. Taking into account the technical differences among potentiostats and the user-defined variability, there are many ways of recording a cyclic voltammogram with a given scan rate. Despite this, detailed descriptions of the applied ramps and current recording modes are rarely reported as experimental conditions [1]. This practice is acceptable only when the results of a staircase ramp are equivalent to an analog experiment. But it is not obvious what set of conditions apply for a given electrochemical process. It is well established that surface reactions are more sensitive to the staircase shape than diffusive processes. [2] One such surface phenomenon is the hydrogen underpotential deposition (HUPD) on platinum electrodes, which is the most studied electrode material in electrocatalysis. Surprisingly, the practical effects of staircase ramp parameters on the HUPD response are not widely understood.

In this contribution, we showcase some experimental settings that can drastically affect the HUPD response on platinum when measured with a staircase potential ramp. The size of the potential step for a given scan rate was systematically varied, as was the parameter α of the current sampling delay. The settings that yielded a response equivalent to an analog ramp will be discussed. The advantages of averaging multiple current measurements within one potential step will also be demonstrated. This study aims to point out the pitfalls of the established practice of not reporting fundamental experimental parameters when studying the HUPD process on Pt electrodes.



Cyclic voltammograms of polycrystalline Pt electrode in 0.1 M $HClO_4$ recorded with different potential steps ΔE at a scan rate of 20 mV s^{-1}. The current was measured at the end of each potential step (α=1).

The production of hydrogen peroxide (H_2O_2) using renewable electricity, oxygen (O_2) and water (H_2O) is an alternate ''green'' route to the current anthraquinone process[1]. There are two approaches for the electrochemical synthesis of H_2O_2. One pathway is the partial reduction of O_2 at cathodes employing either noble metal alloys or doped carbon. Another possible route is the two-electron oxidation of water to H_2O_2, which competes with the four-electron oxidation of H_2O to O_2[2]. This anodic production of H_2O_2 is desirable since it can be coupled with other cathodic reactions, such as CO_2 reduction reaction to valuable products. However, it remains a great challenge to develop efficient electrocatalysts for H_2O_2 anodic synthesis, which can suppress the thermodynamically favored oxygen evolution reaction (OER). The objective of our research is to identify the parameters that will allow maximizing the efficiency of the catalyst and the electrochemical process for the anodic production of H_2O_2. Carbon has been used as an electrocatalyst due to its large surface area, conductivity, chemical stability in alkaline electrolytes, and low cost. Selective oxidation of water to hydrogen peroxide on different carbon materials was conducted using a two compartment H-cell, where copper was used as a counter electrode. The impact of electrolyte concentration, current density, pH values of the electrolyte, temperature, and ion exchange membranes, have been investigated in order to optimize reaction conditions for the anodic production of H_2O_2. A concentration of 1.73 mM for H_2O_2 was achieved at the applied current density of 100 mA cm^{-2} in 2.7 M $KHCO_3$ electrolyte using a cation exchange membrane in a flow cell. (**Figure 1**).

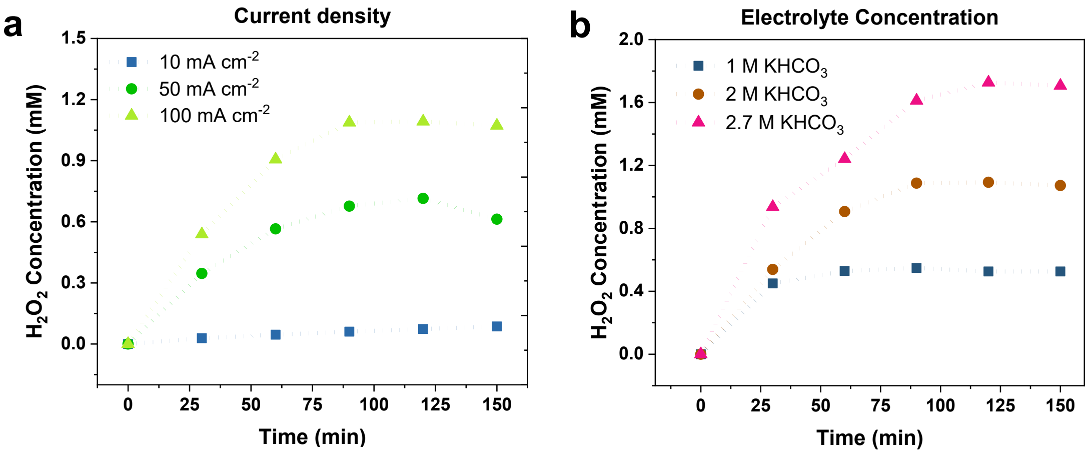

Figure 1: Hydrogen peroxide concentration in the anolyte during electrolysis at **(a)** different current densities using 2 M $KHCO_3$ and **(b)** in different electrolyte concentrations of $KHCO_3$ at 100 mA cm^{-2}

The demand for lithium resources is rapidly increasing with the production of lithium-ion batteries. Today's lithium is produced from brine or ore [1]. The issues of the former are long process time and large environmental burdens. The latter issue is the high cost for high purification [2]. To establish a better lithium recovery method, we have investigated lithium recovery by electrodialysis using lithium ion conductive solid electrolyte $Li_{0.29}La_{0.57}TiO_3$ (LLTO). The electrochemical impedance of electrodialysis is affected by the concentration of cations in solution. When this recovery is performed in a batch system, the lithium ion concentration of the solution changes as the recovery of lithium proceeds. Therefore, it is important to elucidate the influence of the lithium ion concentration in the solution on the electrochemical impedance. In this study, we investigate the effect of lithium ion concentration in the secondary solution on lithium recovery rate by electrodialysis using LLTO.

An anode (primary side) and a cathode (secondary side) electrodes were prepared on the surface of LLTO using a platinum paste. Reference electrodes was prepared on both surfaces of the LLTO at positions apart from the anode and cathode. A DC voltage of 2.0 V was applied between the anode and cathode. Electrochemical impedances were measured by the 3-terminal method using the reference electrodes and 2-terminal method. The primary side solution was a 1.0 M aqueous lithium hydroxide solution. The secondary side solution was pure water or an aqueous lithium hydroxide solution having a concentration of 10^{-3}-1.0 M. The amount of transferred lithium was estimated by Faraday's law using the current value.

As shown in Figure 1, the migration rate of lithium depended on the concentration of lithium ions in the secondary solution and reached a maximum at 10^{-2} M. The cause of this dependence was clarified by the AC impedance method.

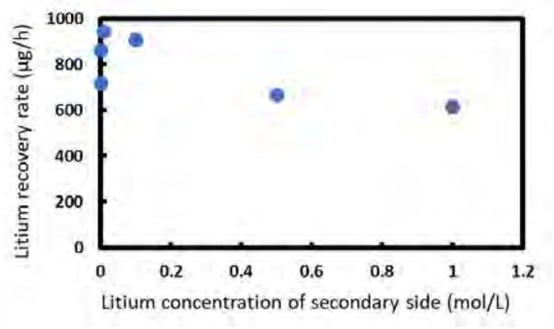

Figure 1 Lithium recovery rate at different lithium concentration in electrodialysis secondary solutions.

Investigation of Aniline and p-aminodiphenylamine Oxidation Products formed using Fe_3O_4 NPs/H_2O_2 system: Structure and Electrochemical Behavior

Jana Mišurović, Gordana Ćirić-Marjanović, Danica Bajuk-Bogdanović
University of Belgrade-Faculty of Physical Chemistry, Studentski trg 12-16, 11158 Belgrade, Sebia
e-mail address: janamisurovic@gmail.com

Polyaniline (PANI) is one of the most studied conducting polymers thanks to its simple synthesis and wide range of favorable properties [1]. In this work we present a comparative study of polymeric products obtained from two different monomeric species, aniline and p-aminodiphenylamine (p-ADPA) oxidized in similar conditions using Fe_3O_4 nanoparticles (NPs)/H_2O_2 catalyst/oxidant system. So far H_2O_2, as a clean oxidant (the product of its reduction is only water), has mostly been used in polymerizations catalyzed by enzymes. In our approach Fe_3O_4 NPs replace much expensive enzymes, while synthetic conditions are tuned to achieve good conductivity of products.

The process of p-ADPA oxidation occurred much faster than the oxidation of aniline, due to lower oxidation potential of p-ADPA, which is documented by the color changes of reaction mixtures and changes in UV-Vis spectra with time. Based on the structural characterization of products (PANI/Fe_3O_4 and Poly(p-ADPA)/Fe_3O_4) it was found that the oxidations of aniline and p-ADPA led to the formation of PANI in the electroconductive, half-oxidized form called emeraldine salt (ES) [1,2]. FTIR spectra of both products contain characteristic bands of PANI-ES and evidence that the materials have very similar molecular structure. On the other side, Raman spectra showed that there are some fine differences in the molecular structure of the two materials. The Raman spectrum of Poly(p-ADPA)/Fe_3O_4 contains some bands indicating the intramolecular oxidative cyclization in the polymer chains, which are absent in the spectrum of PANI/Fe_3O_4 sample. SEM images evidenced considerably different morphology of the two samples. PANI/Fe_3O_4 has heterogeneous morphology with a large content of regularly shaped microspheres, while Poly(p-ADPA)/Fe_3O_4 contains dominant plate-like morphology. Such differences in the materials' surface implicate that their electrochemical behavior differs largely, which was confirmed by cyclic voltammetry measurements (Fig.1.). The electrochemical behavior of both materials was tested in 1M HCl solution. The cyclic voltammogram (CV) of PANI/Fe_3O_4 shows typical redox pair of PANI: the dominating redox couple at lower potentials corresponds to the interconversion between nonconducting leucoemeraldine base and ES, and the redox couple at higher potentials corresponds to the interconversion between ES and fully oxidized pernigraniline salt form. In CV of Poly(p-ADPA)/Fe_3O_4 the redox pair at higher potentials is more pronounced and the two oxidation (reduction) peaks are merged. Differences in molecular structure and surface morphology of the two samples clearly support the electrochemical behavior and higher capacitance of PANI/Fe_3O_4 (~180 Fg^{-1}) in comparison to Poly(p-ADPA)/Fe_3O_4 (~50 Fg^{-1}), even though their electrical conductivities are of the same order of magnitude (10^{-2} Scm^{-1}). This makes PANI/Fe_3O_4 a better electrode material for charge storage applications.

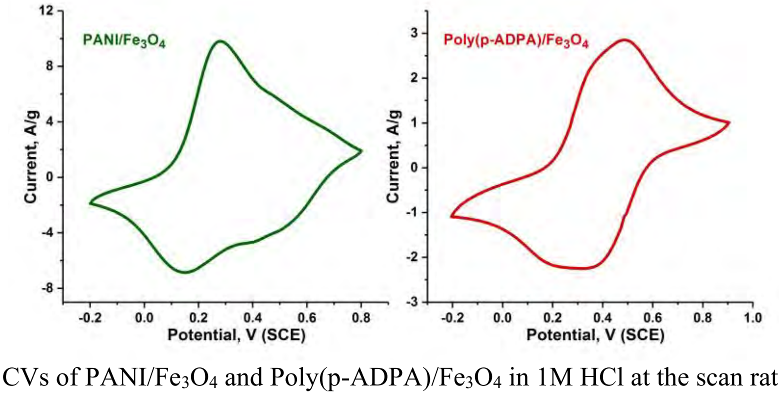

Figure 1. CVs of PANI/Fe_3O_4 and Poly(p-ADPA)/Fe_3O_4 in 1M HCl at the scan rate 20 mVs^{-1}.

Polyanionic compounds attract attention as a cathodic materials for Li- and Na-ion rechargeable batteries. The main advantages are open 3D framework capable of intercalating large amount of alkaline ions, an excellent thermal/structural stability and high safety. Mixed phosphate-pyrophosphate $Na_4Fe_3(PO_4)_2P_2O_7$ and pyrophosphate $Na_2FeP_2O_7$ possess attractive sodium insertion structures, displaying low activation barrier for Na-ion diffusion. The idea of this work is to hybridize these polyanionic phases through the control of synthesis conditions and capture each individual redox process during charging/discharging of the hybridized powder. By adjusting the synthesis conditions in the citric acid-assisted sol-gel process, followed by a heat treatment at 500 °C under Ar/5%H_2, the composite containing $Na_4Fe_3(PO_4)_2P_2O_7$ and $Na_2FeP_2O_7$ (denoted as NFPP/C) was synthesized, as confirmed by X-ray diffraction. The contribution of these phases was found to be ~29% for $Na_4Fe_3(PO_4)_2P_2O_7$ and ~71% for $Na_2FeP_2O_7$. Vibrational modes of PO_4^{3-} and $P_2O_7^{4-}$ groups are identified by means of Infrared and Raman spectroscopy. The total carbon content of 21.7 %, which originates from citric acid and sucrose, was determined by thermogravimetry in air atmosphere. Both cyclic voltammetry (CV) and chronopotenciometry (CP) indicate that NFPP/C behaves differently in Li- and Na-nitrate solutions, Fig.1. Comparative CV and CP curves, measured under common current conditions, reveal better intercalation ability of 3D polyanionic framework for Na- than for Li-ions. Individual redox processes of both $Na_4Fe_3(PO_4)_2P_2O_7$ and $Na_2FeP_2O_7$ phases can be recognized in CV of NFPP/C obtained at 1mV s^{-1} in $NaNO_3$. As a result, a very high specific capacity of ~ 108 mAh g^{-1} (at ~ 300mA g^{-1}) was measured in $NaNO_3$, while the corresponding value in $LiNO_3$ was ~ 69 mAh g^{-1}.

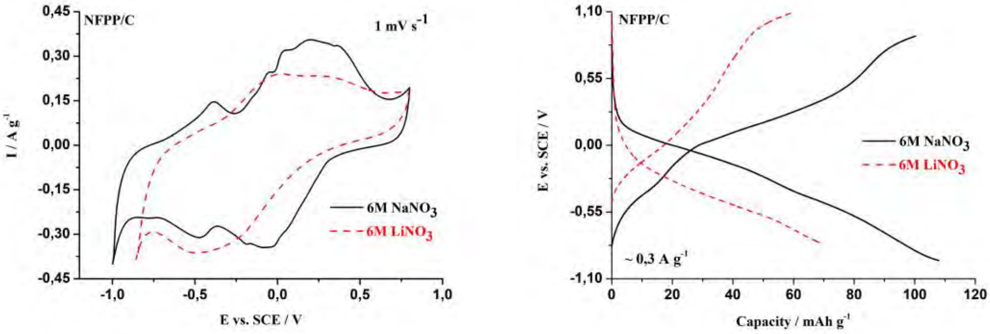

Figure 1. Comparative CVs (left, scan rate was 1 mV s^{-1}) and charge/discharge curves (right, current density was ~ 0,3 A g^{-1}) of the NFPP/C composite measured in $NaNO_3$ and $LiNO_3$ solution.

Abstract

Due to their large-scale production and extensive application synthetic dyes are the major industrial pollutants and water contaminants[1]. Because of that wastewater from dye production and application industries presents a serious threat to the environment. Adsorption due to its simplicity and high efficiency is one of the most often employed methods for the treatment of wastewater[2].

The aim of this research is electrochemical synthesis of basic bismuth nitrate from water and ethanol Bi^{3+} solutions and its application as a sorbent. The main advantages of electrochemical synthesis are simplicity, rigid control of film thickness, uniformity, deposition rate and low cost of equipment and starting materials[3]. Organic electrolytes have been usually used to realize a wide electrochemical window, avoid hydrogen embrittlement, improve the wettability of the electrode and improve anti-wear performance of deposit[4].

Materials were synthesized by galvanostatic electrodeposition in the two electrode cell with a Ti sheet as a substrate (cathode) and a stainless steel sheet as an auxiliary electrode (anode), followed by thermal treatment in air at 200 ºC. Electrodeposition was done from an acidic Bi^{3+} solution in water or 96% ethanol at constant current density of 150 mA cm^{-2} for 5 minutes. Obtained materials were characterized by SEM-EDX, XRD, BET and FTIR methods. The results of analyses showed that both materials (synthesized from water and ethanol solutions) are pure trigonal $[Bi_6O_5(OH)_3](NO_3)_5\cdot 2H_2O$ with high crystallinity. Morphologically, they are composed of aggregates which were formed of several smaller particles of various shapes and sizes, some smaller than 100 nm. According to the IUPAC classification the N_2 adsorption/desorption isotherms of materials are type II, which is related to unrestricted monolayer-multilayer adsorption and nonporous or macroporous adsorbents. The material synthesized from the ethanol solution has the specific surface area of 1.43 $m^2\ g^{-1}$, while the specific surface area of the material synthesized from the water solution is 0.95 $m^2\ g^{-1}$.

The sorption performances of these materials were investigated by removal of textile dye Reactive Blue 19 from water. The results showed that both materials have significantly higher sorption capacities comparing with the inorganic sorbents found in literature, making them promising means for the textile dyes removal from water[5–7]. The material synthesized from the ethanol solution has higher sorption capacity (1344.99 mg g^{-1}) than the material synthesized from the water (1049.19 mg g^{-1}). The main reason of improved sorption capacity by using ethanol solution is higher specific surface area of obtained material. Also, important characteristics of material synthesized from ethanol solution that affect a better sorption performance of that material is its higher hydrophilicity, i.e. higher tendency of getting solvated by water.

ampantic@chem.auth.gr

A semi-transparent $NiCo_2O_4$/ITO electrode for supercapacitor applications has been prepared by an ink-printing method using a Dimatix 2D materials printer (Fujifilm) *(Figure 1)*. Structural and morphological characterization of the $NiCo_2O_4$ film was performed using XRD, SEM and AFM measurements. The average nanoparticle size in the film was estimated by SEM to be ca 100 nm whereas film thickness for films produced after two successive printing steps varied between 200-300 nm, as measured by AFM *(Figure 1)*. Film transparency in the 400-800 nm range was measured to be 35-50%. The electrochemical characterization of the $NiCo_2O_4$/ITO thin film electrodes was carried out by Cyclic Voltammetry (CV), Electrochemical Impedance Spectroscopy (EIS) and Galvanostatic Charge-Discharge (GCD) in 1 M NaOH electrolyte *(Figure 2)*. A nearly constant areal capacitance in the 30-25 mF cm^{-2} range is obtained for discharge rates up to 1 mA cm^{-2}. This is among the highest reported for very thin, transparent/semi-transparent supercapacitor electrodes [1-2]. The onset of capacitance loss at higher discharge current densities indicates electron transfer and/or reactant diffusion limitations of the associated faradaic reaction. In summary, the present work has proven the feasibility of preparing low cost and high performance binary metal oxide materials for semi-transparent supercapacitor applications, by a facile inkjet printing method.

Effective water splitting via electrolysis driven by renewable energy requires highly active catalysts to minimize the sensitivity of the hydrogen generation rate to fluctuating operating conditions [1,2]. NiMo alloys can potentially replace platinum as hydrogen evolution reaction (HER) catalysts because of their low overpotential over the entire pH range [3,4]. However, the pH-dependent kinetics of NiMo are not fully understood. In addition, it is still not clear if the low HER overpotential of NiMo is caused by high intrinsic catalytic activity or by extrinsic factors, such as increased surface area or mass loading [5,6], which would have cost implications for large-scale hydrogen production. Herein we present a study of HER kinetics of NiMo electrodeposited on fluorine-doped tin oxide glass in alkaline, neutral and acidic media by polarization and electrochemical impedance spectroscopy (EIS) techniques.

The polarization measurements indicated that the high HER activity of NiMo film was caused by both its high active surface area and high intrinsic catalytic activity. In subsequent measurements, the NiMo films showed the lowest HER activities in neutral conditions and the highest activities in acidic conditions. We found that the higher HER activity in acidic media was accompanied by more favorable hydrogen adsorption and charge transfer kinetics than in neutral and alkaline media. While two different Tafel-slope regions were observed for acidic and neutral media, only one was obtained for alkaline conditions. The EIS results suggested that the change of Tafel-slope was caused by the increased hydrogen surface coverage at high overpotential region. In acidic and neutral media, both Volmer and Heyrovsky steps significantly affected the HER kinetics at the low overpotential region, while at high overpotentials the Volmer step limited the HER kinetics. In alkaline conditions, however, the HER rate was controlled by the Volmer step, and other steps were not visible in the EIS data.

NiMo films with different thicknesses were also measured in electrolytes with different pH and in all cases the thickest layers provided the best HER performance due to highest active surface area. Because the highest HER activity was due to surface area, initial performance optimization by increasing film thickness should be quite simple, but further development of deposition methods for even higher specific surface area could also prove beneficial.

This research was done under the PECSYS project. The project has received funding from the FUEL CELLS AND HYDROGEN 2 JOINT UNDERTAKING under grant agreement No. 735218. This Joint Undertaking receives support from the EUROPEAN UNION'S HORIZON 2020 RESEARCH AND INNOVATION programme and Hydrogen Europe and N.ERGHY. The project started on the 1st of January 2017 with a duration of 48 months.

Since the discovery of the electrochemically active $LiFePO_4$[1], the three-dimensional frameworks built on transition metals and polyanions $(XO_4)^{n-}$ have experienced a huge expansion in the research field of alkaline-ion batteries. $NaFePO_4$ exists in two polymorphic structures: triphylite and maricite (thermodynamically more stable). The maricite $NaFePO_4$ phase was initially considered as electrochemically inactive for sodium rechargeable batteries, but somewhat later its activity was demonstrated[2]. In this paper, the maricite $NaFePO_4$/C composite, is synthesized in an unusual way, by targeting the stoichiometric composition of the $Na_4Fe_3(PO_4)_2P_2O_7$/C using the glycine-nitrate process and then applying the temperature corresponding to the structural decomposition of this polyanionic compound (650°C). XRD, FTIR and Raman spectroscopy observations of such obtained powder confirmed the formation of the maricite phase, while the cyclic voltammetry, measured in the electrochemical stability window of $NaNO_3$ aqueous solution, showed its electrochemical inactivity. By exposing the maricite phase to high anodic potentials in $NaNO_3$ (beyond the stable potential window), the redox peaks have appeared and electrochemical performance of the maricite itself is improved. Further holding the electrode at a deep positive potential (1.6 V vs. SCE) for a certain periodic time, results in the gradual increase of redox peaks, Fig.1a.The integrated surface area under CV curve of anodic or cathodic part (which corresponds to the specific capacity of the material) was increased by ~50%. The shape of redox peaks remains retained upon changing the scan rate, Fig.1b. To reveal what really happens at the $NaFePO_4$ surface under deep anodic polarization and what is the most responsible for the observed electrochemical activation, the activated powder was subjected to further characterization. Based on FTIR and Raman measurements, it can be concluded that the high anodic polarization results in the phase transformation of electrochemically inactive maricite $NaFePO_4$ to active $FePO_4$ phase. Whether the active phase is triphylite or amorphous maricite is still a question which will be addressed. The obtained results open novel directions regarding the use of $NaFePO_4$ in Na-ion rechargeable batteries.

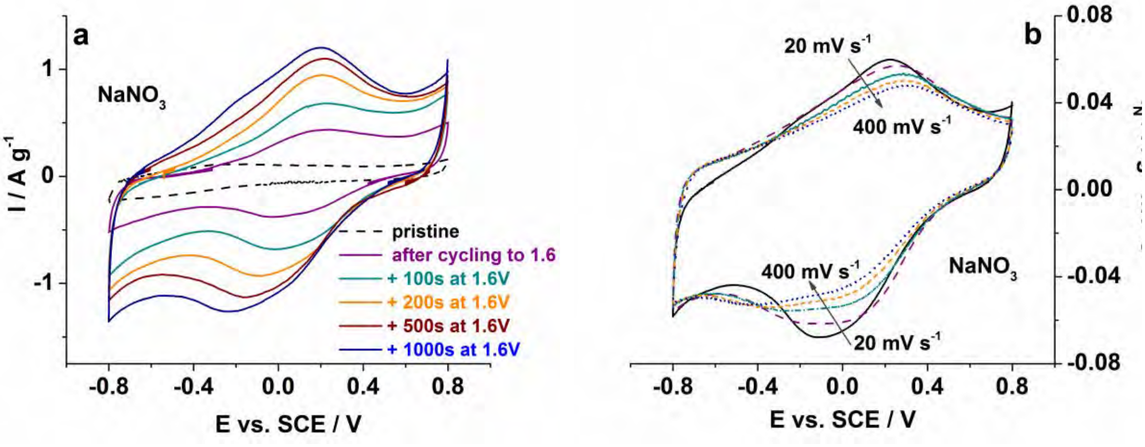

Figure 1.a) CVs of maricite NaFePO4/C before (pristine) and after anodic polarization, at 20 mVs^{-1}; CVs of activated $NaFePO_4$/C at different scan rates (b). The electrolyte is aqueous solution of $NaNO_3$.

The usage of fossil fuels as energy source and the excessive emission of CO_2 into the atmosphere is proven to be a major threat for the environment. Therefore, the research on sustainable and efficient energy storage and alternative fuels is of great importance. Hydrogen can be produced using renewable energy via water electrolysis but catalyst materials are required to run the reaction efficiently. For the electrocatalytic evolution of molecular hydrogen, materials based on noble metals such as Pt and Pd show the highest activity. Due to the cost-intensity of rare precious noble metals the development of active and stable non-noble metal based electrocatalysts for the hydrogen evolution reaction (HER) is promoted.[1]

In recent years, thin film dichalcogenides, like MoS_2 and WS_2, have been established as promising candidates for the HER and various reports indicate that the edges and defects show higher catalytic activity compared with the basal plane.[2] Aiming on materials with increased activity defect engineering comes into focus. One approach for a controlled formation of defects into thin film materials is the irradiation with ions that also results in an increase of the catalytic activity for the HER.[3]

Different electrochemical methods can be used to evaluate the electrocatalytic activity of materials. From this, scanning electrochemical cell microscopy (SECCM) was established in the recent years as a powerful tool to assess the electrocatalytic activity of different materials at nanoscale. Using pulled nanocapillaries as probes, measurements can be performed utilizing electrolyte droplets in the size of less than 100 nm as electrochemical cells. This results in an unparalleled resolution in the observation of electrochemical reactions leading to a better understanding of catalytically active sites or intrinsic activity of a single catalyst particle.[4,5]

IrO_2-modified Ti electrodes have been prepared by either a simple galvanic deposition process or a Ni-mediated galvanic replacement method. In the former case a freshly etched Ti substrate has been treated with an Ir(IV) solution, resulting in the spontaneous deposition of metallic Ir on the surface of the Ti substrate with the simultaneous oxidation of nearby freshly etched Ti sites [1]. In the latter case, a smooth Ni film has been electrodeposited on the Ti substrate from a Watts bath and its surface layers spontaneously exchanged with metallic Ir upon treatment with an Ir(IV) solution [2-3]. Anodization of the resulting Ir/Ti and Ir(Ni)/Ti electrodes by means of continuous potential cycling in acid solutions resulted in the formation of IrO_2 porous surface layers (or IrO_x, depending on the positive potential limit), showing typical Ir oxide surface electrochemistry (*Figure 1*). SEM pictures revealed that the thus prepared IrO_2/Ir/Ti electrode is made of sparse IrO_2/Ir micrometer-sized islands and nanoparticles, while the IrO_2/Ir(Ni)/Ti electrode consisted of a continuous film with a nodular morphology (as confirmed by AFM). The composition of the coatings was estimated by EDS and XPS spectroscopy while Ir mass loading was determined by ICP-MS following etching in acid. These electrodes have been tested as oxygen evolution reaction (OER) anodes by slow potential sweep voltammetry *(Figure 2)*. IrO_2/Ir/Ti electrodes exhibited mass specific activities for OER (ca 200 mA mg_{Ir}^{-1} at η=300 mV) better or comparable to traditional Ir DSAs [4] or state-of-the-art thin thermal films [5], whereas the IrO_2/Ir(Ni)/Ti electrodes were proven comparable or better than both state-of-the art thin thermal films [6] and nanoparticle $IrNiO_x$ catalysts [7] (ca 2 A mg_{Ir}^{-1} at η=300 mV). The recently established enhancement of IrO_2 OER activity by Ni, combined with the widespread use of Ti as a stable electrode substrate, make IrO_2/Ir(Ni)/Ti attractive DSA electrodes.

Surface-alloys can form spontaneously during the deposition of one metal onto another, especially in systems with a very large lattice mismatch that do not have bulk counterparts (so-called immiscible systems). The spontaneous surface alloying has been widely studied in Ultra High Vacuum (UHV) [1], but these new materials have not been exploited much in practical applications. Because the high control and scalability make the transfer to real and practical systems viable and versatile, surface-alloying in an electrochemical environment is an ideal route to the design of new functional materials.

In this study, we have investigated the surface-alloying process during underpotential deposition (UPD) of Pb on Au(111) [2,3] and Cu(100) in the presence of various anions, e.g. perchlorate, chloride or bromide. This phenomenon has been studied using several electrochemical protocols such as repeated potential cycling over a limited UPD range (as illustrated in Fig. 1) or polarisation at a fixed potential in the UPD region. By following the changes in electrochemical behaviour, we established the range of potentials and conditions at which the surface-alloys form and quantified their composition. In addition to that, we investigated the structural and compositional changes by surface sensitive techniques such as in-situ Scanning Tunneling Microscopy (STM), X-ray Photoelectron Spectroscopy (XPS), Ultraviolet Photoelectron Spectroscopy (UPS), Energy-Filtered Photoemission Electron Microscopy (EF-PEEM) and Work Function (WF) mapping.

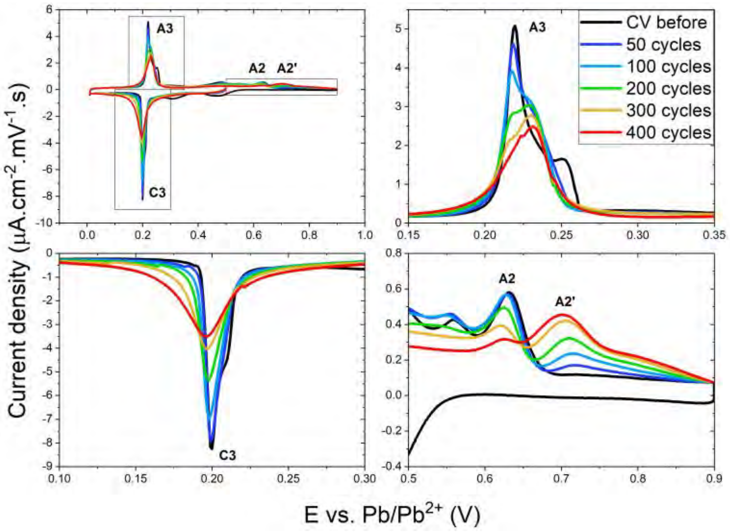

Fig. 1. Cyclic Voltammetries of Pb UPD on Au(111) in 1 mM Pb(ClO_4)$_2$ + 0.1 M $HClO_4$ solution after different numbers of potential cycles. Scan rate 10 mV/s.

thomas.collet@vub.be

Electrorefining is an essential technique to obtain pure (LME grade A) copper. During this process a consumable and impure copper anode is placed near a steel cathode. A direct current supplies the necessary energy to oxidize the anode (dissolve the copper in the electrolyte) and reduce (deposit) the dissolved copper onto the cathode while impurities remain in the refining bath, resulting in a pure copper cathode [1]. Electroplating processes need the support of additives, which are added to produce smooth copper deposits without nodules and striations [1]. In the case of electrorefining is thiourea one of the common additives. The thiourea concentration decreases, during the time span of the electrorefining, since it partially becomes incorporated in the cathodes and partially reacts with cupric ions to form formamidine disulfide (FDS) [1]. This evolution in additive composition subsequently affects the copper deposition. An EIS study of copper plating with and without certain additives is already performed by Gabrielli [2] and Gladysz [3] to name a few. Although, to the best of our knowledge, the effect of thiourea and FDS on the copper plating is not yet investigated to the fullest.

We perform operando Odd Random Phase EIS (ORP-EIS) measurements on the copper reduction system by applying the sum of a bias current and a multisine signal. This allows us to study the effect of thiourea on the copper reduction process. With ORP-EIS we are able to quantify the impedance, noise, non-linearities and non-stationarities at the measured frequencies [4] and to quantify the non-stationarities of a linear system by estimating a time-varying impedance [5]. An extension of this technique allows us to model weak non-linear and non-stationary systems and to calculate the uncertainty intervals -containing: noise, non-linearities or both- at every time interval and around every measured frequency of the instantaneous impedance. The estimation of the instantaneous impedance and the quantification of the non-linearities in the non-stationary system enables us to approach the transfer function of the systems as close as possible.

In our study we notice the presence of non-linearities, even and odd, even with an RMS potential value of 10mV or less for the multisine output signal. We also discovered non-stationarities, present by skirts at the even and odd non-excited frequencies, and calculated the time evolution of the impedance spectra. Both observations, non-linearities and non-stationarities, demonstrate the importance of our technique in this research.

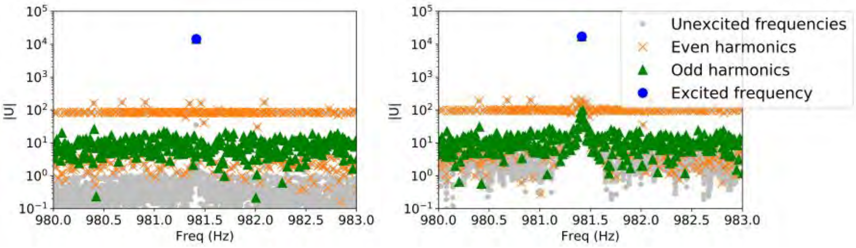

Figure: The presence of non-linearities (left) and skirts (right) in the frequency domain of the output potential signal.

According to the World Health Organization up to 1 in 10 people fall ill and around 400,000 die every year all over the world after consuming contaminated food and/or water[1]. Foodborne diseases do not only affect the wellbeing of individuals but hinder the socio-economic development of communities through the loss of days of school and work, medical costs and economic losses. One of the main vectors of food/water contamination are bacteria.

The standard methods of detection of bacteria, based on cell culture, are reliable but present a very important drawback: detection times extend into days making it difficult to stop outbreaks. Other faster methods are too complex or expensive to be used in most affected populations.

Electrochemical biosensors are a promising alternative with their high sensitivity, simplicity, low-cost, fastness and portability[2]. Herein we present the first stages of development of an electrochemical biosensor for the detection of the subunit B of the cholera toxin (CTB). Galactose (Gal) was used as a biorecognition element to mimick the mechanism of recognition of our intestinal cells by CTB.

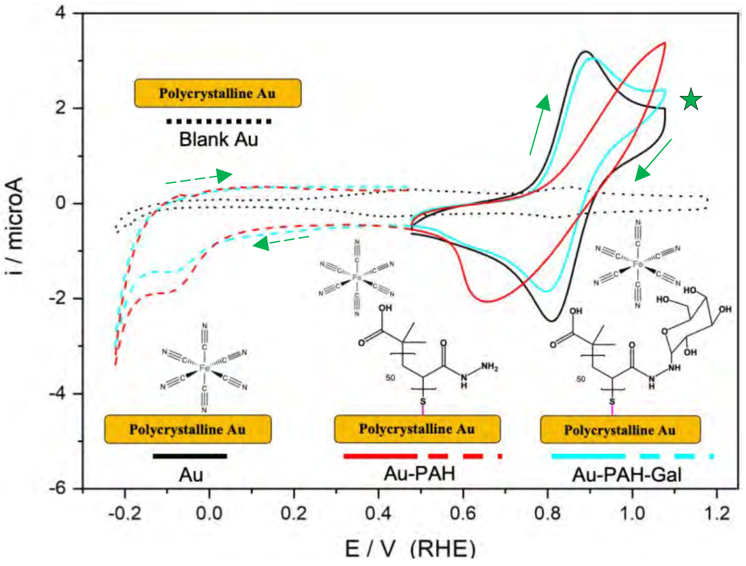

Fig. 1 – *CV characterization of polycrystalline Au electrode with redox probe [K$_4$Fe(CN)$_6$]; dashed lines indicate stripping processes.*

A polymeric linker, poly(acryloyl hydrazide) (PAH)[3], was employed to immobilize Gal on the surface of a polycrystalline Au electrode (Au-PAH-Gal): first, Gal was coupled to PAH (PAH-Gal); then, PAH-Gal was adsorbed onto the electrode from aqueous solution.

Cyclic voltammetry (CV) and a redox probe [K$_4$Fe(CN)$_6$] were used **(Fig. 1)** to study the surface of the electrode modified with PAH (Au-PAH, red scan) and PAH-Gal (Au-PAH-Gal, blue scan). For Au-PAH the voltammogram indicates, either a diffusion limited process across the layer; or a much slower electron transfer. With Au-PAH-Gal, only an attenuation of the signal of the probe with respect to the obtained on the bare electrode (black scan) is observed. The stripping peaks at low potential (dashed scans) corroborated the adsorption of PAH and PAH-Gal on the electrode.

These results point towards the immobilization of Gal on the electrode surface. The signal obtained with Au-PAH was probably due to a slower electron transfer forced by the chelating character of the hydrazide groups[4] of PAH. Another redox probe, FcMeOH, will be used to study this circumstance.

Chemically modified electrodes (CMEs) based on 2-(azulen-1-yldiazenyl)-5-phenyl-1,3,4-thiadiazole (**L**) has been prepared for heavy metal ions recognition [1, 2]. **L** electrochemical characterization was carried out by CV, DPV and RDE. The film formation has been evidenced by cyclic voltammetry, electrochemical impedance spectroscopy, atomic force microscopy and scanning electron microscopy [3].

Different conditions for CMEs preparation have been examined. **L** direct electropolymerization by controlled potential electrolysis lead to the immobilization of **L** complexing monomer on the electrode surface. The complexing properties of **L** and poly**L** have been investigated towards heavy metal ions in water solutions by anodic stripping technique. The obtained results confirmed that CMEs are sensitive tools for lead ions identification and detection in comparison to Cd(II), Cu(II), Hg(II) ions.

giovanni.sotgiu@uniroma3.it

Thin-film of metals oxides coating titanium supports (MMO films) have been extensively used in industry for a long time. Several metals and various compositions have been used for the construction of electrodes, in particular for the treatment of wastewater.

In previous works [1], [2] we have prepared different types of MMO and studied their electrochemical performances. In a standard procedure, the films were obtained by drop-cast. This method is very simple but unfortunately, it is not easy to obtain a uniform and well-controlled film.

In this work, electrodes coated with thin-film of ruthenium (RuOx) and manganese oxide (MnOx) were fabricated by thermal decomposition after deposition on a titanium substrate by spin-coating, a more accurate and controllable technique. In particular, we studied the influence of different salt precursors on the electrocatalytic properties. The investigated salts were: Ruthenium (III) acetylacetonate (Ru(acac)3), Ruthenium(III) chloride (RuCl3·xH2O), Manganese(II) nitrate (Mn(NO3)2·4H2O) and Manganese(III) acetylacetonate (Mn(acac)3).

A ruthenium salt and a manganese salt were mixed in a 1:1 molar ratio and dissolved in an organic solvent. Organic solutions were spin-coated on titanium foil (Ti) with a multilayer approach. All titanium substrates were previously cleaned by ultrasound treatment and then used as is or with a further HF etch.

The aim of this work was to determine if and how the specific combination of salt precursors could influence the morphology and the electrochemical performances.

A scheme of prepared substrates is reported in table 1.

Table 1

Id	Ti surface	Ru salt	Mn salt
1	smooth	$RuCl_3$	$Mn(acac)_3$
2	etch	$RuCl_3$	$Mn(acac)_3$
3	smooth	$Ru(acac)_3$	$Mn(acac)_3$
4	etch	$Ru(acac)_3$	$Mn(acac)_3$
5	smooth	$Ru(acac)_3$	$Mn(NO_3)_2$
6	etch	$Ru(acac)_3$	$Mn(NO_3)_2$

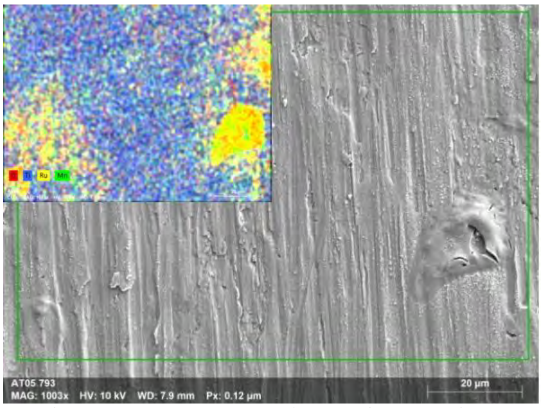

Figure 1: SEM & EDX image for sample 5

The thin-film electrodes were characterized by scanning electronic microscopy (SEM) and X-ray diffraction (XRD). In figure 1 is presented the SEM image for sample 5.

The electrochemical activity was investigated by potentiodynamic polarization, cyclic voltammetry and electrochemical impedance spectroscopy (EIS).

sabrina.rosoiu@cssnt-upb.ro

As a result of the imposed restrictions on the use of hazardous materials by electronic industries, an increased interest was focused towards the development of cost-effective lead-free solders. Candidate additives that are usually introduced to improve the performance of solder alloys include Ag, Cu, Ni, Bi, In, Zn, rare elements and nanoparticles. Sn-Cu based solders with nickel additions are considered as lower-cost alternatives to the well-known Sn-Ag-Cu ones [1].

Electrodeposition represents a faster and cheaper route suitable to synthesize solder layers, with a great potential for scaling up to industrial level production. Moreover, in the last decades the use of electrolytes based on deep eutectic solvents (DESs) was considered as a "greener" route for a large range of metals and alloys. Compared to classical aqueous electrolytes, the DESs allow the obtaining of quite constant alloys composition without the addition of surfactants, grain refiners, brighteners or oxidation inhibitors, thus providing an easier bath control especially for binary and ternary alloys electrodeposition.

Here we report the synthesis and characterization of the Sn-Cu-Ni alloy electrodeposited from choline chloride-ethylene glycol (denoted ILEG) eutectic mixture containing 500mM $SnCl_2$+0.055 mM $NiCl_2$+0.345 mM $CuCl_2$. The alloys were electrodeposited onto Cu substrate under direct and pulse current conditions. The influence of several operation parameters such as: the electrolyte temperature, the applied current density and pulse frequency on the morphology and crystallite size of the final alloy deposit has been investigated and discussed. The objective was to optimize the main operation parameters in order to achieve the corresponding alloy composition (Sn99.4Cu0.6 + Ni) able to possess the eutectic or near eutectic melting temperature of about 227 °C.

Electroanalytical characterization of polysulfides (S_X^{2-}) in model solution and euxinic seawater conditions

Sarah Mateša, Irena Ciglenečki
Ruđer Bošković Institute, Division for Marine and Environmental Research
Bijenička 54, Zagreb, Croatia
Sarah.Matesa@irb.hr

Sulfur (S), an ubiquitous element in the environment, occurs in different oxidation states from -2 (sulfide, S^{2-}) to +6 (sulfate, SO_4^{2-}). Between the thermodynamically stable end members (S^{2-}, SO_4^{2-}), a variety of intermediate S species exist, examples of which are sulfite, polythionates, thiosulfate, elemental sulfur (S^0), and polysulfides (S_X^{2-}). S species with intermediate oxidation states are produced during a variety of biotic and abiotic processes including the oxidation of hydrogen sulfide (HS^-) and sulfide minerals, SO_4^{2-} reduction, and the transformation of organic S compounds. Reduced forms of S, reduced sulfur species (RSS: S^{2-}, HS^-, S^0, S_X^{2-}, RSH), are most important forms for processes related to S biogeochemistry and environmental quality [1, 5]. Polysulfides are important RSS which play a role in numerous environmental processes, and so far there is not methodology for their direct determination in natural water environments, and conditions with presence of other RSS.

In this work for the first time differential pulse voltammetry (DPV) at the Hg electrode [1], was used for determination of S_X^{2-} in natural euxinic seawater environment (Rogoznica Lake, pH=7.0 - 7.5; oxygen concentration = 0 – 0.4 mg L^{-1}), i.e. conditions where total RSS (mainly in form of HS^-) could varied between 10^{-8} M to 10^{-3} M [2, 5]. In this approach an adsorption phenomenon associated with S_X^{2-} or a product of it's cathodic reaction with the Hg electrode created a characteristic current minimum at -1.0 V (vs.Ag/AgCL), which magnitude is proportional to the concentration of S(0) existing in the form of polysulfidic sulfur [1]. In our case, well defined DPV peaks were recorded for model K_2S_X (42% K_2S basis) NaCl/$NaHCO_3$ carbonate buffer solution (pH~9.5) in the concentration range between 10 mg L^{-1} and 500 mg L^{-1} (Figure 1a). The same approach, and obtained calibration, demonstrated presence of S_X^{2-} in the chemocline and anoxic euxinic layer of Rogoznica Lake, in the concentration range between 18 mg L^{-1} to 75 mg L^{-1} (Figure 1b). Additionally, sampled DC polarography (SDC) at the Hg electrode revealed in the studied samples a ratio between anodic and cathodic currents, i.e. the ratio between sulfide and S(0) presence in the S_X^{2-} [1,2]. Established electrochemical approach for RSS determination [2-5], based on accidification and purging step, determined total concentration of RSS and presence of its volatile and non-volatile fractions.

Concentration of S_X^{2-} as well as total RSS varied with environmental conditions (depth, oxygen concentration, light intensity) that are seasonaly dependent (Figure 1b).

Ion transfer voltammetry of drugs at the liquid-liquid interface towards electrochemically controlled crystallization

Magdalena Kaliszczak,[1] Grégoire Herzog,[1] Damien W.M. Arrigan[2]
[1] Université de Lorraine, CNRS, LCPME, F-54000 Nancy, France
2 Institute for Functional Molecules and Interfaces, Curtin University, GPO Box U1987, Perth WA 6845, Australia

magdalena.kaliszczak@univ-lorraine.fr

The development of new crystallization methods for sparingly soluble drugs is a subject of constant interest since 50% of the products are organic salts, which polymorphs may have different activity, bioavailability, toxicity or solubility[1]. A novel class of pharmaceutical substances which can improve these properties are co–crystals of drugs. Such homogeneous crystalline materials may contain two or more components incorporated in crystal lattice in definite stoichiometric amounts. Pharmaceutical co-crystals can incorporate pharmaceutically acceptable guest molecules into a crystal lattice along with the API (active pharmaceutical ingredient) and simultaneously not affecting pharmacological activity the drug[2].

In this work, the formation of crystals (co-crystals) by using ion-transfer processes at the interface between two immiscible electrolyte solutions (ITIES)[3], the control of the crystallization process by means of electrochemistry. For the purpose of this study, three drugs with low solubility in water, chemical structure proper for creation of co-crystals, amphiphilic properties with $0 < \log P < 3$, and bearing an electrical charge were selected: piroxicam[4], sildenafil[5] or diclofenac[6]. Such drugs are classified as a Class II API (low solubility and high permeability) based on the Biopharmaceutics Classification System.

Cyclic voltammetry at ITIES and μITIES was used to investigate of the ion transfer from an organic phase to an aqueous phase and to initiate precipitation of crystals (co-crystals). The selected drugs were dissolved in the organic phase in ionic form to allow the transfer of cationic or anionic form of the drug into the aqueous phase with the aim of forming insoluble drug (co-)crystal on the aqueous side of the liquid-liquid interface. A range of experimental parameters: nature of the drugs, composition of both organic and aqueous phases, nature of the polarization (electrochemical or chemical), dimension of the interface (macro- or microscopic) were investigated to control the interfacial processes and induce the formation of drug crystals. Such an electrocrystallization process at the ITIES will open new opportunities for the formation of organic drugs crystals.

Electrochemical-Mechanical Characterisation of Energy Storage Materials

Svetlozar Ivanov, Daniel Sauerteig, Andreas Bund
Technische Universität Ilmenau, Electrochemistry and Electroplating Group,
Gustav-Kirchhoff-Straße 6, 98693 Ilmenau, Germany,
svetlozar-dimitrov.ivanov@tu-ilmenau.de

The in-situ/operando mechanical behavior of materials for electrochemical energy storage is an important factor, having a major influence on the cell performance and ageing phenomena. There is a broad variety of materials and involved reaction mechanisms, displaying a specific impact on the mechanical properties during battery operation. For example, the process of Li ion intercalation into the active material is typically accompanied by accumulation of mechanical stress, which is followed by volume increase, deformation, disintegration or phase transition [1,2]. Most of the alloying and conversion materials experience a huge volume expansion when accommodating Li [3]. Furthermore, considerable change of the mechanical properties of structures for next generation batteries (e.g. sodium-, potassium intercalating and polymer active materials) has been detected as well [4,5].

Depending on the material structure and reaction mechanism the cumulative impact of these phenomena can finally result in a deteriorated performance, i.e. considerable reaction irreversibility and capacity loss. Therefore, the in-situ characterization of these processes and minimizing the induced mechanical stress and the subsequent material disintegration are amongst the major challenges on the road to the effective and safe battery operation.

The current talk will provide a brief overview and corresponding discussion on the recent achievements in our lab, related to the in-situ characterization of the mechanical properties of electroactive materials for reversible energy storage. The presentation will comprise several sub-topics, including, 1) reversible and irreversible volume change of battery materials (Li intercalating materials, electroactive polymers and electrodeposited silicon layers); 2) Impact of the external pressure on the electrochemical performance; and 3) actual strategies for modeling of the electrochemical-mechanical behavior.

The main techniques employed in our studies are electrochemical dilatometry (ECD) [6,7], electrochemical measurements under external mechanical load [8], electrochemical quartz crystal microbalance with damping monitoring (EQCM-D) [9] and finite element method (FEM) [8].

ito.kentaro.p7@dc.tohoku.ac.jp

Many approaches are proposed to improve the sensitivity of electrochemical sensors. Among them, the redox cycling in nano-space which amplifies amperometric current by repeating reduction and oxidation of redox molecules at neighboring electrodes in nano-scale applied at different potentials is an especially powerful tool for a highly sensitive electrochemical sensor[1, 2]. In this research, we applied redox cycling to the endotoxin sensing[3] which requires high sensitivity for medical safety. Previously, we successfully developed an electrochemical endotoxin detection method with detecting *p*-aminophenol (pAP) liberated from peptide-conjugated pAP (LGR-pAP) by *Limulus* amebocyte lysate (LAL) reaction[4]. Here, we detected pAP using redox cycling in nano-space for ultra-high sensitive endotoxin sensing (Fig. 1).

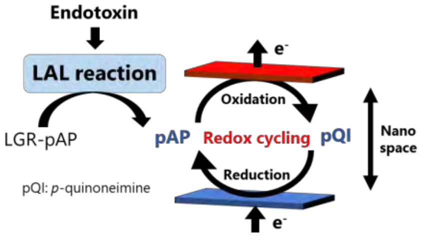

Fig. 1 The principle of this study

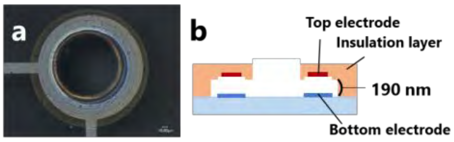

Fig. 2 Nanogap device. (a) Optical image. (b) Illustration of cross-sectional view.

First, the device with a pair of electrodes facing each other across a 190 nm gap was fabricated using photolithography and sputtering. Ti/Pt bottom electrode, Cr sacrificial layer, and Pt top electrode was deposited onto glass slide with lift-off process. An insulation layer was fabricated on the device except for sensor area using SU-8 negative photoresist. Finally, the sacrificial layer was removed by etching, and then the nanogap device was obtained (Fig. 2a and b). Characterization of the nanogap device was performed using cyclic voltammetry (CV) with 500 µM ferrocenemethanol (FMA) dissolved in 0.1 M KCl introduced onto the device. An Ag/AgCl electrode was used as a reference and a counter electrode. The potential of the bottom electrode was biased at 0.0 V, while the bottom electrode was swept at a scan rate of 20 mV/s. CV of non-redox cycling condition was also simulated using COMSOL Multiphysics with the model of the nanogap device without the bottom electrode. Finally, endotoxin assay was performed using 0.5 mM LGR-pAP as substrate for LAL reaction. After 60 min of LAL reaction, the solution was introduced onto the nanogap device, and then the current of the bottom electrode biased at -0.2 V was monitored while the top electrode was stepped from -0.2 V to 0.5 V.

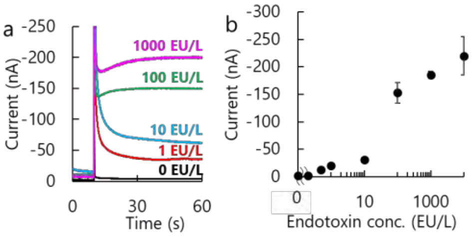

Fig. 3 Endotoxin assay. (a) Amperograms. (b) Calibration plots (n=3).

From the result of CV for FMA with redox-cycling condition, the cycling efficiency (the steady-state current from the bottom electrode/the steady-state current from the top electrode) of the nanogap device was 98%. This result indicates almost all of oxidant generated at top electrode reached the bottom electrode. Comparing to the CV with redox-cycling condition and non-redox cycling condition, the current was amplified by 1680 fold by redox cycling. These results showed that our nanogap device can be used for highly sensitive sensor. From the result of the endotoxin assay, the detection limit was 0.2 EU/L with 60 min of LAL reaction time. This result showed the sensitivity was improved by 5 fold comparing to our previous study[2]. This nanogap device can be used for sensitive, rapid and easy-to-use endotoxin sensing system to ensure the medical safety.

Lithium metal anode batteries are promising candidates for next-generation energy storage systems as they have a high theoretical energy density. The cyclability has to be improved to make them commercially viable. It is limited by the irreversible loss of active lithium due to the formation of a solid electrolyte interface (SEI) and the formation of unreactive “dead” metallic lithium. The latter is the dominating source of capacity loss in certain battery systems [1]. Experiments show that during the dissolution of lithium whiskers, the tip cannot be dissolved, hint that mechanical instabilities occur [2]. We developed a generalized phase-field model of the dissolution process to gain insights into the underlying mechanisms of “dead” lithium formation and capacity fade.

Our phase-field model describes the dissolution of a single lithium whisker in a liquid electrolyte based on lithium surface tension and the interaction between lithium and the SEI, utilizing the framework of non-equilibrium thermodynamics [3,4]. We study the shape evolution of the lithium whisker under galvanostatic conditions and under which circumstances instabilities occur. Our model predicts the nucleation of a Rayleigh instability induced by interactions with the SEI. Thus, the lithium whisker does not dissolve completely, and an electrically disconnected metallic lithium droplet is formed (Fig. 1). This is in agreement with optical microscope observations of lithium dendrite dissolution [2].

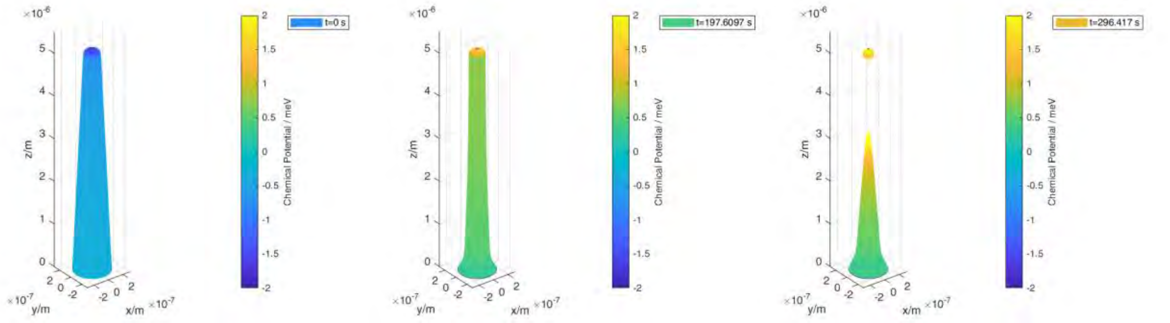

Figure 1: Droplet formation during galvanostatic discharge at different times. The dendrite tip disconnects from the base and a stable droplet forms while the rest of the dendrite dissolves.

This work has been developed in the project Lillint. Lillint is partly funded by the German ministry of education and research (BMBF) under grant 03XP0225A.

Investigation of Solvothermally Prepared $NaTi_2(PO_4)_3$ Nanocubes as Anode Material with High-Rate Capability for Aqueous Na-ion Batteries

G. Plečkaitytė, J. Juodkazytė, M. Petrulevičienė, J. Pilipavičius, L. Vilčiauskas

Center for Physical Sciences and Technology (FTMC)
Saulėtekio al. 3, Vilnius LT-10257, Lithuania
jurga.juodkazyte@ftmc.lt

Recently, NASICON-structured $NaTi_2(PO_4)_3$ (NTP) has attracted a lot of attention as potential Na-ion battery material. This 3D open framework structure exhibits great potential for long cycle life due to strong covalent P-O bond and insignificant volume changes during sodium ion insertion/extraction. Moreover, it shows high Coulombic efficiency, good thermal stability, excellent rate capability for reversible intercalation of two sodium ions per formula corresponding to a theoretical capacity of 133 mAh/g at ~2.1V vs. Na^+/Na. In addition, its favorable potential, low cost and environmental friendliness makes NTP a good candidate as anode material for aqueous sodium ion batteries [1]. However, its poor electronic conductivity affects the sodiation kinetics and overall performance as an electrode material. Two common methods have been reported for improving the NTP electrochemical properties: reducing ionic and electronic transporting path by decreasing the particle size and by particle surface coating with carbon or other conductive additives [2].

In this study, NTP nanoparticles were synthesized via solvothermal method using ethanol by heating the mixture at 180 °C for 12 hours. Powders were coated with glucose and calcinated at 700 °C for 2h in nitrogen atmosphere. The average size of nanocubes was 70 ± 9 nm (Fig. 1a). The slurry for the working electrode was prepared by mixing 70 wt% of active material, 20 wt% of carbon (Super-P, TIMCAL) and 10 wt% of polyvinylidene fluoride (HSV1800, Kynar) in N-methyl-2-pyrrolidone (Sigma Aldrich, 99.5 %) solvent. After ball-milling the mixture for 1 hour at 900 rpm, it was coated on stainless steel mesh and dried in vacuum (120 °C) for 3 hours. The electrochemical performance of the synthesized samples was measured in a three-electrode beaker-type cell with Ag/AgCl as reference and graphite rod as counter electrodes in 1M Na_2SO_4(aq.) electrolyte.

The results show the material capable of extremely high-rate cycling performance even up to the rates of 100C (~13.3 A/g) with relatively slow degradation on cycle number. However the low-rate performance at 0.1C – 1C rates showed much faster capacity fade rates upon cycling, indicating significant degradation issues of the active material in simple aqueous electrolytes (e.g. Na_2SO_4(aq.)) and the need for new strategies to mitigate these issues in aqueous batteries.

Electrochemical energy conversion from renewable resources offers promising routes to alternative energy resources, as well as to significant reduction of CO_2 emission. For their functionality at high temperatures and high stability of the components, solid oxide cells (SOC) demonstrate many potential applications, e.g. fuel cells and Power-to-X (P2X) technologies, of high efficiency and durability for long term operation. P2X technologies cover various processes converting electric energy into heat, hydrogen or synthetic fuels, while reducing CO_2 emission and providing huge capacity of energy storage. Proton conducting ceramic cells (PCC) were developed and their potentials for fuel cells and P2X applications were reported decades ago. The PCC geometry allows to supply and to produce pure hydrogen in fuel cell and steam electrolysis operations, respectively, which prevents fuel dilution and maintains P_{H_2O} low in Ni-based fuel electrode, in contrast to conventional SOCs. PCCs are also promising in the application of hydrogen extraction, pumping and compression as well as direct synthesis of hydrocarbons. However, the refractory character of the PCC electrolytes restricts upscaling of cell size and the manufacturing yield, and reliable air electrode materials are not yet well identified to realize highly efficient and reliable PCCs. In contrast to ceramic supported cells, metal supported (MS) architecture offers intrinsically superior mechanical strength, tolerance under thermal/re-dox cycles and cost reduction by replacing expensive ceramic based supporting materials with cheap metal alloys. One of the specific challenges is to find a process for the manufacturing of gas-tight electrolyte layers below 1000 °C that MS can withstand.

Transferring the know-how and technologies developed on MS-SOCs with thin film electrolyte [1], here we report our development of MS-PCC in the project DAICHI (EIG CONCERT-Japan): Thin and dense electrolyte coatings of $BaZrCeO_3$-based perovskites were successfully fabricated by pulsed laser deposition (PLD) technique implementing macro-/mesoporous electrode layers laminated onto ITM supports – commercial porous metallic substrate – having pore size of a few tens of µm [2]. Latest status of the MS-PCC development will be presented and prospects and challenges will be discussed towards the manufacturing of robust, durable, efficient and cost-effective MS-PCCs.

Proton exchange membrane fuel cells (PEMFC) are widely considered as an effective means of reducing the carbon footprint of transport. PEMFC electrodes commonly comprise a carbon support on which a platinum catalyst is deposited, an ionomer and gas diffusion media, collectively ensuring the transfer of reactants, electrons and protons. Although the reaction is kinetically slow, carbon is thermodynamically unstable under PEMFC operating conditions, and oxidation of the carbon support leads to aggregation and/or electrical insulation of platinum, increased hydrophilicity, and a decrease of fuel cell performance.
The main goal of this work is to increase the durability and the activity of the PEMFC cathode[1 2]. With the aim of modifying the carbon support to improve its corrosion resistance and its interaction with catalyst and ionomer, carbon blacks were functionalised by a nitrogen plasma treatment. A range of carbon supports with different specific surface area and porosity were used to study the impact of their properties on the functionalisation.

Elemental analysis and X-ray photoelectron spectroscopy were performed to quantify and determine the chemical speciation of formed nitrogen functionalities (pyrrolic, pyridinic, *etc*…). The influence of the nitrogen plasma treatment on the morphology of carbon supports was observed by transmission electron microscopy (TEM, Fig. 1). The interaction strength between the carbon support and the ionomer was quantified by isothermal titration calorimetry[3]. The impact of the functionalisation on the stability of the carbon supports was studied by chronoamperometry at high potential giving access to their corrosion resistance.

By modifying the experimental conditions, carbon blacks with different nitrogen contents were obtained in a controlled way, allowing a relationship to be established between the level of functionalisation and the properties relevant for their application as catalyst support in PEMFC cathodes.

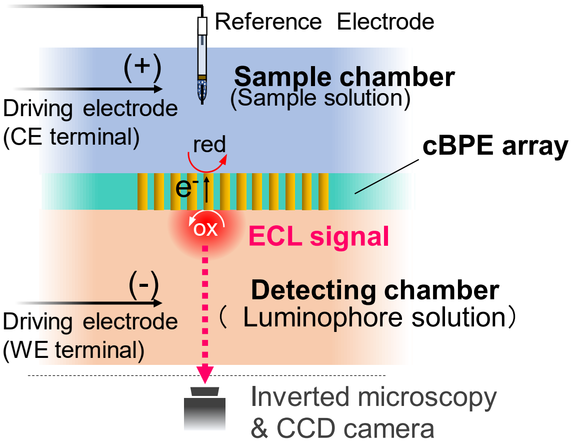

Fig. 1 Schematic of BEMs

Electrochemical imaging based on amperometric detection using multi-electrode array has been used for various biological sample observations such as metabolic activity of cell spheroids, and a neurotransmitter release activity in a rat brain slice, with its advantages of high sensitivity, high temporal resolution, label free feature. However, conventional multi-electrode arrays require the presence of connecting lines between the voltage supplier and individual electrodes, which severely limits the spatial resolution of the resulting electrochemical images. Therefore, the behavior of biomolecules associated with some biological phenomena which occurs in small area couldn't be observed with conventional multi-electrode array method. To overcome this problem, we have developed "Bipolar electrochemical microscopy (BEMs)" for high spatio-temporal resolution imaging of biological molecules. The BEMs employs closed bipolar electrode (cBPE) with electrochemiluminescence (ECL) detecting system as a pixel unit of images. Due to the feature that each cBPE need no connecting lines, high density cBPE array can be realized, and high spatio-temporal resolution imaging of target molecules using ECL signals can be realized.

Figure 1 shows the schematic of cBPE imaging system. Two driving electrodes (Counter electrode, reference electrode, working electrode) were inserted to the sample chamber and the detecting chamber. By applying a driving voltage, reduction reaction of sample molecule and oxidation reaction of the luminophore molecules occurs simultaneously, therefore, ECL signal generates on the surface of the cBPEs in the detecting chamber.

To monitor the MCF-7 respiration activity, living MCF-7 spheroid and a dead MCF-7 spheroid treated with paraformaldehyde was put on a cBPE array. Driving voltage was applied while observing the ECL signal by CCD camera. As a result, a larger ECL signal decrease was observed at the position where the live cell spheroid was placed. The results indicate that the cBPE imaging system can be applied in the observation of biological activities (Figure 2).

In future, various biological phenomena will be observed by enhancing the target molecules by using enzyme modification on cBPE array. Moreover, higher spatial resolution imaging will be realized by fabricating higher density cBPE array.

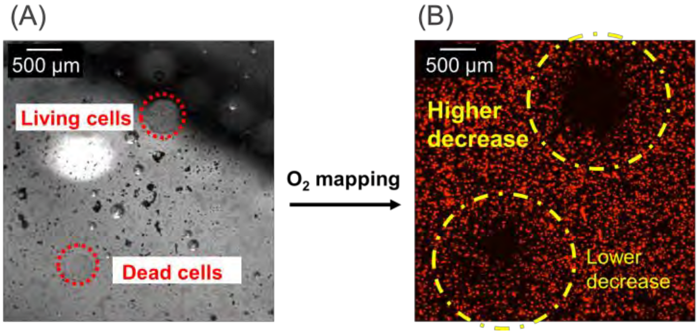

Fig. 2 (A) The living/dead cell spheroids placed on the surface of cBPE array, (B) ECL image observed while applying the O_2 mapping voltage.

via F. Selmi 2, 40126 Bologna (Italy)

E-mail: morteza.rahmanipour@unibo.it

Achieving stable dendrite-free and corrosion-free lithium metal anode is regarded as the utmost challenge in battery applications. Dendrite formation stemming from the non-uniform plating of Li during the battery charge will eventually perforate the separator and will internally short circuit the battery causing serious safety concerns. Besides, lithium metal is intrinsically very reactive and can easily react with the electrolyte and lithium salt, and thus solid electrolyte interphase (SEI) will be formed on its surface that is an unstable layer and leads to a substantial capacity loss. Moreover, regarding lithium-sulfur (Li-S) batteries, the migration of the soluble polysulfides through the separator towards the anode (polysulfide shuttling) and the subsequent reaction with the lithium will complicate the SEI composition and hinders a stable SEI formation.

To circumvent the abovementioned issues, several approaches have been investigated through designing lithium interphase via electrolyte additives or artificial SEI, designing lithium metal hosts with and without pre-stored lithium as well as any hybrid solutions.[1]

Herein, we have initially examined the role of the electrolyte additive in tuning the SEI formation by applying $LiNO_3$ as one of the most promising and widely used additives in two different concentrations. The comparison of the overpotiential profiles of the Li//Li symmetric cells during galvanostatic cycling showed that symmetric cells with concentrated $LiNO_3$ electrolytes demonstrated very small and relatively smooth overpotential profiles suggesting that $LiNO_3$ at higher concentration is beneficial to have stable interphase between Li metal and the electrolyte. With the aim of suppressing the formation of the lithium dendrites and achieving prolonged cycling, the study was further broadened to fabricate ex-situ protective layers on lithium anode. The attention was given to choose artificial layers that are mechanically and chemically stable, possess simple fabrication methods, and are preferably lithium ion conductors. Considering these criteria, Poly-dimethylsiloxane (PDMS) and Li_3N were chosen as artificial layers of interests [2,3]. A facile, economical synthesis method is proposed to fabricate each modified lithium anode. The electrochemical behaviors of the modified electrodes in terms of galvanostatic cycling performance and electrochemical impedance spectroscopy were probed in both symmetric configurations and later as anodes in Li-S cells. In-situ dilatometry can be adopted to investigate the volumetric fluctuations of the Li-S cells with pristine and modified anodes during the charge/discharge cycles.

Metal ion batteries are the most familiar energy storage figured for consumer electronics, portable devices, and electric vehicles. Accordingly, it is fundamental to improve their safety, to prevent failures and damages as well as to increase energy density and reduce the production costs. To understand the structural properties of electrodes materials during the battery operation and simulate their ageing are trivial steps to let a reliable battery functioning. The insertion/deinsertion of metal ions in the battery electrode's lattice leads to structural changes and expansions/shrinking that can limit the performance of the battery. [1, 2]

Between the different approaches useable for studying these volume changes, electrochemical dilatometry enables us to deliver versatile information about macroscopic in-situ expansions helpful for material design, details about SEI formation and irreversible/reversible components of dilatation which can be used to predict the long term stability. [3]

The present study aims to take this information into three typologies of batteries using various operating conditions such as use sundry electrochemical techniques and different applied forces. The thickness changes were investigated in lithium ion, sodium ion, and lithium sulfur systems during galvanostatic charge-discharge as well as cyclic voltammetry. Recording the dynamic behavior of the thickness change over several cycles was possible to consider the eventual structural instability during the operation of the systems investigated and dimensional change mechanisms.

Since implantation success strongly depends on the osseointegration process, current trends in dental implant research are based on surface properties modifications by biomimetic and bioactive coatings that mimic biochemical surroundings and architecture of the human bone. Calcium phosphate ceramics, like hydroxyapatite, with mineral composition similar to natural bone, as a single compound coating or as a composite with collagen, bioglass, or silica are used to promote osseointegration or overall implant system's characteristics [1]. Drug-based coatings with bisphosphonates like Zolendronate or Alendronate, drugs for bone diseases, promote mechanical fixation of implant and bone mineralization[2].

However, it must not be forgotten that a fundamental prerequisite for the success of osseointegration is a long-term corrosion stability of implant materials. Human body fluids, especially oral cavity fluids, in which pH is constantly changing, represent very aggressive media with high concentrations of chloride ions that are among the most aggressive and corrosive to metals. Although titanium is a gold standard in dental implantology due to its exceptional biocompatibility and corrosion resistivity, there is an increasing data reported regarding complications caused by titanium dental implant fixation. It was shown that titanium ions, that originated as product from corrosion reaction in body fluids, caused negative immune reactions or skin allergies immediately or shortly after implant fixation [3]. Therefore, it is crucial to design a coating which will make titanium surface more bioactive/osseoinductive and at the same time more corrosion resistant during a long-term exposure to oral cavity fluids.

In this study the titanium surface was modified by vitamin D3, molecules that are crucial for maintaining bone mineral density and normal functioning of the immune system [4]. The main goals were (i) to improve titanium corrosion resistivity during exposure to an artificial saliva solution and simultaneously (ii) to induce *in vitro* processes of "new bone" formation. According to results of all techniques, the D3 vitamin layer imparted very good corrosion protection to the oxide-covered titanium and induced a formation of biocompatible bone-like calcium phosphates what confirmed enhanced titanium's bioactivity level.

There is a paramount importance for us to develop a cost-effective electrolysis technology for green hydrogen in power supply system. On this point, polymer electrolyte membrane (PEM) electrolysis stands out due to its compactness and high efficiency and Alkaline exchange membrane with non-precious catalyst becomes a future primary choice. Herein we develop a novel alkaline anion exchange membrane with SEBS as the backbone and piperidine based diamine as the cross-linking agents. In detail, first Membrane with mutication crosslinking structure has better conductivity than and replace the quaternary ammonium with quaternary piperidine groups can increase membrane's chemical stability. Then, adding oxygen in the crosslinking structure can further increase its conductivity and 6 carbon between functional group has relatively balanced conductivity and chemical stability. Finally, SEBS-P2O6 has a conductivity of 20.8mS/cm (OH-) at room temperature, which is much higher than SEBS piperidine membrane published before.

samuel.martintreceno@pg.canterbury.ac.nz

The use of molten oxide electrolysis to produce metals has been proven more sustainable and environmentally friendly than most common traditional metallurgical processes. The potential to reduce emissions to the environment increases if large-scale waste materials are to be used as feedstock for this process. Previous work has shown that the electrochemical recovery of metals from the molten TiO_2 – SiO_2 – Al_2O_3 – MgO – CaO slag, a by-product of the ironmaking process, is feasible. However, a more extensive understanding of the electrochemical behaviour of this complex oxide system in its molten state is paramount in the design of industrial electrolytic cells. In this work, we study the effect of the experimental processing conditions, such as atmosphere, electrode material and electrolyte composition, on the electrical properties of the slag, crucial information to foster its recycling.

Electrochemical Dealloying as a Tool to Tune Composition, Porosity and Catalytic Activity of Nanoparticles

Christian.Rurainsky@rub.de

Electrochemically dealloyed nanoparticles have been the focus of electrocatalyst research work for more than a decade. This research ranges from fundamental understanding of the dealloying processes[1] to practically relevant materials that show highly increased catalytic activity for important reactions like the methanol oxidation reaction[2]. Despite all these research efforts, general guidelines what to look for during dealloying and how to properly tune a dealloying process to receive the best results, are lacking up until now.

Our work investigates in detail how different numbers of cycles influence the resulting morphology, composition and catalytic properties, using cyclic voltammetry (CV). Using AgAu nanoparticles as an easy to understand bimetallic system[3] and the hydrogen reduction reaction (HER) as an example reaction, we reveal the existence of an optimal amount of cycles and how it can be easily spotted in a dealloying CV. When the CV gets featureless and does not change in the consecutive cycles, then the highest catalytic activity was found. Interestingly, complimentary identical location electron microscopy analysis showed that at this point the particles did not show the highest porosity. Longer cycling increased the porosity found in the particles, but decreased the overall catalytic activity, which indicates that higher porosity in nanoparticles does not necessarily lead to a higher catalytic activity.

Tracking Structural Changes using Electrocatalytic Reactions – HER on Au(111) during Potential-Induced Reconstruction

Johannes M. Hermann, Areeg Abdelrahman, Timo Jacob, Ludwig A. Kibler
Institut für Elektrochemie, Universität Ulm, 89069 Ulm, Germany
johannes.hermann@uni-ulm.de, areeg.abdelrahman@uni-ulm.de, timo.jacob@uni-ulm.de,
ludwig.kibler@uni-ulm.de

Au(111) is one of the extensively studied single crystals. Its surface is able to reconstruct not only in UHV but also in electrochemical environment [1]. The phase transitions between the reconstructed and unreconstructed electrode surfaces have mostly been investigated by means of *in-situ* scanning tunneling microscopy, which revealed the existence of a variety of potential-dependent morphologies [2]. Kinetic studies are sparse and in the case of potential-induced reconstruction limited to *in-situ* surface x-ray scattering [3]. Classical electrochemical methods such as cyclic voltammetry can provide structural information of the electro-neutral reconstruction in an indirect way by considering changes in the signals of anion adsorption processes. Since, the electrocatalytic hydrogen evolution reaction (HER) on gold electrodes is strongly structure-sensitive [4], it is used in this study to monitor structural changes of the Au(111) surface. The electrocatalytic activity is highest at $t = 0$, directly after the surface reconstruction had been lifted, and decreases while the potential-induced reconstruction proceeds, following a simple first-order rate law (Figure 1a). In contrast to expectations from conventional electrode kinetics, the rate of the reconstruction process is decreased with more negative potential, as the reconstructed surface is stabilized by increasing negative excess charge. The observed trend can further be explained by a change in bond strength between Au surface atoms, as indicated by a potential-dependent compression of the topmost Au layer [5]. The systematic investigation clearly exhibits an exponential potential-dependence of the rate constant if specific adsorption is avoided. Temperature-dependent measurements at -0.4 V yield an apparent activation energy of ~0.6 eV. The adsorption of anions slows down surface reconstruction (Figure 1b), while the adsorption of carbon monoxide leads to an enormous enhancement of the reconstruction rate.

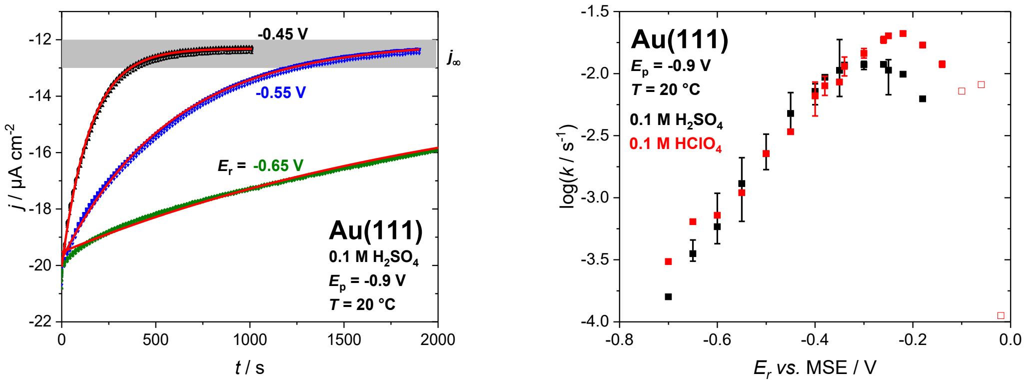

Figure 1: (a) Current density-time curves of HER at Au(111) in 0.1 M H_2SO_4 at probing potential E_p = -0.9 V and 20 °C for different reconstruction potentials, E_r = -0.45 V (black), E_r = -0.55 V (blue), and E_r = -0.65 V (green). Corresponding exponential fits are depicted in red. The range for stationary current density j_∞ derived from the fitted curves is indicated in gray. (b) Logarithm log(k / s^{-1}) of average rate constants extracted from exponential fits *vs.* reconstruction potential for Au(111) in 0.1 M H_2SO_4 (black) and 0.1 M $HClO_4$ (red). Error bars indicate scattering of different measurements.

luka.pavko@ki.si

Proton exchange membrane fuel cells (PEMFCs) have attracted wide attention due to their high energy efficiency and zero harmful emissions. However, providing high catalytic activity and long-term stability of the electrocatalyst remains a challenge. Currently, the most common oxygen reduction reaction (ORR) electrocatalysts are based on Pt or Pt-alloy nanoparticles (NPs) supported on high surface area carbons (commercially available carbon blacks such as Ketjen Black EC300J or Vulcan XC72) [1]. Despite many inherent good properties of carbon black supports (*e.g.* low cost, high conductivity, high surface area, etc.), poor electrochemical stability (*i.e.* carbon corrosion) as well as sub-optimal Pt utilization (*i.e.* nano-porosity) hinder performance under operational conditions of the PEMFC. Carbon corrosion results in secondary degradation mechanisms such as agglomeration of Pt/Pt-alloy NPs or their detachment which both consequently lower the active Pt surface area. On the other hand, Pt/Pt-alloy NPs located in nano-pores of carbon blacks are known to not efficiently contribute to the electrocatalyst performance at high current densities. This is due to their sub-optimal three-phase boundary as a consequence of poor ionomer coverage and accessibility for reactants and products. Past studies have revealed that many properties of the carbon support such as degree of graphitization, surface area, porosity type and size, functional groups etc., play a key role on both the aspects of carbon corrosion as well as Pt utilization [2].

This work is, thus, focusing on improving the properties of the supporting material by exchanging conventional carbon blacks with graphene-based materials. Graphene oxide with different degrees of oxidation, graphitic particle size and functional groups was used as precursor for preparation of various reduced graphene oxide supports (rGOs) that were decorated with nanoparticles of less noble metals (namely Cu and Ni). Using our in-house developed double passivation with galvanic displacement method [3], Pt-alloy nanoparticles were prepared on different types of rGO supports. Various structural and electrochemical analysis methods were performed for comparison of the Pt-alloy/rGO electrocatalysts. This includes X-Ray diffraction (XRD), scanning electron microscope (SEM), Energy Dispersive X-Ray Spectroscopy (EDX), Brunauer–Emmett–Teller (BET) specific surface area, Raman spectroscopy and elemental analysis for structural analysis as well as half-cell TF-RDE (ORR and CO electrooxidation) and a proprietary high temperature disk electrode (HT-DE) for electrochemical analysis. Specifically HT-DE was used to gain insight into the electrochemically induced carbon corrosion at an elevated temperature (60 °C - temperatures more relevant to operation of PEMFCs) by comparing Pt surface area degradation of different rGOs and carbon blacks.

The continuously growing demand of lithium ion batteries (LIBs) for portable electronics and in the rapidly increasing sector of electric vehicles raises concerns about the long term availability of critical raw materials employed in the LIB industry, such as lithium, cobalt, graphite and copper [1]. Owing to their potential lower cost and higher sustainability compared to the current lithium-based technology, SIBs have the potential to dominate the future stationary storage market. Among the anode materials proposed for SIB application, easy-to-synthesize TiO_2 nanoparticles exhibit promising properties especially in terms of high reversible delivered capacity and excellence cyclability [2,3], however the understanding of the processes occurring at the electrode/electrolyte interfaces (EEIs) and their degradation modes is still incomplete.

It is evident that the EEIs in SIBs play a key role, indeed, the successful design of well-performing SIBs relies in the stabilization of the interfaces governing these complex systems. The formation and evolution of the solid electrolyte interphase (SEI) layer as well as its morphology, chemical composition, and stability significantly influence the cell lifetime and performance.

Due to its high chemical sensitivity and tunable penetration depth, photoelectron spectroscopy is a powerful technique for the investigation of the chemical composition and in-depth profile of the SEI layer. In particular, hard X-ray photoelectron spectroscopy (HAXPES) allows probing the relevant near-surface region including the SEI/anode interface. HAXPES thus enables the differentiation of the components of the SEI from those related to the Na^+ uptake in the electrode.

In order to gain more insights on the formation of the SEI on a high-performance carbon-coated TiO_2-based SIBs anode, electrode samples at different stages of (dis)charge have been investigated with 2 different excitation energies (i.e. different probing depths) in the HiKE endstation [3] at the BESSY II KMC-1 beamline [4] at HZB. A detailed evaluation of the core-level spectra associated with the electrode, reveal the formation of a stable SEI layer partially composed of polyethylene oxide, sodium alkyl carbonates, sodium alkoxides, and minor contributions from sodium fluoride and sodium chloride derived from salt, binder and carbonate-based electrolyte decomposition. In addition to the formation of a polyolefin-based layer between the electrode surface and the SEI during the first cycle, the appearance of an accumulation layer could be detected, which could account for the charge neutrality of the system in highly sodiated states of the electrode and which induces an observable downward band bending. By considering the different inelastic mean free paths (IMFP) used in the experiment, the thickness of the SEI on the C-TiO_2-based electrode as well as the change of the Ti oxidation state due to Na^+ insertion in the discharging process has been estimated. The results provide comprehensive insights into the SEI formation and composition on C-TiO_2-based anodes used in SIBs, representing a useful dataset toward a better understanding of the complex nature of the interfacial processes occurring in SIBs.

The sodium ion battery (SIB) technology has the potential to represent a readily available, cheaper, and more environmentally friendly alternative electrochemical energy storage system to the most widely adopted lithium ion batteries, especially for stationary energy storage application filling the gap between clean energy produced by renewable sources and its utilization. In order to meet the requirements for practical applications, research on improved electrode materials is necessary. Recently, the excellent performance of a TiO_2 nanoparticles (np-TiO_2) anode for application in SIBs has been reported [1,2]. TiO_2 is certainly an attractive candidate, especially in terms of sustainability, cost and promising electrochemical performance. Nonetheless, the Na uptake and release mechanism is still heavily debated as well as a comprehensive understanding of the process occurring upon sodiation [2].

In particular, one of the main challenges is to unravel the structural and electronic changes of the anatase TiO_2 nanoparticles and the loss of crystallinity of the anodic nanomaterial upon Na uptake.

In this work, X-ray absorption near edge spectroscopy (XANES) at the Ti *K*-edge is used to investigate the electronic and geometric structure around the Ti atom and its nearest neighbors, allowing the identification of the sodiation effects on the TiO_2-based electrode. To gain direct, relevant insights into the insertion process of Na into the anatase-TiO_2 nanoparticle anode material, we designed an *operando* XANES experiment using a modified coin cell equipped with an X-ray transparent Kapton® window and a 6 µm-thick Al foil current collector adapted for the HiKE endstation [3] at the BESSY II KMC-1 beamline [4] at HZB. This setup allowed the measurement of the highly sensitive Ti *K*-edge of the np-TiO_2–based anode upon cycling, i.e. (de-)sodiating the electrode.

The analysis of the Ti *K*-edge absorption reveals a change in the average oxidation state of Ti upon sodiation from Ti^{+4} in the original anatase structure to around +3.4 (i.e. 0.6 Na atoms per unit formula). The *operando* results show that the oxidation state increases upon desodiation but does not reach the original Ti^{+4}, which is attributed to the presence of irreversibly trapped Na (~0.2 Na atoms), most likely responsible for the permanent loss of crystallinity in the nanoparticles observed during the first cycle. The analysis of the evolution of the pre-edge structure of the Ti *K*-edge, which is highly sensitive to coordination and oxidation, reveals that upon sodiation the pre-peak changes from the four-peak feature typical of the anatase structure [5] to a structure dominated by a single peak, suggesting a change in the number of nearest neighbors around the probed Ti atoms (from 6 to 5 neighbors) [6]. The subsequent cycling shows the same spectroscopic trends in the pre-edge feature, revealing a stable Na^+ uptake process after the initial irreversible structural rearrangement of the TiO_2 during the first sodiation process. The analysis performed enables an identification of the structural changes upon (de)sodiation of the np-TiO_2–based anode, which is crucial for a further insight-driven optimization of the electrode material.

Ultrapure hydrogen fuel produced by water electrolysis using renewable electricity from photovoltaic modules or wind turbines is seen as a viable future solution to alleviate the growing energy and environmental concerns of the modern world. The platinum group metals (PGMs) are unparalleled electrocatalytic materials for the cathodic hydrogen evolution reaction (HER) in terms of activity and chemical stability in acidic environments. However, their scarcity and expensiveness impede further development of the water electrolysis systems, so more cost-effective PGM-based electrocatalyst designs are in demand to bring the hydrogen economy concept closer to reality. Herein, we introduce a galvanic displacement strategy to decorate self-standing, protonated TiO_2 nanotube (H-TNT) arrays with ultrafine Ir nanoparticles. The procedure is based on a galvanic displacement-type reaction between the Ir(III) ions in $IrCl_3$ solutions and the H-TNTs serving as reducing agents. We demonstrate that a controlled morphological change from neat open-top tubes to disordered nanostripe bundles ("nanograss") during the step of anodic formation of TNT supports is beneficial for providing an abundance of exposed Ir active sites at the final self-standing Ir@TNT composites. Combined experimental evidence and computational modeling show that the nanograss H-TNT structures act as conductive supports that optimize the hydrogen adsorption energy of the firmly anchored Ir and regenerate its active sites during the HER, thus enabling the obtained Ir@TNT composite electrocatalysts to deliver an amazing HER performance. With only 5.7 μg_{Ir} cm^{-2} in the optimum Ir@TNT, we achieve an overpotential of –63 mV at –100 mA cm^{-2}, a low Tafel slope of –36 mV dec^{-1}, a mass activity of 34 A $mg^{-1}{}_{Ir}$ at –80 mV and superior durability in 1 M $HClO_4$. Moreover, the Ir@TNT catalytic structures outperform commercial Pt/C and Ir/C as well as most state-of-the-art PGM catalysts at high current densities. This work highlights the great perspective for the application of H-TNT arrays in HER electrocatalysis.

Nanosecond laser fabricated monolayer of gold nanoparticles on ITO for bioelectrocatalysis

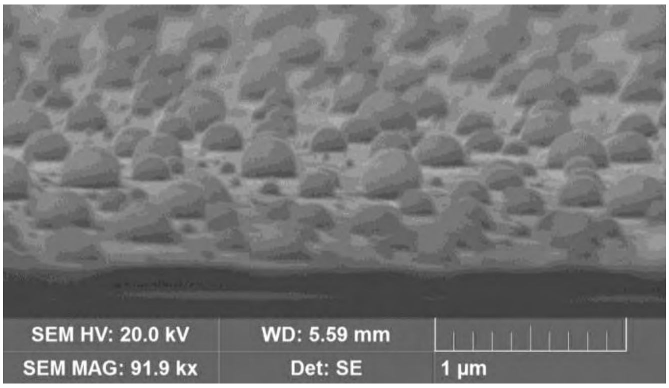
Redox enzymes can be envisioned as biocatalysts in various electrocatalytic-based devices. Electrode nanostructuration allowed enhanced loading of biocatalysts, hence higher current output. However, a weak percentage of loaded enzyme is operating, increasing the costs linked to enzyme production. Enhanced electron transfers were obtained by controlling key parameters for efficient immobilization. However, stability is limited to days in most cases (1-3). Among factors that play roles in these two limitations, the effect of enzyme-enzyme neighboring interaction on electrocatalysis has rarely been investigated, although critical *in vivo* (4).

Gold nanoparticles prepared by laser ablation may be a way for determining the relationship between activity and enzyme density on electrodes (5-6). We report in this work nanosecond laser interaction with nanometric gold films deposited on indium tin oxide support to generate in-situ AuNPs free from any stabilizers. A comprehensive analysis of AuNP size and coverage, as well as total geometric surface versus electroactive surface is provided as a function of the thickness of the treated gold layer. Using microscopy and electrochemistry, the long-term stability of AuNP-based electrodes in the atmosphere and in the electrolyte is demonstrated. AuNPs formed by laser treatment are then modified by thiol chemistry and their electrochemical behavior is tested with a redox probe. Finally, enzyme adsorption and bioelectrocatalysis are evaluated in the case of two enzymes, i.e. the *Myrothecium verrucaria* bilirubin oxidase and the *Thermus thermophilu*s laccase. Behaving differently on charged surfaces, they allow demonstrating the validity of laser treated AuNPs for bioelectrocatalysis.



SEM images of Au nanoparticles obtained from laser ablation of Au film on ITO.

Revealing degradation and recovery mechanisms of Co_3O_4 nanocatalysts for oxygen evolution by *in situ* impedance analysis

Zhibin Liu, Julia Linnemann and Kristina Tschulik*
Faculty of Chemistry and Biochemistry, Analytical Chemistry II, Ruhr University Bochum, 44801 Bochum, Germany
*Presenting author: Zhibin.Liu@rub.de; *Corresponding author: Kristina.Tschulik@rub.de*

Co_3O_4 is one of the most active precious metal free electrocatalysts for the oxygen evolution reaction (OER).[1] Hence, extensive efforts have been made on studying its active sites.[2] In contrast, few investigations exist on its degradation mechanism and so comparably little is known about this important process. Herein, Co_3O_4 nanoparticles are used as OER catalysts under alkaline conditions and their degradation and re-activation are investigated by electrochemical studies linked to spectroscopy and high-resolution electron microscopy. A degraded activity is observed after chronopotentiometric catalyst ageing, which can be recovered by a simple experimental procedure. This behavior of the Co_3O_4 nanoparticles used in this study is further explained by extracting *in situ* information at different stages from electrochemical impedance spectra (EIS, Figure 1). By systematically varying experimental conditions, such as potential, catalysts' loading and pH, and by applying several EIS analysis methods, mechanistic insights into the OER catalysis mechanism of Co_3O_4 are gained.

Based on this, a feature appearing in the high-frequency region described by an RC element with increasing resistance and decreasing capacitance by several orders of magnitude, is identified as crucial for the catalyst deactivation. The corresponding structural changes are affected by the amount of OH^- available at the interface and the near-surface region of the cobalt oxide. Moreover, the evolution of the structural alteration with time and, hence, the decrease of OER performance during aging is influenced by this factor. This emphasizes the importance of solvation states and processes occurring during the linear sweep pre-OER wave. The easy-to-access *in situ* method of EIS is, highlighted as a powerful tool to analyze changes of electrocatalysts under working conditions and to shed light on the underlying catalysis mechanism.

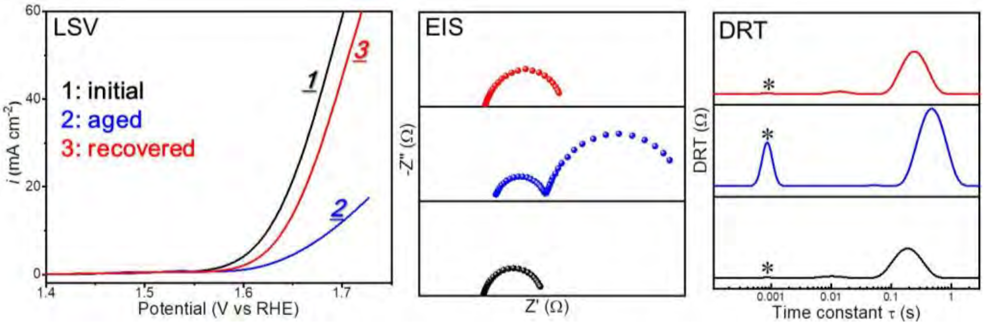

Figure 1. LSV, EIS and DRT graphs of Co_3O_4 nanoparticles in their initial, aged and recovered state.

Organic Electrocatalytic Synthesis of Dimethyl Carbonate: Production, Analysis and Quantification

Bethan J. V. Davies, Matthias Arenz, Jan Rossmeisl and Maria Escudero-Escribano

University of Copenhagen
Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen, Denmark
bethan@chem.ku.dk

Electrification is a potential solution to solving the challenges of the chemical industry, such as environmental pollution and use of petroleum as a starting material. Organic electrocatalysis offers a chance to perform cleaner chemical synthesis, ultimately with renewable energy and sustainable resources. In order to develop new synthesis routes, we ideally must first study and optimise reactions suitable for electrocatalysis. Dimethyl carbonate (DMC) is one candidate for investigation. DMC is a valuable chemical used on industrial scale for both production (e.g. carbonylation reactions) and in end products (e.g. paints and batteries). DMC is currently formed by thermal catalysis but can be formed electrocatalytically, it is a carbonylation product of methanol[1], formed electrochemically by the reaction $2CH_3OH + CO \rightarrow (CH_3O)_2CO + 2H^+ + 2e^-$.

The purpose of the work is to understand the fundamental aspects of the carbonylation reaction over an electrode surface, i.e. by heterogeneous electrocatalysis, rather than homogeneous or indirection electrosynthesis. Knowing the steps of formation and the reaction intermediates involved will allow us to develop the catalytic system in a rational manner as well as apply the knowledge to later reactions of interest (e.g. carbonylation of other alcohols, such as phenol, to form valuable products). Understanding the active site and mechanism of the reaction is paramount for rational optimisation strategies.

Different transition metals (Cu, Au, Pt) have been tested for their activity towards DMC production[1,2,3]. Au is more active than Pd in terms of current efficiency as well as current density (Figure 1), whereas Cu catalysis DMC synthesis via an inefficient solution phase mechanism. We have used different techniques to understand different aspects of the reaction and catalyst activity: in situ infrared spectroelectrochemistry (in situ FTIR) is used to study the interface and the reaction at relatively short timeframes while headspace gas chromatography mass spectrometry (HS-GC-MS) has allowed us to determine the selectivity and reaction efficiency, whilst learning about chemical steps that occur after electrolysis to the products in the solution. Detecting such reactions in solution are important for determine the catalyst mechanism of the end products. The results that we have obtained so far have been discussed in combination with a theoretical analysis which has helped us understand the mechanisms involved. Further development is underway for optimising the catalyst as well as reactor system.

The aim of present study is to investigate numerically an effect of the IrO_2 loading on anode onto proton-exchange membrane (PEM) water electrolyser (WE) performances. The rate of the IrO_2 dissolution depending on WE operation modes has been estimated as well.
Physicochemical model [1] was used as the basis for the calculations. Two-phase mass transport in current collectors/gas diffusion electrodes has been considered. Electrochemical reactions in catalytic layers associated with IrO_2 dissolution have been included in the developed mathematical model as well. The rate of anode dissolution of the IrO_2 was estimated depending on the anode overvoltage based on the results reported in [2, 3]. Figure 1 shows the cell voltage V and the rate of degradation of WE performances due to the anode dissolution of the supported and unsupported IrO_2.

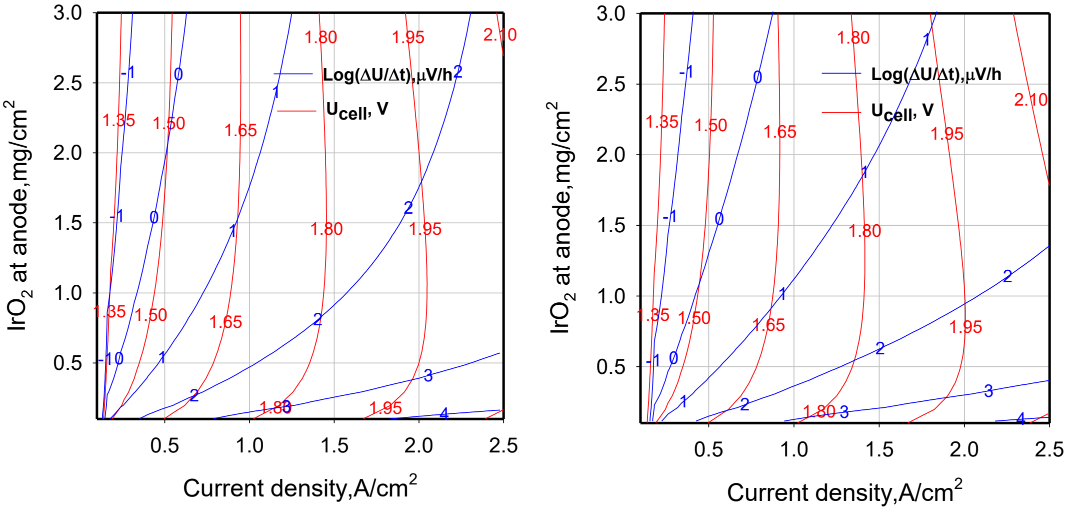

Figure 1. Dependence of WE voltage (U_{cell}) and it's degradation rate ($\log(\Delta U_{cell}/\Delta t)$ upon current density and IrO_2 loading in catalytic layer for the cases of unsupported (left) and TiO_2-supported IrO_2 (right).

The calculation data demonstrate good correlation with the experimental results [2, 3]. In particular, calculations show that the use of an ultra-low IrO_2 loading on the anode increases the rate of the performance degradation by a factor of 1-2. The use of the supported catalyst allows to reduce this degradation rate by 2-3 times. It should be noted that the degradation rates of PEM WE performances observed in experimental studies may be caused not only by the dissolution of the IrO_2. Therefore, the calculated degradation values may differ from those determined experimentally. The proposed numerical data allow to estimate the trend of performance degradation of WE at change of membrane-electrode assembly parameters.

The present study was financially supported by the Russian Foundation for Basic Research and Czech Science Foundation according to the research project No. 19-58-26022 and 20-06422J, respectively.

Hybrid aqueous rechargeable batteries are very attractive alternative to conventional rechargeable lithium ion batteries for stationary application because of production and usage safety, reduced production cost and environmental friendliness. Previously aqueous rechargeable batteries with Zn/LiCl-$ZnCl_2$/$LiFePO_4$ system with liquid electrolyte has been reported [1]. The system performed a high rate capability up to 60 C with the average operation voltage 1.2 V and cycling performance with a capacity retention of 80 % over 400 cycles at 6 C.

However, there are several drawbacks including water decomposition and zinc dendrite formation hindering the commercialization [1]. The present study aimed to develop a PAAm-based hydrogel electrolyte with inclusion of montmorillonite and halloysite clay nanoparticles for hybrid aqueous rechargeable zinc/lithium ion batteries to overcome above mentioned problems. Polyacrylamide hydrogel was chosen because of its high ionic conductivity, high water content and simple fabrication method in which cross-linking degree, thickness, etc. were optimized. Inclusion of clay could improve mechanical stability of hydrogel electrolyte, prevent water decomposition and dendrite formation.

All tests performed in Zn/$LiFePO_4$ cell operating in an optimized LiCl/$ZnCl_2$ aqueous electrolyte based hydrogel.

The burgeoning field of miRNA detection using electrochemiluminescence (ECL) has garnered a great deal of attention in recent times.[1] ECL presents many advantages over alternative detection strategies as ECL analyses generally exhibit low-background signals, high sensitivity, are reproducible and scale-able.[2] When combined with magnetic-beads for the immobilisation of biological recognition elements, ECL biosensors offer exceptional sensitivity owing to the ability to disperse the beads in large sample volumes to capture the biological target of interest *via* mixing then concentrate prior to analysis *via* magnetic extraction.[3, 4]

Herein, we present a novel biosensor for the sensitive detection of miRNA-21 comprising a molecular beacon ECL probe immobilised on magnetic beads. We obtained a limit of detection of 500 attomoles for miRNA-21 without enzymatic amplification or the addition of detection probes or intercalating labels, negating the need for lengthy and stringent washing procedures to reduce the background signal. Furthermore, we demonstrate the immense potential for point-of-care applications by developing a fully integrated miRNA detection platform.

The platform comprises a portable-potentiostat for ECL generation, mobile phone for ECL detection and a custom 3D-printed cell holder to readily interface a disposable screen-printed electrode with the potentiostat and phone camera. When combined with point-of-care miRNA extraction methods, the molecular beacon based ECL system we have developed presents a promising tool for point-of-care diagnosis and management of numerous diseases.

The Haber-Bosch process which is currently responsible for the whole production of ammonia for nitrogen (N)-fertilizers, operates at high temperatures and pressures releasing around 1.6-3.8 tons of CO_2 per ton of NH_3 produced. The process also operates on a vast scale in a few locations worldwide, necessitating a network of transportation to deliver the final N-fertilizer to individual farmers. Thus, there is an unmet need for a distributed ammonia production process that can operate locally at a smaller scale under ambient conditions for a single farmer or a group of farmers. This study presents the steps towards the realization of this goal through the alternative of electrochemistry.

Electrocatalytic conversion of N_2 to NH_3 at ambient and semi-ambient conditions in an aqueous electrolyte, using a zirconium nitride catalyst – predicted by density functional theory (DFT) calculations –was comprehensively studied in batch-cell and flow-cell. The catalysts were deposited as thin films in various single-crystal structures with orientations of (111), (100), and (110) facets and polycrystalline thin films, using reactive magnetron sputtering. For each surface, two electrolytes were tested in an H-type batch-cell and depending on the cyclic voltammograms obtained in N_2 vs. Ar gas, the most promising electrolytes were tested further in a micro-reactor flow-cell which was connected in-line to an ammonia quantification unit. A new electrochemical pulsing methodology was developed to address persistent challenges associated with this electrochemical reaction, namely low current efficiencies and low reaction rates. The experiments aimed to understand the effects of the applied potential and its duration on the surface reactivity and stability for each of the ZrN facets. X-ray photoelectron spectroscopy (XPS) and X-ray reflectivity (XRR) analysis were carried out on pristine and used catalysts to study the surface changes throughout the electrochemical processes. Control experiments in Ar gas and isotope-labeling experiments were performed, as well, to investigate the source of ammonia produced. Presence of hydrazine and nitrate was ruled out as side-products. The results show significant differences between surface structure and applied potential for both reaction rates and current efficiency towards ammonia formation and indicate that surface engineering may help in designing more efficient catalysts for nitrogen reduction reaction (NRR).

Flow batteries have recently become one of the most promising technologies in the field of large scale energy storage since they provide a possibility to adjust their power-to-energy ratio in the wide range with minimal expenses. In the search for novel types of such devices it was demonstrated [1] that it is possible to carry out the electroreduction of bromate anions in acidic solution on carbon electrodes due to the presence of bromine, even in trace amounts. In this case, an autocatalytic cycle consists of a heterogeneous reaction on the electrode surface for a reversible redox couple of Br_2/Br^- and an irreversible homogeneous reaction of the BrO_3^- and Br^- comproportionation into Br_2. Use of bromates as energy-intensive substances is a promising approach because it allows one to increase the energy density of flow batteries from tens to hundreds of W h/kg.

The main purpose of this study has been to investigate the whole process of electrooxidation of a bromide anion and then inverse electroreduction of the bromate anion in a testing cell with one membrane electrode assembly. Two modes of the cell operation were studied - for acidic and alkaline sodium bromide solutions. Also, different methods such as spectrophotometry and electrospray ionization-mass spectrometry (ESI-MS) were applied to control the composition of solution at the outlet of anodic compartment. It was found that after deep oxidation of acidified sodium bromide solution the resulting bromate-containing electrolyte might be successfully used ~~for~~ in combination with electrochemical hydrogen oxidation at anode inside the same electrochemical unit for the current generation, thus demonstrating for the first time the whole charge-discharge cycle of the hydrogen-bromate flow battery (Fig.1). Its energy efficiency exceeding 72% was achieved for the second redox cycle in the 5-cycle series. Among the reasons of capacity decay, the main role is played by degradation of porous carbon material ~~at positive side~~ of the positive electrode of the cell. Several strategies to overcome this drawback have been formulated.

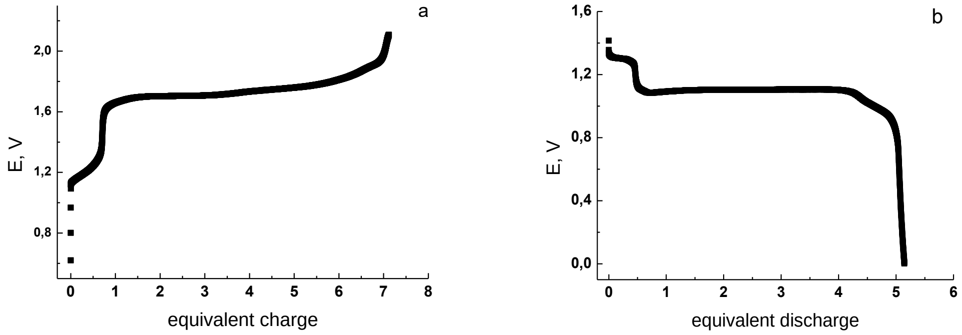

Figure 1 - Charge-discharge curves of H_2/BrO_3^- redox flow battery. Membrane electrode assembly design: positive electrode - Toray EC-TP1-120 carbon paper, negative electrode - Freudenberg H23C8 carbon paper (loading Pt / C 1 mg/cm^2), membrane - Nafion 117. a) galvanostatic mode:1 A, positive electrode - 0.5 M NaBr 1 M H_2SO_4, 50 ml/min, the negative electrode is open to the atmosphere, termination after passing 7 equivalents of the Br^-/Br_2 transformation charge; b) galvanostatic mode: -1 A, positive electrode -product of the stage (a), negative electrode - hydrogen, 10 ml / min.

A promising direction of modern electrochemical energy science is redox flow batteries (RFB), which allow to generate and store electric energy as a result of electrochemical reactions of liquid reagents with high energy capacity - an oxidizing agent and a reducing agent. In the article [1] it was shown that it is possible to carry out the electroreduction of bromate anions in acidic media on catalytically weakly active electrodes (for example, carbon) via the redox mediator mechanism provided by the Br_2/Br^- redox couple. Later in the article [2], a hybrid chemical power source was demonstrated — a hydrogen-bromate redox flow battery using the cathodic reaction of the reduction of bromates in an acidic medium. In order to expand the range of oxidizing agents that are potentially prospective for chemical power sources of this type. We studied a flow cell with hydrogen gas oxidation at anode anв reduction of solutions of chlorates and their mixtures with bromates at cathode.

Positive electrode based on Toray TGPH 120 carbon paper and the negative one consisted of Pt / C catalyst with a Pt loading of 1.175 g/cm^2 spread on Sigraset 39AA gas diffusion layer were separated by Nafion 117 membrane. Hydrogen gas was supplied to the negative electrode, and 25 ml of an acidified solution of sodium halogenates of various compositions were pumped through the positive electrode in a cyclic mode. The current generated by the cell was measured at a constant voltage of 0.5 V (the OCP voltage was about 1.4V) until the oxidizer has been completely exhausted. The moment of complete conversion of catholyte solution was determined by the current approach to zero. It was found that for sulfuric acid concentration in the bromate-chlorate mixture below 1 M, the current generated by the cell is associated with the process of bromate reduction only, while chlorate acts as an indifferent additive. With ~~an~~ increase of the acid concentration over 3 M, the fraction of chlorate ions involved in the redox transformation increases and reaches unity at 6 M H_2SO_4. In addition, the use of oxidizing solution containing 6 M H_2SO_4 acid without addition of bromate results in a discharge current that flows after a certain induction period up to the complete reduction of chlorate to chloride. To study the processes occurring at cathode, we used the method of spectrophotometric analysis of the electrolyte at the outlet of cathode half-cell, which allowed us to determine the nature of the redox-mediator couple during reduction of the chlorate anion.

Ionic liquids (ILs), room temperature molten salts, can be considered as electrolytes for next generation of lithium-ion batteries (LIBs), because of their low flammability, thermal stability, good conductivity and wide electrochemical stability window. In order to decrease viscosity and further increase conductivity ILs are usually combined with some organic solvent (cosolvent) for LIBs applications[1,2]. In this work the 0.5 M solution of LiTFSI salt in low viscosity ionic liquid 1,3-diethylimidazolium *bis*(trifluoromethylsulfonyl)imide, (C_2C_2imTFSI), without cosolvent, was tested as electrolyte for LIBs by using robust anatase TiO_2 nanotube arrays (NTAs) electrode. The galvanostatic (GS) testing was performed at different current rates and also at different temperatures, 25-55°C, at current rate 3C, Fig. 1. Capacity of TiO_2 NTAs is due to both bulk and surface storage of Li^+-ion, and significantly increases with temperature increase. GS experiments demonstrated excellent capacity retention with improved Coulombic efficiency during final cycling at current rate ~3 C, but with the decrease in capacity of TiO_2 NTAs comparing to values before temperature raise or change of current rate[3]. The decomposition of electrolyte was observed by detecting the change of colour of electrolyte in bottle type cell during experiments at elevated temperatures. The formation of film on electrode surface and its increase after GS cycling at elevated temperatures was confirmed by electrochemical impedance spectroscopy.

Redox flow batteries (RFB) is a promising secondary chemical source of current for long-term energy storage used for smart energy networks [1]. Recently the attention of researchers has been attracted to various RFBs organic redox couples which are characterized by good kinetics, availability of primary products and variability: the addition of certain functional groups can significantly change the solubility or standard potential of the redox pair.

Anthraquinone-bromine RFB was presented in [2], where anthraquinone-2,7-disulfonic acid used as negolyte can be synthesized by relatively simple anthraquinone sulfonation process. This RFB demonstrated promising characteristics, however, the possibility to use the products of synthesis as negolyte was not demonstrated ether in this or in subsequent papers.

In this study, a series of anthraquinone sulfonic derivatives was obtained by sulfonation of anthraquinone with oleum varying following key parameters: synthesis time, concentration of reagents, temperature. As a result, we obtained various mixtures of anthraquinone (2,6 and 2,7-) disulfonic acids as well as monosulfonic acids, the quantitative ratios of which were estimated using deconvolution of cyclic voltammetry data.

The resulting mixtures were tested as negolyte in anthraquionone-bromine RFB. It was shown that the characteristics of tested RFBs do not differ and in some cases even surpass the similar characteristics for RFBs, using pure anthraquinone-2,7-disulfonic acid as negolyte. For example, a mixture of products with a total concentration of 0.212 M disulfonic acid with the trace concentration of monosulfonic derivative demonstrated maximum discharge power about 145 mW/cm^2 (similar characteristic for RFB with pure anthraquinone-2,7-disulfonic acid was 105 mW/cm^2), energy efficiency and electrolyte utilization during cycling tests are about 70 and 85%, respectively. The data obtained confirm the possibility to use sulfonation products of anthraquinones as negolytes in organic RFB.

Ever growing need for energy has led the world to the edge of complete exploitation of fossil fuels, and the verge of irreversible environmental damage. It is imperative that we start fully relying on renewable sources, and for that, the electrochemical energy conversion and storage systems are required. Fuel cells, as energy conversion devices, are the most promising ones, using hydrogen or small organic molecules - SOMs as fuels (energy carriers). SOMs such as methanol, ethanol or formic acid have been used as an alternative to hydrogen, due to their low production cost, safe handling and use in the liquid sate and ease of implementation in the existing distribution systems. The reactions of methanol oxidation (MOR) and formic acid oxidation (FAOR) are studied in the present study.

State of the art anodic catalysts are usually platinum group metals (PGM) or their bimetallic combinations, in the form of nanoparticles (NPs), supported on high area carbons. One of the ways to synthesize them is the water in oil microemulsion method [1], which allows the use of surfactants and capping agents to affect the particle shape. Since MOR and FAOR are structure sensitive, NP shape and composition affect the catalytic performance. In our previous work we have successfully synthesized shaped Pt/C catalysts, and then bimetallic PtAu/C catalysts with this method, using the simultaneous reduction approach (both precursors are in the same microemulsion - ME) [2,3], while at this point the successive approach is employed (reduction of Pt in one ME, joining with other ME with Au precursor, second reduction), with low Au loading of less than 5%. The results of Energy Dispersive X-ray Spectroscopy (EDS) and electrochemical characterization are shown in Fig 1 (A-D). This way, more Au was obtained on the surface, as expected, which contributed to a better catalysis in FAOR – higher activity and favoring of a direct mechanism (due to more pronounced ensemble effect), and better catalyst stability in MOR (due to weaker CO bonding). The change in particle shape and surface structure with extremely fine distribution of Au, and a higher share of Au at particle surface, as benefits of the successive reduction synthesis procedure have a high impact on catalytic performance.

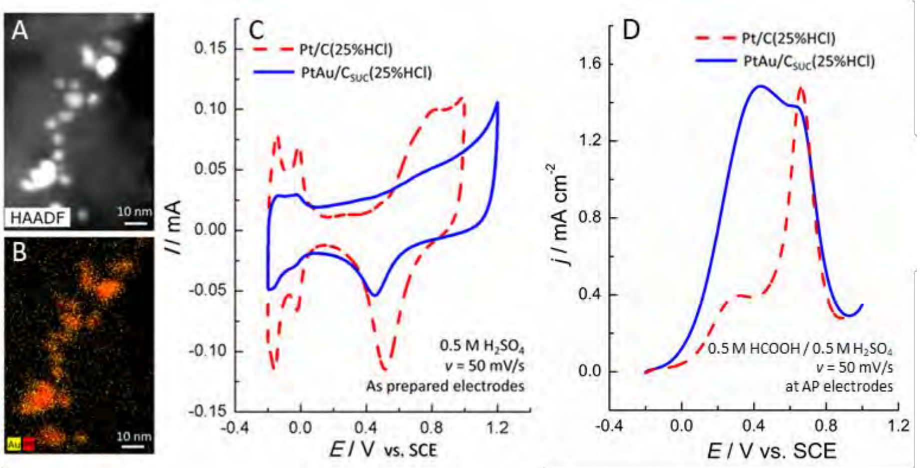

Fig 1. HAADF image (A) and EDS map (B) of the PtAu/C$_{SUC}$(25%HCl) sample; initial CV at AP surface of Pt and PtAu samples (C), initial anodic scan of FAOR at AP surface of Pt and PtAu samples (D)

Electrolyte pH as a means of controlling the selectivity of CO_2 reduction reaction and the kinetics of H_2 evolution reaction

Akansha Goyal, Marc T.M Koper*
Leiden Institute of Chemistry, Leiden University
PO Box 9502, 2300 RA Leiden, The Netherlands
a.goyal@lic.leidenuniv.nl

It has long been recognized that metal-electrolyte interactions at the electrified solid-liquid interface play an important role in controlling the intrinsic kinetics of electrocatalytic reactions. Additionally, reaction (heterogeneous and/or homogenous) induced concentration gradients in the diffusion layer can further alter the mechanistic pathways of electrocatalytic reactions by modifying the availability of the competing reactant species. In this framework, (local) electrolyte pH is one of the most important parameter in aqueous electrocatalysis, since it affects both the composition and the structure of the electrical double layer. In this work, we emphasize the importance of this crucial parameter, by first discussing the role of electrolyte pH in controlling the selectivity of the CO_2 reduction reaction (CO_2RR) on Au electrodes in weakly buffered bicarbonate electrolytes and thereafter, by presenting a detailed quantitative understanding on the pH dependent kinetics of hydrogen evolution reaction (HER) on Au electrodes under alkaline conditions.

At present, the economic feasibility of electrochemical CO2RR remains an issue, primarily due to efficiency losses from the concomitant HER. In this context, a better understanding of polarization induced local pH gradients at the interface and their role in the kinetic competition of CO2RR and HER will be crucial for the optimization of this reaction. Here, we will present a new implementation of the well-known rotating ring-disk electrode (RRDE) technique to study the role of local pH gradients on the selectivity of CO2RR under well-defined mass transport conditions[1]. In essence, this work shows that enhanced mass transport acts as a pH regulator and suppresses the local build-up of hydroxyl ions, which in-turn inhibits the HER (water mediated) during CO2RR and dictates the overall Faradaic selectivity of these two competing reactions (as shown in Figure 1).

Interestingly, this work also shows that OH^- ions affect the kinetics of water reduction reaction on Au electrodes such that the HER activity improves with the increasing pH. This deviates strongly from the previously reported trend for the Pt(111) surface and the well-established trends for pH dependence of HER under acidic pH conditions[2]. In addition to the pH dependence, we observe that the activity of HER also increases with the cation concentration in the electrolyte. Here, we will show that these two seemingly independent trends are in-fact caused by the same phenomenon, namely, the cation assisted enhancement of the rate determining water dissociation step (Volmer step). It is well known that the interfacial electric field shifts with the electrolyte pH (on the RHE scale). We propose that this pH dependent electric field induces cation concentration changes near the surface, leading to a pseudo pH dependence for HER (as shown in Figure 2). We also present a quantitative analytical model formulated from theory, which captures the pH (and/or mass transport) dependence of HER as an inherent feature of the cation dependence of HER which further validates our experimental findings. Therefore, this work provides crucial insights for the design of optimized electrolyte pH conditions for HER in alkaline media.

Over the past two decades, DNA-based nanotechnology has largely focused on developing ultrasensitive bioelectronic nanodevices that are capable of processing environmentally generated signals.[1] Consequently, branched DNA Holliday Junctions (HJ) have attracted increased attention as cation-controlled nanoscale switches.[2-3]

In this work, we investigated the feasibility of controlling reversible switching of DNA HJ and formation of the DNA HJ-based origami scaffolds by Zn^{2+} ions, introduced in the form of either chloride or sulfate. Besides being one of the most abundant essential microelements in the human body, Zn^{2+} ions are not directly involved in redox reactions in biological systems,[4] which have made them appealing cation candidates for our research. The conformational switching of HJ was monitored using Fluorescence Resonance Energy Transfer (FRET) between donor and acceptor dyes each located at the terminus of one of the arms, while liquid Atomic Force Microscopy (AFM) was used for visualization of the switching process by the construction of DNA origami assemblies in Zn^{2+} solutions.

Surprisingly, the Cl^- ions, unlike the SO_4^{2-} ions, detrimentally affected the HJ switching process in the presence of Zn^{2+} ions. The evidence of that outcome was clearly visible using AFM imaging technique which displayed Zn/Cl-containing deposits formation within DNA HJs, which was also confirmed electrochemically. However, further research demonstrated that the presence of ascorbic acid or other antioxidant species prevented the effect of zinc removal from solutions caused by Cl^- ions. Thus, this work represents a plain way of controlling the switching/assembly processes induced by zinc chloride with the presence of biologically relevant antioxidants and allows a flawless design of new DNA HJ-based nanoswitching biosystems.

Sensitive, specific and rapid detection of bacterial colonies is becoming the need of the hour. Food spoilage, prevention of pathogenic infections and antimicrobial resistance put such detection systems at highest priority in food and medicine industry. [1] Among these microbial communities, the bacterial strain of *Escherichia coli* (*E. coli*) is most commonly found, with pathogenic and non-pathogenic strains being biomarkers of bacterial contamination. [2] Here, we developed a novel electrochemical assay for *E.coli* utilizing DNA as electrical wires, mediating electron transfer between gold electrodes and a well-known DNA intercalator, Methylene Blue (MB).The binding of *E. coli* specific target DNA to the capture DNA-modified gold electrode surface triggers the intercalation of MB present in solution within the hybrid structure. The signal from MB is further electrocatalytically amplified in reaction with a commonly used redox indicator ferricyanide whose electrochemical reduction is otherwise very slow on the DNA-modified surfaces. The developed assay allows down to attomolar detection of both synthetic and isolated *E. coli* DNA and RNA. The high sensitivity of the assay allows direct application of it in point-of-care and industrial platforms for analysis of raw or minimally processed samples.

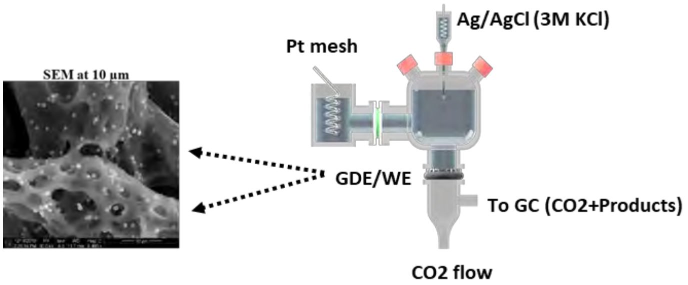
The efficient electrochemical conversion of CO_2 to valuable energy-dense chemicals and synthetic fuels such as e.g. ethylene and ethanol is an attractive route for curbing greenhouse gas emissions.[1] However, the reduction of CO_2 is quite tedious as it involves multi proton-multi electron transfer reactions to overcome the inherent large energy barriers. Among various metals, Cu is the only metal that can reduce CO_2 into various value-added multi-carbon (C_{2+}) products.[2] Recently, metal-nitrogen-doped carbon materials (M-N-Cs) have emerged as a class of materials displaying up to 80% faradaic efficiency for CO formation (Fe-N-C) at comparatively low overpotentials (-0.55 V vs. RHE)[3] compared to metals alone. These M-N-C materials contain $M\text{-}N_x$ sites which have been shown to be active sites in the CO_2RR. Gas diffusion electrodes (GDEs) were recently reported as ideal electrodes for conversion of gaseous reactants in aqueous environment at relevant current densities (> 200 mA cm^{-2}).[4] The presence of a three-phase boundary allows a higher gas concentration to reach the catalyst's active sites, since a high solubility of gaseous reactants in aqueous environment is no longer required. Additionally, the use of GDEs allows that CO_2RR is performed in alkaline environment which was shown to favour the C-C coupling and formation of high C products ($C\geq2$) via CO_2RR together with suppression of the H_2 evolution reaction. Herein, we report the fabrication of a CuO/Cu-N-C type electrocatalyst directly immobilized on the current collector by using a benzoxazine monomer[5] and copper acetate as carbon, nitrogen and Cu precursor, respectively. This involves direct catalyst synthesis on the current collector by spray coating the mixture of the benzoxazine monomer and Cu acetate onto a carbon paper followed by pyrolysis. The catalyst coated carbon paper is further converted into a gas diffusion electrode by spray coating of a Teflon layer. As control experiment, the "classical" approach in which the catalyst is pre-synthesized and then spray coated on a commercial gas diffusion layer is also presented and the results are comparatively discussed. Scanning electron microscopy (SEM) was used to assess the electrode morphology. The influence of the electrode structure on the CO_2RR selectivity performed in H-type modified cell in alkaline environment (pH ~ 13) evaluated based on gas chromatography (GC) and high liquid performance chromatography (HPLC) will be presented.



Scheme: Electrochemical cell and SEM image of CuO/Cu-N-C.

Nanoscale architecture is very important for complex and advanced products like electrocatalysts. The position and coordination of each atom define its activity, selectivity and also stability. In order to understand and optimize these properties, it is crucial to have control over these nanostructures. For the optimized operation of electrocatalysts also the mass transport of reactants and products must be optimized. Typically movement of molecules is effected at the nano- to micro-scale. In order to combine both, mass transport and intrinsic electrocatalyst activity, electrospinning is recognized as a suitable method, where nano-sized fibers are produced with great precision and relative ease. [2]

The objective of electrospinning, as a simple, versatile, cost-effective and up-scalable approach, in our study was to fabricate one-dimensional mesostructured carbon nanofibers of controlled hierarchical features with Pt nanoparticles on the surface as electrocatalyst model electrode (Fig. 1a,b,c). By taking advantage of the modern advanced characterization techniques like in-situ heating transmission electron microscopy (TEM) and electrochemistry (cyclic voltammetry, methanol oxidation reaction, oxygen reduction reactions, floating electrode) together with classical characterization like scanning electron microscopy (SEM), we reveal several new insights. By appropriate annealing protocol (Fig. 1d), we were able to produce carbon nanofibers decorated with Pt nanoparticles from polyacrylonitrile (PAN) mixed with Pt salt in one step; with no Pt trapped inside the carbon matrix. This synthesis provides a facile way to produce effective high surface area Pt-electrodes.

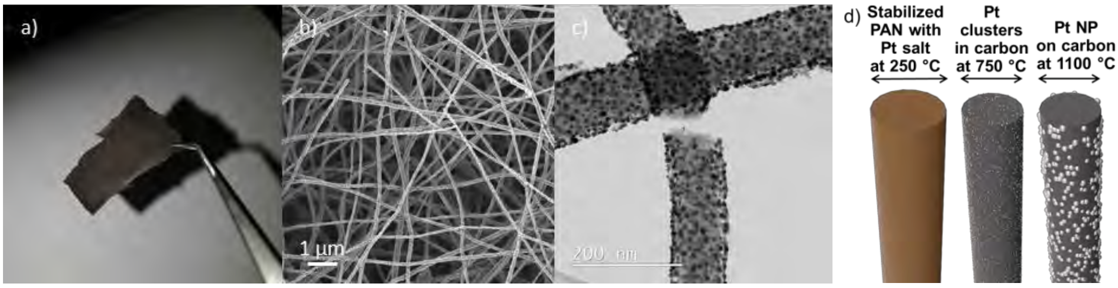

Figure 1. a) photography, b) SEM, c) TEM and d) STEM of electrospun and subsequently annealed at 1100°C Pt/C electrode. In the c) and d) Pt nanoparticles are clearly distinguished on the carbon nanofiber.

Conventional ensemble-based electrochemical techniques such as rotating disk electrode and rotating ring disk electrode experiments provide insight into the electrocatalytic reactions and henceforth provide information about activity, possible reaction mechanisms and understanding about the long-term stability of materials of interest. However, any further improvement in the intrinsic activity for a given electrocatalytic reaction of such nanoparticles necessitates a thorough understanding of their structure-property relationships, particularly with respect to the size and shape-dependent electrocatalytic activity. Importantly, in case of non-precious metal-based catalysts, the impact of the exposed crystal lattice including defects, local compositional changes as well as its dynamics during catalytic turnover needs to be understood to allow for a rational design of improved electro catalysts for complex multi-electron/multi-proton transfer oxidation reactions.[1,2]

In this direction, scanning electrochemical cell microscopy (SECCM) provides vital insight into the structure-activity correlation at the nanoscale and is effective to study the morphology-based activities within the confined area on a single substrate.[3,4] In the present work, Co_3O_4 nanoparticles with different structural morphologies were studied using SECCM for the oxygen evolution reaction. Co_3O_4 nanoparticles with different morphologies were deposited on glassy carbon plates as well as on transmission electron microscopy (TEM) grids. Cyclic voltammograms and linear sweep voltammograms were collected at nanoparticles from a large number of investigated droplet-wetted spots in a suitable potential range in presence of a redox couple as internal potential standard. Electrochemical results of SECCM scan were correlated with the particle morphology imaged by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) to elucidate the structure activity relations.

kuriganova_@mail.ru

Nanoparticles of platinum group metals (PGMs) in particular Pt, Pd, Rh, are still the most effective catalysts for processes that occur in low-temperature fuel cells [1]. As a rule, chemical and electrochemical methods for producing nanostructures containing nanoparticles of PGMs are based on a "bottom-up" approach, when simple elements (atoms, ions or molecules of precursor compounds) form systems with a complex structure. We propose a "top-down" method for producing electrocatalysts (M/C) based on Pt, Pd and Rh nanoparticles, which is based on the electrochemical dispersion of metal electrodes (Pt, Pd or Rh) under the action of an alternating pulse current.

For the M/C catalysts preparation two metal electrodes (Pt, Pd or Rh) with the same area immersed in the suspension of carbon support Vulcan XC-72 (CabotCorp., 240 m^2g^{-1}) in aqueous electrolyte contained Na^+ cations. The electrodes are connected to ac source operating at 50 Hz, current density 1 A cm^{-2}. Bulk metal electrodes were disperse to nanosized metal particles. Then, suspension was filtrated; prepared catalyst was rinsed with H_2O to a neutral pH and dried at 80°C to constant weight.

The mechanisms of the formation of Pt, Pd, Rh nanoparticles in the conditions of electrochemical dispersion were established [2-4]. It has been established that platinum and rhodium electrodes are dispersed to Pt and Rh nanoparticles, while palladium electrodes are dispersed with the formation of Pd-PdO particles. Electrocatalystic activity of synthesized materials was studied using ethanol and formic acid oxidation reactions as an example and a high catalytic effect compared to standard materials was detected.

Based on the data obtained on the processes of electrochemical dispersion of Pt, Pd and Rh electrodes and the formation of metal nanoparticles under the conditions of electrochemical dispersion of metals, we developed methods for the synthesis of Pt/C, Pd-PdO/C and Rh/C materials and investigated their electrocatalytic activity in anode processes [2-4].

Thus, the proposed method M/C obtaining as a result of electrochemical dispersion of metals is technologically simple and environmentally safe because it does not involve the use of organic solvents and capping agents.

paula.pascual@chem.ku.dk

The conversion of greenhouse gases such as CO_2 into renewable fuels and chemicals is one of the most important technological and environmental challenges facing humanity. Electrochemical reduction of CO_2 and CO on Cu is a promising and sustainable alternative to produce fuels and chemicals, while contributing to close the unbalanced carbon cycle [1]. Recently, efforts have been dedicated to find rational description of the mechanism of both CO_2 and CO reduction on Cu, which continues being focus of debate [2]. Well-defined studies on Cu single-crystalline surfaces are key to elucidate the properties of the Cu-aqueous electrolyte interface, necessary to understand the electrocatalytic properties of Cu.

Herein, we study the interfacial properties of Cu(100) and Cu(111) in contact with different classical electrolytes such as phosphate buffer solutions, bicarbonate solutions and 0.1M NaOH solutions. In this study, we have combined cyclic voltammetry and the laser induced jump temperature technique to elucidate the structure of the Cu-electrolyte interface. Voltammetric experiments aim to provide the fingerprint of both Cu(111) and Cu(100), to be used as a parameter control of the surface state and experimental conditions in studies with Cu [3][4]. The laser induced temperature jump technique has been employed to obtain information about the distribution of the charge on both Cu(111) and Cu(100) surfaces, and then determinate their potential of zero charge (*pzc*) [5]. Overall, we discuss different aspects that we consider essential while investigating the interfacial properties for both CO and CO_2 reduction on Cu: evolution of the voltammogram features at different selected potential windows, specific anion adsorption and pH effects. This experimental study provides deep insights of the interfacial properties of Cu(111) and Cu(100) which are crucial to reach deeper understanding of the reduction of CO_2 and CO on Cu electrocatalysts.

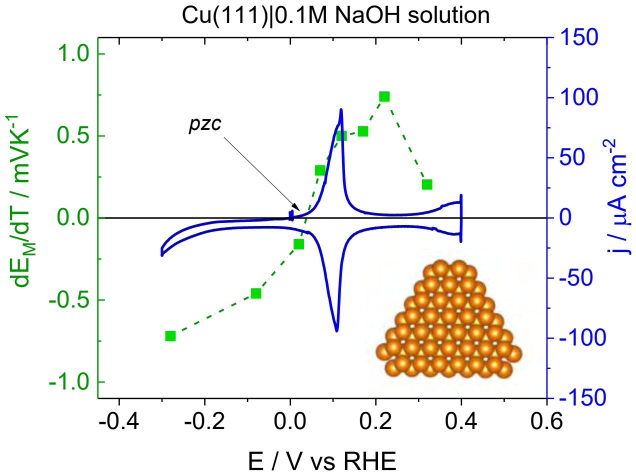

Figure 1: Blank voltammogram of Cu(111)-0.1 M NaOH solution interface at 50mV/s and thermal coefficients of the interfacial potential drop.

Hardness and Wear Resistance of Multilayered Ni-P Films Fabricated by Pulsed Electroplating

Hiroshi Kanemoto, Takuya Aoyagi, Toshinori Kawamura
Hitachi, Ltd.
Hitachi, Ibaraki, Japan
hiroshi.kanemoto.uz@hitachi.com

Industrial chrome plating, which has excellent hardness, corrosion resistance and wear resistance, has been widely used for various industrial products. In the plating process, hexavalent chromium specified as a substance of very high concern by environmental regulations is used. Therefore, plating technologies replacing the conventional chromium plating, such as trivalent chromium plating and Ni-based composite plating, have been studied. In particular, multilayer plating in which different kinds of metal layers are alternately laminated, has been also studied as one of the methods to improve hardness and wear resistance of the plated film. We focused on a multilayered Ni-P film to create a plated film that have hardness, wear resistance and corrosion resistance. In this study, multilayered Ni-P films were fabricated by pulsed electroplating, and the effect of multilayering on hardness and wear resistance was evaluated.

A stainless steel SUS303 (thickness 3 mm) was used for the substrate. Typical pretreatments such as mirror polishing, degreasing, acid treatment, and Ni strike plating (0.1 μm thick) were performed. In a multilayered Ni-P plating process, a Ni plating bath containing additives such as phosphonic acid, sulfur-containing organic compounds and others was used. A pulsed constant current was applied to the substrate in the plating bath to fabricate multilayered Ni-P films with different layer thicknesses and layers structures. Heat treatment was performed at a predetermined temperature to harden the films. The plated films obtained by the above process was used as specimens (multilayered films). For a reference, a monolayer Ni-P film was prepared by applying a constant current (monolayer film). Each specimen had a total plating film thickness of 10 μm. The cross section of each specimen was observed by SEM and STEM. Trace components in the film were analyzed by SIMS (Secondary Ion Mass Spectrometry) and 3D atom probe tomography. The Vickers hardness of each specimen was measured under a load of 25 gf. Wear resistance was evaluated using a reciprocating sliding tester in the air, at room temperature, under non-lubricated or lubricated conditions. The worn scar was observed to measure the worn volume quantitatively.

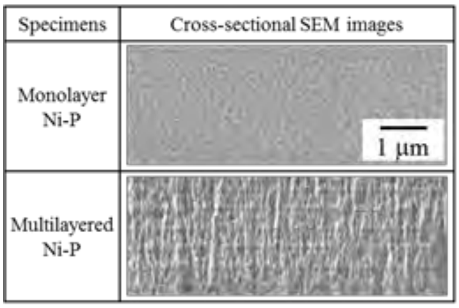

Fig. 1. Cross-sectional SEM images of a monolayer and a multilayered Ni-P films

The cross-sectional microstructures of the monolayer and the multilayered (layer thickness: 500 nm) Ni-P films after annealing are shown (Fig. 1). The monolayer film showed a smooth surface, while the multilayered film showed a layered structure. Analysis of the trace components in the multilayered film showed that P concentration hardly changed and the concentration of the elements such as sulfur and so on derived from the additives increased along the boundary of each layer. This is presumably because the additives were adsorbed on the plated film surface during the period when no current was applied and then were incorporated into the film during the subsequent period when a current was applied, in the pulsed electroplating process. The multilayered structure was maintained even after heat treatment, which is probably due to the suppression of grain growth by the additives solid-soluted between the layers.

Hardness and wear resistance of each film were measured. There was no significant difference in hardness between the monolayer and the multilayered films. The multilayered film exhibited about 1.3 times higher wear resistance than the monolayer film under non-lubricated. This result was discussed by fractography and molecular dynamics simulation for the Ni-P films. During the sliding test, cracks seem to occur not only on the surface of the film but also the inside due to the effect of shear stress distribution. Multiple cracks probably propagated and combined to cause significant delamination in the monolayer film. On the other hand, the interfaces between layers seem to suppress crack propagation in the multilayered film, resulting in small delamination, though cracks occur as in case of the monolayer film.

The above results suggest that multilayering is effective for improving wear resistance, maintaining hardness in the multilayered Ni-P films.

Solid state ionic conductors based on Lu-doped δ-Bi_2O_3

A. Petričević[1], A. Malešević[2], A. Radojković[2], M. Žunić[2], G. Branković[2], A. Dapčević[1]

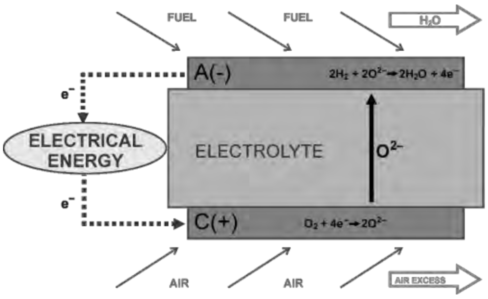
aleksandar.petricevic27@gmail.com



Regarding limited fossil energy resources and hence the increasing demands for new highly efficient and environmentally friendly energy conversion devices, the widespread use of solid oxide fuel cells (SOFCs) might become a keystone in near future. An SOFC is consisted of dense electrolyte which is sandwiched between two porous electrodes. Since the electrolyte is the most important part of an SOFC, oxide ion conductors applicable in SOFCs became the hot topic of modern research. The main requirement is to find a stable dense electrolyte material with increased conductivity at intermediate temperature. Two commercial electrolytes, yttria stabilized zirconia (YSZ) and gadolinia doped ceria (GDC), are far to be ideal. The use of YSZ requires operating temperatures above 1000 °C while devices based on GDC are not efficient enough due to GDC lower conductivity at intermediate temperatures.

The best candidate for an electrolyte in intermediate temperature SOFCs is undoubtedly fluorite structured bismuth oxide, i.e. δ-Bi_2O_3, being the fastest known ionic conductor. However, this material is unstable upon heating/cooling but the use of dopant, such as Tm, led to the impressive stability and high conductivity at intermediate temperatures [1]. Our findings indicated that Lu-doped δ-Bi_2O_3 could show even better performances since Lu is smaller and more rigid dopant than Tm.

In this study, the possibility to stabilize δ-Bi_2O_3 in Bi_2O_3–Lu_2O_3 system was investigated. Two starting mixtures of α-Bi_2O_3 and Lu_2O_3 with the following compositions $(Bi_{1-x}Lu_x)_2O_3$, $x = 0.20$ and 0.25, were dry homogenized in an agate mortar, heat treated at 750 °C for 3 h and then slowly cooled. The obtain powders were characterized by XRD and DTA techniques. Based on these results, the targeted cubic single-phase δ-Bi_2O_3 was successfully obtained within both systems. The unit cell parameter of obtained Lu-doped δ-Bi_2O_3 decreases as the dopant content increases, as expected since Lu^{3+} is smaller cation than Bi^{3+}. According to cyclic DTA curves, no phase transitions (25 – 980 °C) were observed for both phases, $(Bi_{0.8}Lu_{0.2})_2O_3$ and $(Bi_{0.75}Lu_{0.25})_2O_3$, indicating that these δ-Bi_2O_3 phases are stable.

Afterwards, half of obtained quantity of each powder was mechanochemically treated (in planetary ball mill Retsch PM-100) in order to decrease the crystallite size. Namely, before performing EIS measurements the powders undergo to pressing and then sintering to obtain dense ceramic pellets. This is also important for their future application in SOFC since the density of almost 100% is mandatory in order to avoid the direct contact of air (oxygen) and fuel (hydrogen). The density of sintered pellets obtained from both untreated and mechanochemically treated powders will be compared. Using EIS technique, the ionic conductivity will be measured for the samples having the highest density. We expect that these materials will exhibit the conductivities which are higher than those obtained for Tm-doped δ-Bi_2O_3 (0.1 – 0.4 S cm^{-1} at 550 – 800 °C).

Such stability and extraordinary conductivity would open the possibility for application of $(Bi_{0.8}Lu_{0.2})_2O_3$ and $(Bi_{0.75}Lu_{0.25})_2O_3$, which could result in the significant enhancement of electrochemical performance of intermediate temperature SOFCs but also in their good stability over long time service.

Fe_2O_3-HC and Fe_2N-HC Composites as Negative Materials for Sodium-ion battery

Bowen Liu, Andrew L. Hector, Richard G. A. Wills
School of Chemistry, University of Southampton, SO17 1BJ, UK
BL3Y17@soton.ac.uk

Sodium-ion batteries (SIBs) are a low cost and high performance alternative to lithium-ion batteries. [1] Hard carbon (HC) has graphitic regions but overall a disordered structure. HC exhibits fairly good performance as a SIB negative electrode material with over 250 mA h g^{-1} of reversible capacity. The majority of its capacity is utilised near 0V (*vs.* Na^+/Na). [2] Metal oxides and nitrides (MO and MN) have high theorical capacities due to a conversion mechanism in which they are reduced to the metal. [3] Our interest is combining MO or MN with HC to increase the capacity oh HC whilst mitigating some of the deficiencies in the oxide or nitride, including cost and volume changes, by supporting them in nanoparticle form on HC surfaces. [4] Here we have used a hydrothermal method to coat iron (II) oxalate on HC surfaces and calcined the precursor in air to obtain Fe_2O_3-HC composites. Heating the same precursor in ammonia results in Fe_2N-HC composites. The composites were tested in sodium half-cells. The hydrothermal process reduced the performance of the HC itself, but the conversion materials added significant extra capacity to that of the HC and this extra capacity persisted during cycling. Future work will aim to find routes to such composites that do not damage the performance of the HC host but do allow the extra capacity to be accessed.

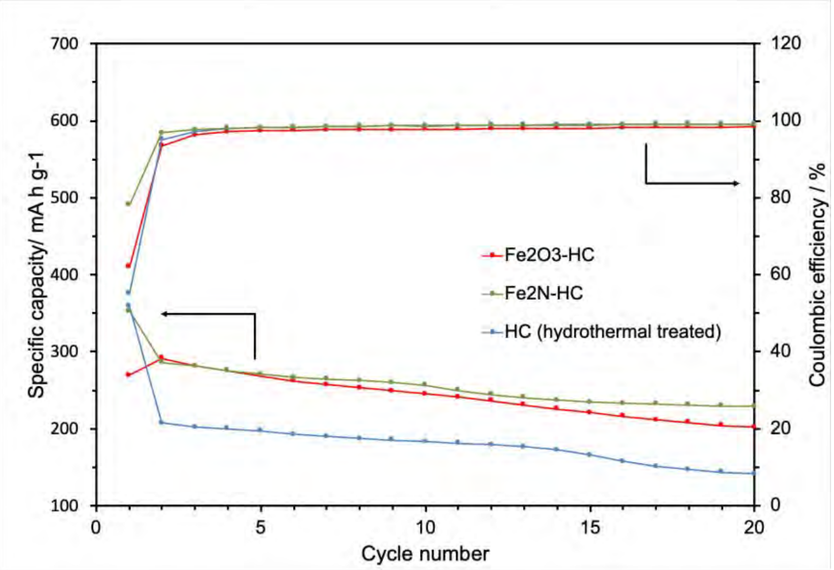

Fig 1 cycling performance of HC (after hydrothermal treatment), Fe_2O_3-HC and Fe_2N-HC between 2 and 0.001V (*vs.* Na^+/Na) at 100 mA g^{-1} in sodium half-cells.

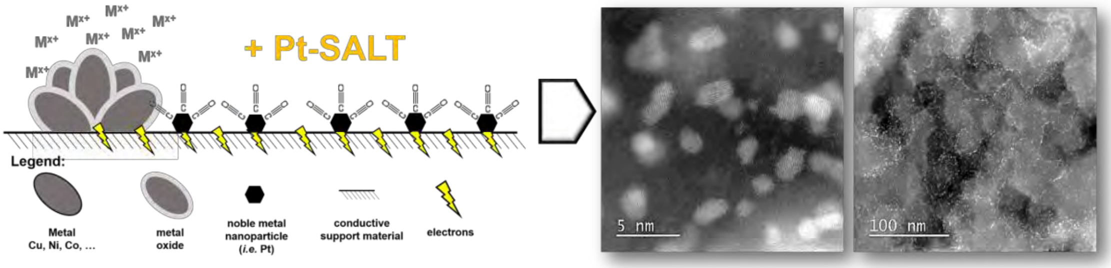
Novel Double Passivation Galvanic Displacement Method for Production of High Performance Pt-alloy Electrocatalysts

Matija Gatalo, Marjan Bele[a], Francisco Ruiz-Zepeda, Ana Rebeka Kamšek, Primož Jovanovič, Nejc Hodnik, and Miran Gaberšček
Department of Materials Chemistry, National Institute of Chemistry
Hajdrihova Ulica 19, 1000 Ljubljana, Slovenia
Matija.gatalo@ki.si

The most vital part of proton exchange membrane fuel cells (PEMFC) – the electrocatalyst still contains too high quantities of critical raw material platinum (Pt). While so-called non-PGM catalysts are expected to become the solution in a quite distant future, the current state-of-the-art approach of lowering the need for Pt can be achieved by alloying Pt with other transition metals. While Pt-alloys (Pt-M; M = Cu, Ni, Co, ...) are already pretty well understood and have already by-far exceeded the targeted goals for sluggish oxygen reduction reaction (ORR), methods for its facile and high scale production are still rather limited. We hereby present a novel approach towards well-known galvanic displacement (GD) method that was initially made popular by R.R. Adržić with the Pt-monolayer electrocatalysts.[1]

Our "trick" is a unique "double passivation" approach towards galvanic displacement method.[2,3] The method enables facile (energy efficient), highly reproducible on several grams scale, water-based (green) production of carbon supported Pt-M nanoparticles. The method offers great flexibility over the electrocatalyst design such as (i) the choice of the sacrificial metal (M), (ii) variation of the chemical composition of alloy (Pt:M ratio), (iii) variation of total metal loading (Pt+M) on carbon support or (iv) even variation of the carbon support itself. Among other benefits of the double passivation method, the sacrificial M on carbon (M/C) precursor does not need to have M in the form of nanoparticles, as well as the methods exploits only spontaneous processes that occur at room temperature and ambient pressures. We have tested the method reproducibly on gram scale or above with respect to 4 different commercially available carbons, 4 different Pt:M chemical compositions, 4 different total metal loadings (Pt+M) and 3 different sacrificial M (Cu, Ni and Co which are the most promising state-of-the-art Pt-alloys).



Scheme 1: Novel double passivation with galvanic displacement method.

Rapid detection of microorganisms in water, food and air is the 1st step in protection of human health. According to WHO, pathogenic bacteria, being one of the major human health threats, caused 15 million deaths only in 2010 and 13 million deaths are estimated for 2050. Sensitive, specific, and yet inexpensive electrochemical biosensing approaches can provide the required tools for fast and robust analysis of pathogens and thus disease prevention [1-3].

Here, I discuss our recent achievements in the development of electrochemical "label-free" sensing approaches for detection of bacteria based on hydrolase-linked DNA and immunoassays on magnetic beads (MB). While bacterial DNA/RNA can be detected at a 1 fM level [4], electrochemical aptamer-based and immunoassays on MBs allow single bacterium cell detection (**Figure 1**), at a cost below 1-2 € that favorably compete with the existing standard microbial counting and quantitative PCR analytical schemes. Fundamental problems and benefits of a single cells detection as compared to traditional 1:1 affinity DNA and protein assays [4,5] and arising specificity issues are discussed.

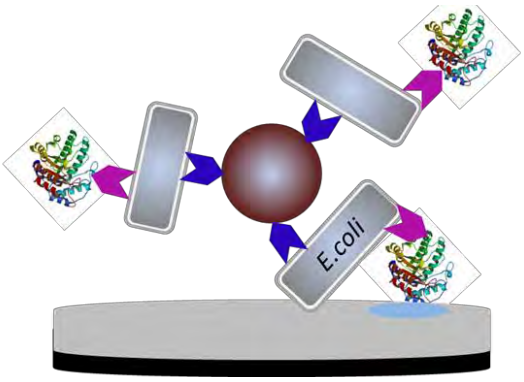

Figure 1: Schematic presentation of the cellulase-linked sandwich assay on MBs. An *E. coli* cell is sandwiched on MB between the aptamer and antibody; the sandwich is labelled with cellulase that digests the nitrocellulose film on the electrode surface. Such digestion changes electrical properties of the film-modified electrodes, which is electrochemically detected.

NiAl layered double hydroxide (NiAl LDH) with nitrates in its interlayer has been studied as anode material for lithium-ion batteries (LIBs). The electrochemical study demonstrates that the NiAl LDH materials can be applied as anodes with a very high specific capacity, with an initial discharge capacity of 2222.0 mAh g^{-1}. The excellent Li^{+}-storage performance is attributed to the expanded interlayer space of the NiAl LDH pillared by the interlayer nitrates, providing effective paths for Li^{+} diffusion [1-4]. CV curves show evident oxidation and reduction peaks corresponding to the flats of charge and discharge in the galvanostatic profile. In this work, we highlight the importance of the binder on the cycling stability. Na^{+} alginate can improve the stability respect to electrodes prepared with PVDF. The hypotesis is that Na^{+} alginate as binder can estabilsh strong bonding between pillared sites which leads to a lower exfoliation of the material during cycling and consequently improve the stability performances.

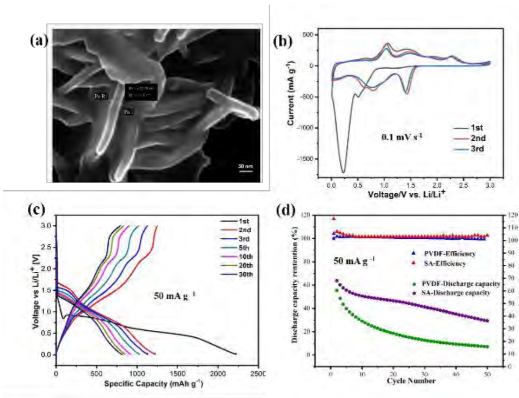

Fig. NiAl LDH's: (a) FE-SEM, (b) Cyclic voltammetry (CV) curve with PVDF as binder, (c) Charge-discharge profile with PVDF as binder (d)cycling performance with PVDF and Na^{+} alginate as binder.

Several chemical scenarios, concerning the reaction of redox enzymes with their substrates, can be accessed electrochemically with the most common electrochemical technique for the kinetic analysis of enzyme reactions being cyclic voltammetry. When direct electron transfer between the enzyme and the electrode surface is possible, some problems that occur are the low currents and the dominance of capacitance currents. One attractive alternative to overcome such problems is the use of FTacV (Fourier transform alternating current voltammetry) which has the advantages of both enhancing the Faradaic signal and eliminating the capacitance [1,2]. In this work, a kinetic analysis is made concerning the reaction of an electroactive immobilized enzyme with a free substrate, based on a Michaelis-Menten scheme, the proposed kinetic equations are investigated numerically, under different reaction states (transient or steady state for the reaction intermediate as well as quasi or complete reversibility of the electrochemical step) and the dependence of two chief observables is examined. The FTacV method is applied experimentally for an immobilized laccase-like multicopper oxidase from *Thermothelomyces thermophila*, *Tt*LMCO1 [3], and its reaction with epinephrine is monitored. From the experimental findings it is shown that the intristic characteristics of the system do not lead to the extraction of the desired kinetic data, although indications on the relation between the kinetic constants is revealed. Finally, the response of the third harmonic for the first additions of epinephrine at subnanomolarity range can be exploited for the detection of epinephrine at rather low concentrations.

Lithium ion capacitors (LICs) are aimed to cover the gap between lithium ion batteries (LIBs) and electrical double layer capacitors (EDLCs), providing both high energy and high power densities. However, the performance of LICs can be hindered due to the high reduction potential of some negative electrodes or the limited electrochemical stability of the electrolyte at high potential values, ultimately reducing the operational voltage window of the device. Thereby, in order to increase the operational voltage window of LICs and target high energy applications, the use of new solvents providing a wide electrochemical stability window at high potentials is foreseen.

In this work we report for the first time the use of 3-cyano propionic acid methyl ester (CPAME), with vinylene carbonate (VC) as additive, as an alternative solvent when targeting high voltage LICs [1]. In view of the promising viscosity, conductivity and electrochemical stability window, its use in a LIC is explored. To this end, a hard carbon (HC) is selected as the negative electrode, while an activated carbon (AC) is the preferred choice as the positive electrode, both being biomass (olive-pits) waste derived. Electrochemical characterization of the HC shows good specific capacities at both low and high current densities (*e.g.* 322 mAh g^{-1} at C/10 and 80 mAh g^{-1} at 10 C). In addition, the cyclic voltammogram of the AC reveals a stable electrochemical potential window rising to 4.6 V *vs.* Li^{+}/Li. This fact allows to develop a LIC operating at 1.5 - 4.5 V able to deliver high energy and high power density values (*i.e.* 121 Wh kg$^{-1}_{AM}$ at 299 W kg$^{-1}_{AM}$ and 69 Wh kg$^{-1}_{AM}$ at 2217 W kg$^{-1}_{AM}$, Figure 1). Moreover, it shows a capacitance retention of 70% after 5000 cycles.

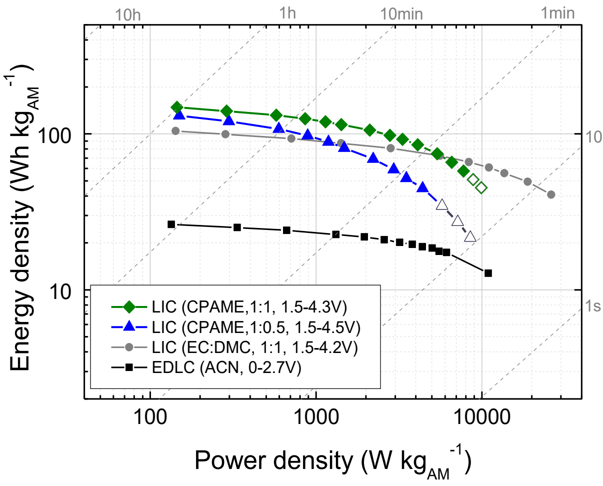

Figure 1. Ragone plot with the studied LICs and their EDLC counterpart. Open points show where lithium plating occurs.

Intermetallic Compounds as Platform Materials to Discriminate Electronic and Geometric Effects in Electrocatalysis

marc.armbruester@chemie.tu-chemnitz.de

Bimetallic systems can provide enhanced electrocatalytic activity and/or selectivity due to their altered electronic and/or crystal structure, which changes the adsorption energies of the reactants and/or the products in a chemical reaction [1-3]. These two effects are the main parameters governing the catalytic properties of a material. However, they are often interrelated and can be difficult to distinguish from one another due to segregation and random distribution of the elements in substitutional alloys. Intermetallic compounds are formed by at least two elements and possess an at least partially ordered crystal structure different from that of the constituting elements. In combination with the reduced segregation tendency, they provide an excellent material platform for a knowledge-based approach aiming for the evaluation and optimization of structural and/or electronic effects in heterogeneous catalysis (Fig. 1). The gradual substitution of one element by another from a different group in isostructural intermetallic compounds allows a systematic variation of the total number of electrons per unit cell with a minor variation of the cell parameters [4]. Thus, electronic influences can be evaluated with only small structural influences. In addition, the substitution of one element by another from the same group allows a systematic variation of the cell parameters, thus interatomic distances, with the same total number of valence electrons per unit cell, therefore limiting electronic influences.

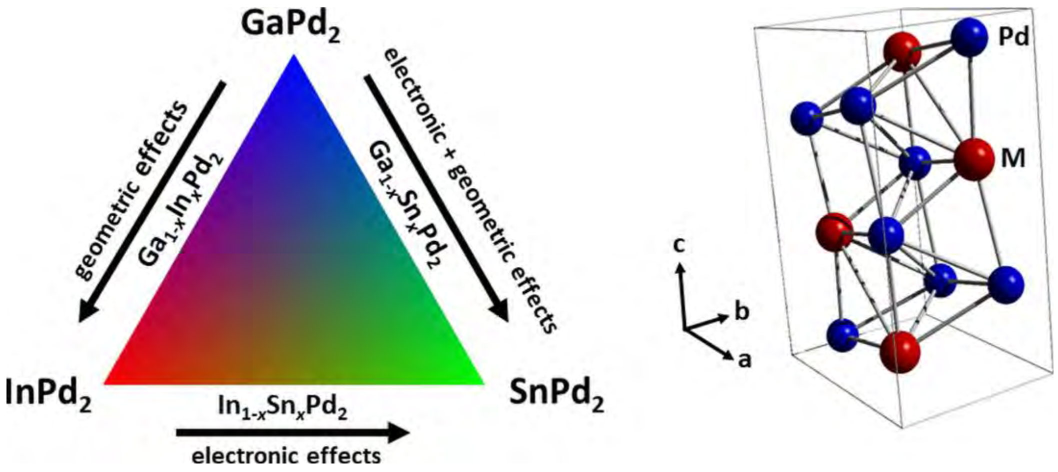

Figure 1. The isostructural triangle MPd_2 *(*M *= Sn, In or Ga) with the corresponding unit cell.*

Herein, the correlation between electronic, geometric and electrocatalytic properties in the electrochemical methanol oxidation are investigated by increasing the valence electron count per unit cell by substitution of indium (three valence electrons) with tin (four valence electrons) in the isostructural series $In_{1-x}Sn_xPd_2$. Furthermore, geometric effects were evaluated by decreasing the volume of the unit cell by substitution of indium with gallium in the isostructural series $Ga_{1-x}In_xPd_2$. The use of unsupported bulk electrode materials enables the evaluation of the electrochemical behaviour of the material without support interference or other phenomena that might occur with the use of supported materials. The results contribute to the knowledge-based development of catalytic materials for electrochemical energy conversion by direct experimental evidence of electronic influences using isostructural intermetallic compounds as platform materials and model catalysts.

Graphene has emerged as a promising material due to its superior electrical conductivity and highly accessible 2D area. The real integration of graphene as electrode material in energy storage devices, however, requires the development of sustainable and scalable approaches for its production and processing. Adenosine monophosphate (AMP) has proven its suitability to act as an intercalation agent for the obtention of high-quality graphene nanosheets by electrochemical exfoliation of graphite. In addition, this natural biomolecule can act as a dispersing agent, enabling the production of stable graphene aqueous bio-inks that can be readily processed into 3D graphene aerogels.[1] This graphene aerogel obtained by an easy, sustainable and scalable method has shown a superior performance in a Na-O_2 battery cathode using a glyme-based electrolyte. The Na-O_2 battery assembled with this unprecedented cathode delivered a discharge capacity as high as 9.64 mAh cm^{-2} (**Figure 1**) while performed 95 cycles with a 97 % efficiency at shallow cycling (0.5 mAh cm^{-2}) and high current density (0.2 mA cm^{-2}). The origin of such performance was studied and ascribed to the phosphate groups present in the natural biomolecule, which is adsorbed on the surface of the graphene sheets comprising the porous aerogel cathode **(Figure 1).** The phosphate groups modify the nucleation mechanism of the discharge products by i) enhancing the interaction of the cathode with oxygen reactive species and ii) catalyzing the ORR/OER reactions which take place while discharging/charging metal-air batteries. The latter aspect is of paramount importance for the real implementation of rechargeable Na-O_2 batteries as their reversible cycling is the major bottleneck for their commercialization.[2]

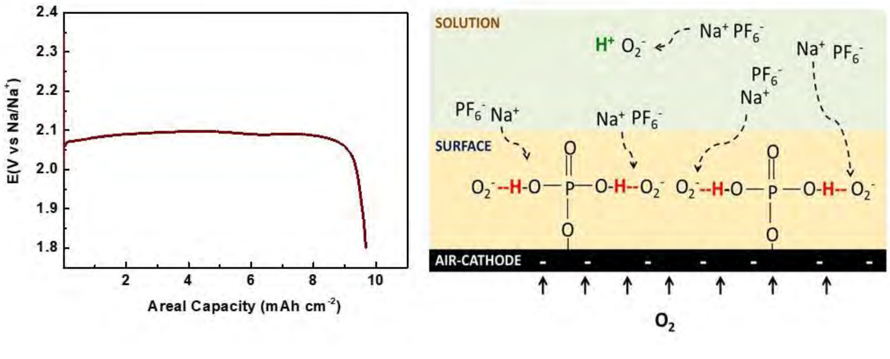

Figure 1. Discharge of the AMP-derived graphene aerogel at 0.2 mAh cm^{-2} using a glyme-based electrolyte and proposed effect of phosphate groups on the cathode performance.

balogadam@chem.u-szeged.hu

Detailed mechanistic understanding of the optoelectronic features is a key factor in designing efficient semiconductor (photo)electrodes. In situ spectroelectrochemical methods and electrochemical impedance spectroscopy provides an opportunity to scrutinize the effect of trap states on the optical and electronic properties of semiconductors. Different metal oxides and halides were studied, and results gathered for TiO_2, NiO and CuI will be presented in this talk. The absorption bands in the UV-visible spectrum and the Raman spectral features were directly influenced by the applied bias potential. These spectral changes correlate with the alterations observed in the electrical conductivity. Interestingly, the population/depopulation of the trap states, that are responsible for both the changes in the optical and electronic properties, occur in a different potential/energy regime.

In the function of these results, we can optimize the properties of the given semiconductor to make it the most appropriate for different applications. The hole transporting behavior of p-type semiconductors is very important for solar cell research, however if there are a lot of defects inside the band gap which can trap the holes, we must know the conditions, which allow us to use the transporting layers efficiently. In the case of TiO_2, hydrogen treatment causes a remarkable increase in the donor density by creating oxygen vacancies which behave as shallow electron donors. I will show how the presence of these states affects the (photo)catalytic activity and the photoelectrochemical performances of TiO_2.

Deep dive into thin film copper oxide layers

Authors: Valentina Belova-Magri, Thomas Fischer, Philipp Haarmann, Martin Thoms, Mirko Kloppisch, Tatjana Königsmann, Constanze Donner

Address: *Atotech Deutschland GmbH, Erasmusstrasse 20, 10553 Berlin, Germany*

Copper has been extensively explored especially since the revolution of the telecommunication industry. Exposed metal copper to air, moisture or temperature forms an oxide duplex film consisting of cuprous (Cu_2O) and cupric (CuO) oxides. Understanding the composition of the oxide layer is immense for the corrosion and conductive properties of copper. The oxide film of well-defined quality can passivate the underlying metal copper thus protecting from environmental damage.

Various surface analytical techniques have been implemented to characterize and differentiate both surface oxides. A double sweep cyclic voltammetry (DSCV), as a promising technique for the quantitative characterization of copper oxide films has been successfully applied to study oxide films at μm scale (1, 2). Reduction of Cu_2O and CuO in the selected electrolytes shows a clear separation between two cathodic well-assigned peaks.

However, as the oxide film gets thinner, characterization of the nature of copper oxides is challenging. This is due to the fact that the stability range of Cu_2O covers only a small potential window and therefore the electrochemical separation of both oxides strongly depends on the thickness of the whole film as well as on its architecture.

In the present paper, we will demonstrate how the DSCV method must be adapted in order to identify the composition of thin oxide films on nm scale. Both the reduction kinetics and the potential separation require a compromise between the oxide differentiation and the quantitative thickness determination. Hence, even in thin oxide layers of 10 nm we were able to distinguish the ratio of both oxides with a sensitivity of 1nm. This opens the opportunity to record external physical parameters such as influence of humidity and type of underlying copper substrates, which can significantly influence the oxide growth and its behavior at high temperatures.

The crystallographic orientation of modified copper substrates will be discussed in relation to its ratio of copper oxides. An impedance study combined with X-ray photoelectron spectroscopy (XPS) as well as Fourier-transform infrared spectroscopy (FTIR) reveals the structure within the copper oxide layers.

Carbon dioxide (CO_2) is a greenhouse gas that produces global warming with undesirable climate effects, such as sea level rising and erratic weather patterns. Reducing the CO_2 atmospheric concentration is a current research priority. Among the different technologies proposed to achieve this goal, the electrochemical reduction reaction of CO_2 (CO_2RR) to useful low-carbon fuels (CO, CH_4, CH_3OH, HCOOH, …) is particularly attractive given its compatibility with renewable electricity sources. Metal catalysts in various forms have been tested for CO_2RR, including bulk or nanostructured metals, and more recently, bimetallics, for which the catalytic activity, efficiency and selectivity is boosted [1].

In this work, we report on the synthesis and characterization of bimetallic $Pd_{100-x}Cu_x$ nanoparticles with different compositions and its application as nanoelectrocatalysts for CO_2RR. Few studies using this kind of alloy under different configurations (Cu overlayers on Pd [2], Pd-decorated Cu electrodes [3], mesoporous CuPd films [4], CuPd NPs of different mixing patterns and morphologies [5]) have pointed out the higher performance of bimetallic PdCu with respect to each single metals (higher current density, lower overpotentials, higher resistance to CO poisoning). In most of these works, electrochemistry has been used as a tool for product generation (i.e. quantitative electrolysis at selected potentials) without attention paid to recording and interpreting the electrochemical signals. More in-depth electrochemical studies could improve our understanding of CO_2RR at $Pd_{100-x}Cu_x$ compounds.

Here, we present and in-depth electrochemical study of CO_2RR at $Pd_{100-x}Cu_x$, with a special focus on the influence of the bimetallic composition on the CO_2RR response and the related CO-poisoning. Cyclic voltammetry and chronoamperometry have been selected, in combination with a cavity microelectrode (CME) for the first time. The low-distorted voltammetric signals obtained with the CME have evidenced that for alloys with low or moderate Cu content (up to 50 at.%) the typical CO_2RR inhibition peak, related to CO blocking Pd active sites, becomes a current plateau. This indicates not only a better tolerance of $Pd_{100-x}Cu_x$ towards CO poisoning but also the attainment of a pseudo-steady state where mass transport should be controlled by diffusion. The synergy between Cu and Pd is thus established for the first time at the level of the voltammograms.

We have observed that the chronoamperometric responses exhibit three well defined regions corresponding to 1) double layer charging and diffusion/reaction establishment, 2) beginning of CO poisoning by formation of a CO adlayer and (3) final collapse of the catalytic activity at a critical time, t_c, which depends directly on the bimetallic composition. A plot of t_c vs. Pd content exhibits a clear volcano shape, from which ~ $Pd_{70}Cu_{30}$ is identified as a close to optimal composition in terms of CO tolerance and $Pd_{35}Cu_{65}$ as the composition from which the advantage of alloying Pd with Cu is lost. Based on these studies, the potential benefit of developing a pulse-based method to increase the lifetime of Pd-based catalysts is demonstrated.

The absence of large-scale electricity storage methods is currently one of the major factors limiting widespread deployment of renewable energy sources such as wind and solar power [1] [2]. The Battolyser –an integrated nickel-iron battery and alkaline electrolyser– can bridge the gap between intermittent energy production and consumption fluctuations [3]. During charging, the pocket electrodes consisting of $Ni(OH)_2$ and $Fe(OH)_2$ powder form NiOOH and Fe, which can evolve oxygen and hydrogen. Thereby, the charged electrodes can electrocatalytically split water efficiently to produce hydrogen as a long-term storage fuel, while fast discharging of the electrodes can provide electricity for short-term fluctuations in renewable energy availability.

To upscale the Battolyser device, a comprehensive characterization of the design parameters was necessary. Using these parameters, we have developed and validated a COMSOL multi-physics model describing the integrated operation of the Battolyser. The model was validated using experimental results, and new configurations of design parameters have been compared and optimized for the upscaling of this lab-scale prototype. Here, we present an optimization study of the integrated electrolyser and battery system with regards to the energy efficiency. The model will be used to design larger and optimized device configurations to allow for efficient large-scale energy storage.

To further optimize the performance of the integrated device, a study on the synergistic effects of alkali metal cations in the electrolyte was performed. In alkaline electrolysis different cations have different effects on the overpotentials of oxygen evolution [4] while certain alkali metal cations are used to improve the cycleability of nickel iron batteries. The addition of LiOH in the KOH electrolyte used in Ni-Fe batteries is widely reported [5]. However, this is not usual in alkaline electrolysis. The integration of both devices must therefore be taken into account when choosing the electrolyte for the Battolyser. Here, we present the effect of the electrolyser alkali cations on the battolyser charge/discharge cycles and electrolyser functionality. This study presents the electrocatalytic response to a change in electrolyte composition. Overall the results presented will allow for ideal electrolyte selection in the upscaling of this device, providing efficient and integrated short-term and long-term energy storage requirements.

Prussian Blue – Nickel Hexacyanoferrate as Superstable Electrocatalyst for Bioanalysis and Biotechnology

E.V. Karpova, E.V. Shcherbacheva, E.E. Karyakina, A.A. Karyakin
Lomonosov Moscow State University
Lenin Hills, 119991, Moscow, Russia
e-mail: karpowa.ew@gmail.com

Prussian Blue (PB) is known to be the most advantageous (thousands times more active and selective than platinum) electrocatalyst for hydrogen peroxide reduction, the very reaction catalyzed by the enzyme peroxidase. PB possesses unique properties of the electrocatalyst allowing elaboration of sensors and biosensors with advantageous analytical characteristics [1]. Probably the only disadvantage of the PB is its inherent instability, particularly in neutral solutions. Non-iron transition metal hexacyanoferrates (isostructural to PB, but chemically and mechanically more stable than PB), especially nickel hexacyanoferrate (NiHCF), being silent in the electrocatalysis of H_2O_2 reduction serve as excellent matrixes for stabilization of Prussian Blue.

In this work PB based advanced hydrogen peroxide transducer is deposited onto screen-printed electrode structures (Rusens Ltd, Russia) and stabilized with NiHCF, both in open circuit mode. In severe conditions under 1 mM H_2O_2 the developed electrodes retain the response for more than one hour. Moreover, we could confirm that operational stability of the oxidase-based biosensors can be significantly improved stabilizing the transducer used. The method describing stabilization procedure was done according to [2]. To develop the biosensors suspending the suspension of lactate / glucose oxidase aqueous solution in isopropanol containing γ-aminopropyltriethoxysilane / Nafion analogue was deposited onto the top of iron-nickel hexacyanoferrate modified electrode. The dynamic range of PB-NiHCF based biosensors is similar to range observed for conventional PB based ones but their performance characteristics are dramatically improved.

Immuno- and DNA- (RNA-) sensors as well as affinity based analytical kits comprise an important part of vital activity for modern society since they are used in a variety of areas from medicine to agriculture. For signal generation these devices use labels, among which one of the leading positions belongs to the enzyme peroxidase. Novel rapidly growing field of modern science is synthesis of nanozymes – nanoparticles with enzyme-like activity. The most progressive and actual application of nanozymes is to substitute natural enzymes in various fields of science and technology allowing to avoid the most important problems of the enzymes: their inherent instability and relatively high cost. Nanozymes obviously require advanced catalysts.

Techniques of catalytic synthesis of PB nanoparticles and elaboration on it basis the nanozymes "artificial peroxidase" were just published [3]. Catalytic rate constants of the nanozymes are up to 4 orders of magnitude higher as compared to the natural peroxidase. Except for the activity defeating even the natural enzyme, the advantages of the reported PB nanoparticles over the known peroxidase-like nanozymes are enzymatic specificity (an absence of oxidase-like activity) and an ability to operate in physiological solutions, similarly to the enzymes.

Unfortunately, PB nanoparticles demonstrate inherent instability in neutral and basic solutions (pH>6). In current research stabilized by nickel hexacyanoferrate composite core-shell PB nanoparticles were synthesized. We also deposited obtained nanoparticles onto screen-printed electrode structures to produce hydrogen peroxide sensors and biosensors. Composite PB-NiHCF nanoparticles demonstrate around one order of magnitude improved stability compared to PB nanoparticles (pH 7.4).

Rechargeable multivalent ion batteries have attracted significant technical and scientific interests, especially aqueous zinc ion batteries, due to their low cost and high safety.[1] Layered $V_3O_7 \cdot H_2O$ is a promising material due to easy intercalation of doubly charged Zn^{2+} ions. This is due to the special structure with extended hydrogen bonding between VO_6 octahedrons and VO^5 trigonal bipyramids.[2] In addition, the mixed oxidation state of vanadium (IV and V) can help improving the electric conductivity. With the addition of reduced graphene oxide, rGO, the active materials obtain high electrochemical stability. Herein, we have synthesized $V_3O_7 \cdot H_2O$ nanowires/reduced graphene oxide composite by a microwave method through controlling pH by a nonoxidizing acid and have thoroughly investigated the reaction mechanisms of the synthesis. A composite used as cathode of the zinc-ion battery can deliver a high specific capacity of 385.7 mAh g^{-1} at a current density of 4 A g^{-1}. Impressively, the capacity retention after 1000 cycle is up to 96%. This excellent performance suggests that vanadium oxide and rGO composite may be a good cathode candidate for aqueous zinc ion battery.

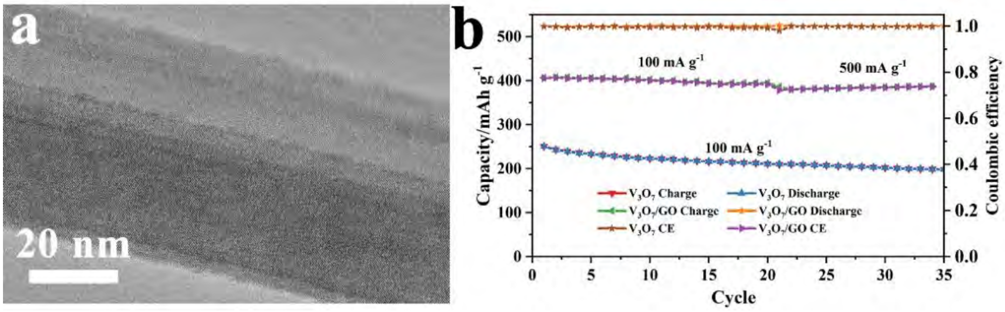

Figure 1 TEM image of the $V_3O_7 \cdot H_2O$ nanowire (a) and cycling performance of the pure $V_3O_7 \cdot H_2O$ nanowire and $V_3O_7 \cdot H_2O$ nanowires/reduced graphene oxide composite (b).

Limiting anthropogenic carbon dioxide (CO_2) emissions and exploiting such compound as a resource to produce valuable chemicals, fuels and materials, especially when using renewable energy inputs, are key strategies to reduce our carbon footprint.[1] We proved in this work that the metal-organic framework (MOF) Bi(1,3,5-tris(4-carboxyphenyl)benzoate), or Bi(btb), promotes the efficient and selective electrocatalytic CO_2 reduction reaction (eCO_2RR) to formate, a relevant compound in industrial applications and in fuel cell technology.[2] The MOF Bi(btb) acts as a pre-catalyst and under eCO_2RR conditions undergoes a structural reconstruction that generates an organic porous matrix embedded with highly active Bi nanoparticles. In a typical H-cell configuration, this new material produces formate with Faradaic efficiencies up to 95(3)% at 770 mV overpotential and exhibits a metal-based mass activity which is competitive or even larger than most state-of-the-art catalysts reported in scientific literature.[3-6] The electrocatalytic features of the MOF-derived material and the structural change leading to the active Bi nanoparticles were thoroughly monitored with a broad ensemble of techniques.[7]

Gold nanoparticles (NP) have attracted significant attention in electrocatalysis, especially for CO_2 reduction to CO [1] and production of H_2O_2 through $2e^-$ oxygen reduction [2]. Despite numerous works on the activity, only a few studies have dealt with the equally important descriptor for the applicability of Au catalysts – stability under the relevant electrochemical conditions [3,4].

Here we present an in-depth study of the electrochemical stability of commercial carbon-supported Au nanoparticles (Au/C). Stability of Au/C samples was probed by an adapted accelerated stress test: 10 000 fast scans (1 V/s) in the potential region between 0.3 V and 1.13 V (*vs.* Ag/AgCl) in a 0.05 M H_2SO_4 electrolyte with and without the presence of chlorides. A significant loss of Au was observed even in Cl^- -free electrolyte, while the addition of Cl^- promoted Au dissolution, as expected (Fig. 1a). TEM imaging clearly showed a variety of changes upon degradation, such as loss and growth of the Au NPs and appearance of various shapes of NPs (Fig. 1b-e), which were more expressed in the presence of chlorides. This implies that different degradation mechanisms occurred simultaneously, including dissolution, redeposition, Ostwald ripening, agglomeration, particle detachment and carbon corrosion. Coupling an electrochemical flow cell with ICP-MS confirmed that the dissolution of Au is highly affected by the presence of chlorides and transient in nature under the applied conditions [5].

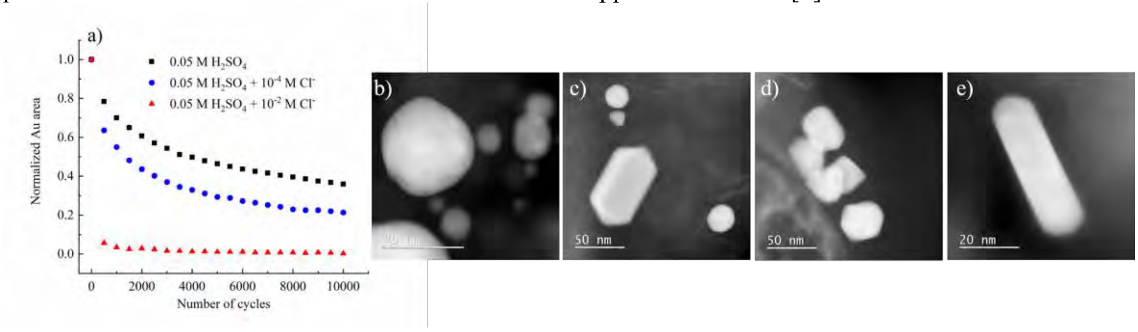

Figure 1. (a) Gradual loss of electrochemical surface area of Au during cycling; (b) STEM imaging of fresh Au/C sample and of samples degraded in: (c) 0.05 M H_2SO_4; (d) 0.05 M H_2SO_4 + 10^{-4} M Cl^- and (e) 0.05 M H_2SO_4 + 10^{-2} M Cl^-.

Besides assessing the stability of Au/C NPs, the results obtained in this study are opening a new perspective towards another very important subject – electrochemical recycling of Au from end-of-life electrodes and, more importantly, from non-conductive samples containing not only Au, but other precious metals as well (such as electronic waste). As shown by Hodnik *et al.* for Pt [6], transient dissolution can be mimicked by alternate changes between oxidative and reductive potentials on metal by alternate exposure to oxidative and reductive gasses. A parallel study on the application of this approach for recycling of gold is currently underway in our laboratory.

A self-powered glucose sensor with optical readout

Jana M. Becker,[a] Tim Bobrowski,[a] Felipe Conzuelo,[a] Adrian Ruff,[a] Wolfgang Schuhmann[a]

[a] *Analytical Chemistry - Center for Electrochemical Sciences (CES), Faculty of Chemistry and Biochemistry, Ruhr University Bochum, D-44780 Bochum, Germany*

As main energy source, glucose has a critical role for living organisms. Diabetes, a metabolic disorder, which is linked to elevated blood glucose levels in the body, can have vast impacts for the people affected. Hence, the glucose levels must be closely monitored, making easy-to-apply point-of-care devices, which allow on-site monitoring of the glucose level in the blood, highly desired. Therefore, substantial efforts have been put into the creation of miniaturized low-cost point-of-care devices[1], which can be handled by the patients themselves.

In this context, we report the fabrication of a self-powered glucose sensor with an optical readout system for simple and fast optical readout with the bare eye. The sensing device consists of a glucose-powered biofuel cell compartment and a poly(3,4-ethylenedioxythiophene) (PEDOT)-based electrochromic reporter for optical readout, both immobilized on a single screen-printed electrode chip (Figure 1). A glucose/O_2 biofuel cell is used, in which glucose is oxidized to glucono-δ-lactone by the oxygen-insensitive enzyme PQQ-GDH that is wired to the electrode surface by the low potential redox polymer poly(1-vinylimidazole-*co*-allylamine)-[Os(dmxy-bpy)$_2$Cl]Cl.[2] A bilirubin oxidase-based biocathode is used for the O_2 reduction to H_2O. The electrochemically deposited PEDOT films reveal a blue color and decolorize upon oxidation by the glucose-limited current of the connected biofuel cell. Using the power output generated by the biofuel cell to oxidize the PEDOT film any necessity for external powering devices is excluded. Thus, the complexity of the system is reduced, showing potential for applications as point-of-care device.

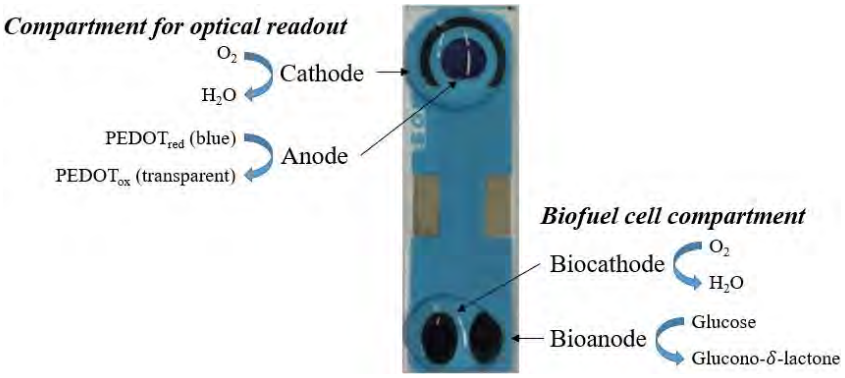

Figure 1: Screen-printed device for glucose detection, consisting of an integrated biofuel cell coupled to an electrochromic reporter for optical readout.

The electrochemical reduction reaction of carbon dioxide (CO2RR) is a promising method for obtaining various carbon-based products such as carbon monoxide CO used in industry. This reaction requires the use of an appropriate electrode material. Molecular materials based on transition metals turn out to be promising catalysts for the CO_2 reduction reaction due to their high selectivity and low overpotentials [1]. The Cobalt 2,2':6',2'':6'',2'''-quaterpyridine complex $[Co(qpy)]^{2+}$ supported on multi-walled carbon nanotubes was shown to be a good candidate with high selectivity and Faradaic efficiency (ca. 100%) for the conversion of CO_2 to CO [2]. It also shows high current densities of up to 19.9 $mA.cm^{-2}$ for an overpotential of 440 mV [2].

Here we show that supporting the $[Co(qpy)]^{2+}$ complex on different carbonaceous materials (carbon Vulcan, graphene oxide GO, reduced graphene oxide rGO, N and N, S doped rGO) induces a significant change in the catalytic current. The nature of the interaction between the support and the complex as well as the onset potential for CO_2 reduction were investigated with cyclic voltammetry, as shown in Fig. 1A. Linear sweep voltammetry coupled to *in situ* FTIR spectroscopy (Fig. 1B) were performed to identify the reaction products and to determine the geometry of the complex on the support. Preparative scale electrolysis was performed on each material to determine the maximum current density and the selectivity for carbon monoxide formation.

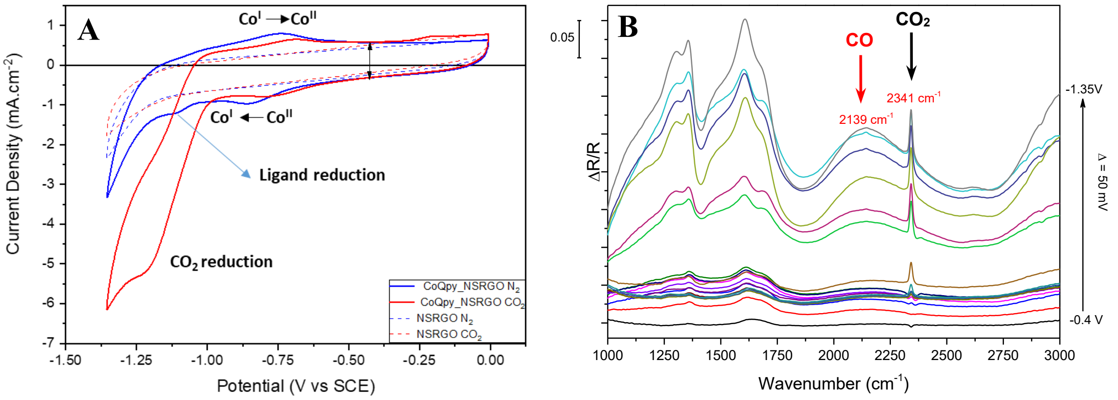

Fig. 1: *Cyclic Voltammograms of Coqpy-NSRGO deposited onto a glassy carbon electrode in 0.5 M $NaHCO_3$ solution saturated in N_2 (blue) and CO_2 (red) at a scan rate v = 50 mV/s **(A)**. Infrared spectra of Coqpy-NSRGO deposited onto a glassy carbon electrode **(B)**.*

Impact of Mn valence on the current during cyclic voltammetry in manganese oxide and mixed cobalt-manganese oxide

Javier Villalobos & Marcel Risch
Nachwuchsgruppe Gestaltung des Sauerstoffentwicklungsmechanismus,
Helmholtz-Zentrum Berlin für Materialen und Energie
Hahn-Meitner Platz 1, 14109 Berlin, Germany
javier.villalobos@helmholtz-berlin.de

Among the wide range of transition metal oxides used for the oxygen evolution reaction (OER), manganese oxides have received much attention because their low toxicity and high abundance[1]. Currently, this attention is being shifted to mixed Mn-based oxides, particularly mixed Co/Mn oxides are interesting due to their low overpotential and high stability at alkaline pH[2]. The catalytic properties of Mn-based oxides have been studied in more detail as compared to Co/Mn oxides, as well as in the context of activation and degradation of the material. Degradation is usually associated with changes on surface or bulk composition, long range order or microstructure. These modifications can be electrochemically observed as changes in overpotential at fixed current or vice versa.

We electrodeposited non-crystalline MnO_x and $(Co,Mn)O_x$ films in alkaline electrolyte and their catalytic stability was studied by electrochemical experiments. Changes in the catalytic properties are especially observed in MnO_x such as a decrease in the maximum OER current during 100 cycles and a decrease in the Tafel slope, in contrast with $(Co,Mn)O_x$ where both the OER current and Tafel slope remains fairly constant after 100 cycles. The current profile as function of cycles was studied during 100 cycles at three selected potentials, namely no OER, onset of OER and OER. An additional 10 cycles were performed after a break at OCP for 30 min (Figure 1). For MnO_x, a monotonous decay is observed at all shown potentials, and after the OCP break, the current is only partially recovered. In contrast with $(Co,Mn)O_x$, where the highest potential shows an increase with cycling, which might be related to an activation process. All these results suggest possible structural changes especially in MnO_x films, but since these materials are non-crystalline, X-ray absorption spectroscopy (XAS) was used to study their chemical structure.

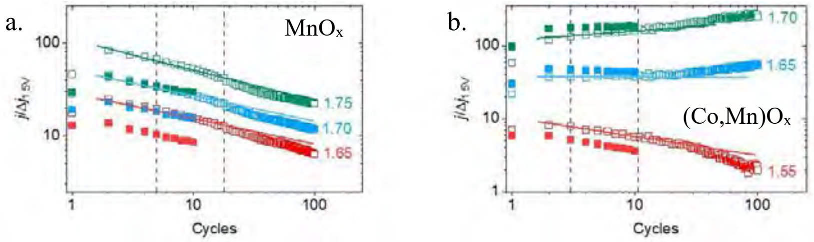

Figure 1. Current profile ($j/\Delta j_{1.5V}$) as function of cycle at selected potentials (shown in figure) for a) MnO_x and b) $(Co,Mn)O_x$. Open square represent data before OCP and solid square after OCP.

The Fourier transform of the EXAFS gives information about the local chemical structure, Co and Mn K-edge spectra suggest an amorphous layered oxide structure. Additionally, the Mn-K edge of $(Co,Mn)O_x$ is shifted to higher energy in comparison with MnO_x, meaning a higher average oxidation state of Mn. The Mn-L_3 edge showed two components in MnO_x: Mn_3O_4 and MnO_2, but after 100 cycles a clear decrease of the peaks corresponding to Mn_3O_4 is observed.

These results suggest that the inclusion of Co in the electrodeposition promotes a higher oxidation state of Mn (between Mn^{3+} and Mn^{4+}) in the structure of the Mn/Co oxides[4], which seems to have key role enhancing stability during catalysis, by means of constant current and Tafel slope. This result agrees with previous reports suggesting more stability in those materials with oxidation states Mn $\geq$+3.7[3]. This study provides insight into the importance of Mn valence for the design of Mn/Co oxide catalysts.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No 804092.

Polymer exchange membrane (PEM) water electrolyzers predominantly employ expensive and rare iridium based anode materials[1], and thus reduction of the noble metal loading will foster their large scale development and deployment. Iridium oxide-based anodes exhibit the best combination of reactivity and stability compared to other anode candidate materials, still they slowly undergo degradation under oxygen evolution reaction (OER) conditions[2]. Considering the high cost of Ir, even a slow dissolution rate presents a challenge for large-scale implementation. The combination of highly active iridium oxide (IrO_x) with a significantly more stable transition metal oxide, e.g. TiO_2, can be a good strategy for stability improvement and reduction of the precious metal loading[3,4]. Considering the semiconducting nature of the Ti oxides and their poor catalytic properties, the chemical and electronic interactions with Ir are thus crucial to result in a long-term stable anode material with high activity. However, the exact nature of the Ir-Ti interaction has not yet been unveiled[5].

To investigate the underlying interactions within the Ir-Ti mixed oxides, co-sputtered libraries of Ir and Ti with a continuous Ir loading gradient of 20 – 70 at.% were annealed at mid-range temperatures to form the mixed oxide. By means of x-ray spectroscopic techniques, insights into the chemical and electronic structure of the resulting material were gained. For instance, depth resolved information of the annealed Ir-Ti alloy libraries was determined using soft and hard x-ray photoelectron spectroscopy in combination with more bulk sensitive photon in/photon-out soft x-ray absorption and emission spectroscopy. Combining the electrochemical activity results with the spectroscopic data, we gain further understanding of the interaction between highly active IrO_x and stable TiO_2, and how this contributes to a better OER electrocatalyst, e.g. preliminary results show that materials containing more than 60 at.% Ir showed catalytic activity comparable to pure IrO_2 while showing a superior stability.

Qian.Zhang@dlr.de

One of the main barriers hindering the commercialization of PEMFC applications is the limited durability caused by a series of chemical and physical degradation phenomena. Mitigation and elimination of the degradation effects has been a research focus during the last several decades. However, some of performance loss can be recovered by certain operation procedures and are therefore considered as reversible losses (also denominated falsely reversible degradation)[1]. Hence, detailed understanding of reversible effects and procedures are of particular interest.

This work evaluates the effectiveness of three recovery procedures. Two are proposed by activities of EU, and DOE and the third is the overnight rest procedure which was recognized as an effective approach in literature[2,3,4]. These three procedures are compared in single cell durability tests using fuel cell dynamic load cycling (FC-DLC). With the polarization curves before and after each recovery procedure the recovered voltage losses (see Figure 1) have been determined. The overnight rest procedure and the EU protocol recovered partial performance, which was not recovered by DOE procedure at low and intermediate current density. However, at current density >1.7 Acm^{-2} all three procedures lead to a recovery of ~60%. Moreover, the recovery efficiency strongly depends on operation history of the cell which was analyzed in this study in detail. Electrochemical Impedance Spectroscopy (EIS) tested before and after each recovery procedure provides insight into the ohmic, charge transfer and mass transport effects during due to recovery (see Figure 2). These preliminary data demonstrate that ohmic resistance is recovered most efficiently by the DOE procedure at low and overnight rest procedure at high current density. Charge transfer resistance is recovered less efficiently by DOE protocol than by the two others. The efficiency of recovery of mass transport resistance is similar for all three protocols.

Direct CO_2 Reduction on Bimetallic Electrocatalysts

Daniël van den Berg, Ruud Kortlever
Process & Energy, University of Technology Delft
Leeghwaterstraat 39, 2628 CB, Delft
d.vandenberg-2@tudelft.nl

The main problem with renewable energy sources is their intermittent nature, which leads to a mismatch in power supply and global demand. Here, large scale energy storage of renewable energy by electrochemically converting CO_2 into renewable fuels can solve this dynamicity in the power supply can be smoothed out. However, the electrochemical conversion of CO_2 particularly suffers from low selectivities, due to its complex and multi-step reaction network. In order to selectively produce one specific reaction product, different adsorption sites need to exist on the surface, each of which optimally bind the reaction intermediates of the desired product to the surface. Until now, mainly copper-based electrodes have been shown to be able to convert CO_2 into higher hydrocarbons yet still at high overpotentials and low selectivity [1, 2].

This is where the alloying of different metals in the electrodes comes into the picture. By mixing different metals, a larger range of different adsorption sites can be achieved on the electrode surface. Here, the electrode surface can be more freely tuned by changing its (bulk) composition or by placing one metal upon another host-metal, i.e. near-surface alloying [3]. Hereby, the adsorption properties of the topmost layer are changed by the subsurface atomic layers. One recent example of this is a gold-palladium electrode by Kortlever et al. which showed the production of higher hydrocarbons, which was even able to produce larger hydrocarbons than copper [4]. This is one of the only electrodes that showed the electrochemical production of higher hydrocarbons from CO_2 reduction other than copper. Also, Nickel-Gallium electrodes have shown similar results [5]. These electrodes show the great potential of electrode alloying.

However, not all PdAu electrodes that were tested in literature, observe the formation of hydrocarbons while reducing CO_2 [6, 7]. In our research, we study what our experimental choices (choice of buffer, surface morphology) might be of influence on this observed difference between the different studies.

shimizu@shinshu-u.ac.jp

The development of Zn-air batteries with a high energy density of 1350 Wh kg^{-1} is one of breakthrough required to achieve a low carbon society. There are, however, two main challenges concerning the morphology control of Zn deposit and the development of catalyst with high activity for oxygen evolution reaction. Focusing on the negative electrode side, Zn undergoes remarkable shape change during charge−discharge, causing poor cycle performance. At a low current density, electrochemical deposition of Zn results in mossy structure. This is caused by continuous two-dimensional nucleation followed by the formation of protrusions on wide terrace and the suppression of microstep growth toward lateral direction. At a high current density in diffusion-limited condition, dendritic growth is dominant. Strategies for the suppression of non-uniform Zn deposition are mainly classified into following five methods; (1) the use of additives such as metal-ion and surfactant, (2) the change from aqueous electrolyte to/mixing with an organic electrolyte or an ionic-liquid electrolyte, (3) the optimization of substrate, (4) the introduction of anion-exchange ionomer between Zn electrode and electrolyte, and (5) the construction of matrix accommodating shape change. Considering simplification of the processes, the strategy of use of additive is industrially preferred, and we have achieved smooth morphologies of Zn deposit in 0.25 M ZnO/4 M KOH. In our previous reports, it was found that cationic surfactant, trimethyloctadecylammonium chloride (STAC) suppressed the shape change and resulted in smooth and dense morphology. Zeta potential measurements, kinetic current densities observed from Tafel plots, and constant potential electrolysis indicate that quaternary ammonium cations (STAC) with bulky size adsorb to protrusions which are cause of shape change and suppress Zn deposition in the region to promote lateral growth. Although the adsorption of STAC increased an average overvoltage for Zn-deposition/stripping in a symmetric Zn|Zn cell under current density of 10 mA cm^{-2}, significantly stable behavior continued during 200 h. In this work, an electrochemical quartz crystal microbalance was applied to study Zn-deposition/stripping behavior in the aqueous-based electrolyte.

An aqueous-based electrolyte solution (so called alkaline zincate bath) was prepared by dissolving ZnO powder at a concentration of 0.25 mol dm^{-3} (M) in 4 M KOH aqueous solution (13.5 mL). An AT-cut quartz crystal coated with Cu (fundamental frequency; 9.0 MHz) was incorporated into an EQCM cell with a Hg/HgO reference electrode was assembled. The mass change on QCM electrode during Zn-deposition/stripping reactions at a galvanostatic condition was calculated from the change in resonance frequency using the Sauerbrey equation. In addition, we studied the influence of current densities on reversibility based on mass changes.

Graphite as a Positive Electrode Material for Aqueous Zn-based Rechargeable Batteries

shimizu@shinshu-u.ac.jp

The development of Zn-air batteries with a high energy density of 1350 Wh kg^{-1} is one of breakthrough required to achieve a low carbon society. There are, however, two main challenges concerning the morphology control of Zn deposit and the development of catalyst with high activity for oxygen evolution reaction. Focusing on the negative electrode side, Zn undergoes remarkable shape change during charge−discharge, causing poor cycle performance. At a low current density, electrochemical deposition of Zn results in mossy structure. This is caused by continuous two-dimensional nucleation followed by the formation of protrusions on wide terrace and the suppression of microstep growth toward lateral direction. At a high current density in diffusion-limited condition, dendritic growth is dominant. Strategies for the suppression of non-uniform Zn deposition are mainly classified into following five methods; (1) the use of additives such as metal-ion and surfactant, (2) the change from aqueous electrolyte to/mixing with an organic electrolyte or an ionic-liquid electrolyte, (3) the optimization of substrate, (4) the introduction of anion-exchange ionomer between Zn electrode and electrolyte, and (5) the construction of matrix accommodating shape change. In this study, we focused on concentrated electrolytes. In addition to this, the concentrated electrolytes were applied to anion-intercalation/deintercalation into/from graphite interlayers. Although the reversible capacity based on the intercalation/deintercalation of anions would be much smaller than a capacity obtained from oxygen as a positive electrode material, the reversibility of the reaction thought to be high and stable in a long-life cycle.

Zn-deposition/striping behavior was investigated by galvanostatic charge−discharge tests using an electrochemical measurement system (HJ-1001 SM8A, Hokuto Denko Co., Ltd.) and by cyclic voltammetry (CV) measurements though the use of an electrochemical analyzer (SP-200; Bio-Logic Science Instruments) at a sweep rate of 1 mV s^{-1} at room temperature. In the test of anion-intercalation, graphite powder and PVDF binder were used for the preparation of a slurry electrode. For investigation of the effect of powder size on charge−discharge capacities was also studied.

Figure 1 shows cyclic voltammograms corresponding to Zn-deposition/stripping on a Ti foil as a current collector in aqueous-based electrolytes at a sweep rate of 1 mV s^{-1}. In a dilute electrolyte of $ZnCl_2{\cdot}50H_2O$ (molar ratio), no response originating from Zn-deposition/stripping reactions was observed. This is because of the narrow electrochemical window. Below 0 V, the hydrogen evolution reaction preferentially took place instead of Zn deposition. In contrast, at concentrations of 2.33 or more, reversible deposition/striping reactions were confirmed. When using the concentrated electrolytes, the anion intercalation into graphite interlayer progressed to form partially graphite intercalation compound even in an aqueous-based electrolyte.

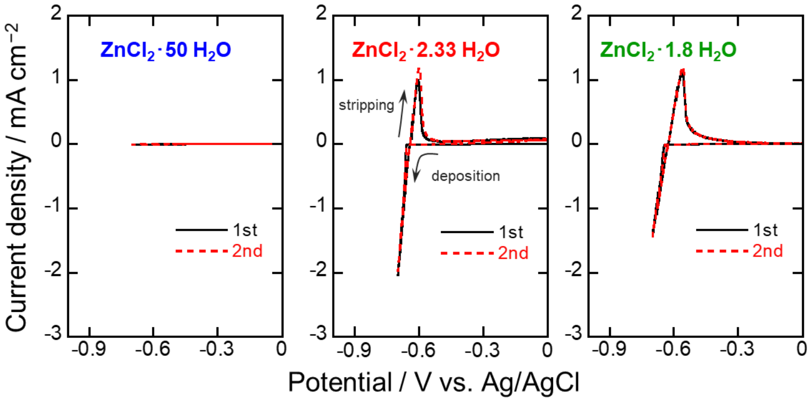

Figure 1 Cyclic voltammograms corresponding to Zn-deposition/stripping on a Ti foil as a current collector in aqueous-based electrolytes at a sweep rate of 1 mV s^{-1}. The counter electrode is Zn foil.

Hydrogen production by electrolysis of methyl pivalate: A first approach to an efficient treatment of PMMA waste

In recent years, hydrogen has become a focus of research and an essential industrial target area, not only because of its use as an energy carrier and practical employment in fuel cells but also for its role as a significant raw material of the chemical industry [1]. Today, the steam reforming of fossil fuels (primarily methane) is the most common and cost-effective H_2 production process [2]. Notwithstanding its advantages, it requires additional units to separate H_2 from the coproduced CO and CO_2, and it actively contributes to greenhouse gas emissions [3],[4]. Hydrogen can also be produced by electrolysis of water; this environmentally friendly process has taken force lately because it can be easily integrated to the electrical grid and use renewable energy sources (i.e. solar or wind) to produce pure H_2 from water, producing only O_2 as a by-product [5].

However, the energy requirement correlated to the thermodynamic data shows a relative standard cell voltage of around 1.23 V to achieve the water electrolysis reaction at room temperature [6]. Consequently, different researchers have proposed to electrolyze organic molecules instead of water to reduce energy demand. Plastic wastes contain an abundant source of hydrogen and can be a promising renewable feedstock for electrolysis. Among the different plastics, poly(methyl methacrylate) (PMMA) is a widely used polymer in several applications [40]. Even if different recycling methods are implemented, such as thermal and chemical processes, any other processes than the incineration for direct *Energy Recovery* is used. In this sense, the present study proposes a new route to valorize plastic wastes by producing H_2 using an electrochemical process. Due to the complexity and the heterogeneity of real PMMA-based plastics, we decided, as a first approach, to investigate a Methyl pivalate (MP) as a model molecule representative of the polymer containing similar chemical units, including atoms, bonds and functional groups (ester). We studied the electrooxidation of MP in a Polymer Electrolyte Membrane-based (PEM) reactor with an acid membrane (Nafion®) and commercial Pt/C electrodes between 50 and 80°C. This system allows operating in aqueous media without an electrolyte and under continuous conditions. A complete study of the operation conditions was carried out to enhance the production of H_2.

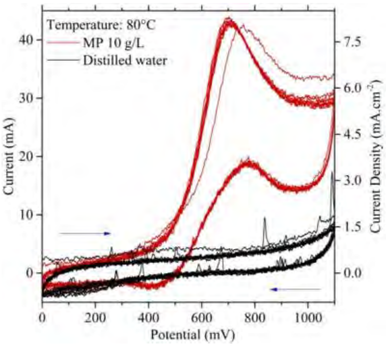

Figure 1. Cyclic voltammetry of water and MP at 80ºC and 10mV/s.

The electrooxidation process of MP shows an entirely different behaviour than the electrolysis of water at similar conditions and higher activity at potentials lower than 1.23 V. Experiences at different temperatures demonstrate that 80ºC is optimal for the electrolysis of MP. As showed in Figure 1, a critical oxidation step takes place at ~700-750 mV when cyclic voltammetry is performed with a second peak registered when the potential is decreasing. That phenomenon is attributed to an unfinished cleavage process of the MP molecule in the surface of the Pt/C anode. Typically, at the presented conditions, the only possible reaction is the electrolysis of the ester group to form pivalic acid and methanol, with a subsequent electrooxidation of the alcohol to produce H_2 and CO_2. Chronoamperometries (Fig. 2) at different potentials have confirmed that higher and stable currents could be achieved when the PEM cells work near 750 mV. The MP electrooxidation leads to a constant production of hydrogen at much lower potentials than in the case of traditional electrolysis of water, with a theoretical value of 103,6 $\mu mol.m^{-2}.s^{-1}$ calculated from Faraday's Law of Electrolysis.

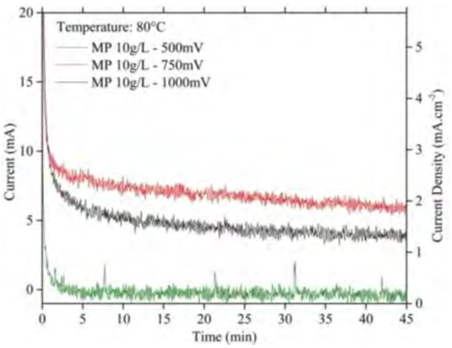

Figure 2. Chronoamperometry at different potentials for MP at 80ºC.

Polydopamine (PDA), a synthetic eumelanin polymer has gained interest in many research areas. PDA films are used as adhesive coatings for cell immobilization, for sensing, as coatings for energy-related research and as biomimetic electron gates for artificial photosynthesis due to its plethora of functional groups [1]. A widely used method for PDA deposition is dip coating by oxidation of dopamine in basic buffer solutions in the presence of oxygen or other oxidants [2]. An alternative method is electrochemical deposition via cyclic voltammetry or pulse deposition. For many applications, the film morphology, thickness and electrochemical properties are crucial and require controllable and reproducible depositions. In addition, the surface properties of PDA films can be altered by external parameters such as applied potential or pH, which plays a role in various applications.

Within this contribution, we present scanning probe microscopy techniques as useful methods to characterize PDA films in respect of the film morphology, film thickness and electron transfer behavior depending on the number of cycles or pulses applied during electrodeposition [3]. Scanning electrochemical microscopy (SECM) is a powerful technique to investigate heterogeneous electron transfer rate constants of modified electrodes using approach curves (**Fig. 1A**) [4]. PDA deposited on gold substrates are investigated with respect to electron transfer kinetics by applying different substrate potential or at different pH values. Using atomic force microscopy (AFM) contact mode the film morphology and film thickness (**Fig. 1B**) is determined in dependence of the applied number of cycles or pulses. Also, adhesion properties of PDA film in dependence of surface groups obtained by AFM force spectroscopy will be discussed.

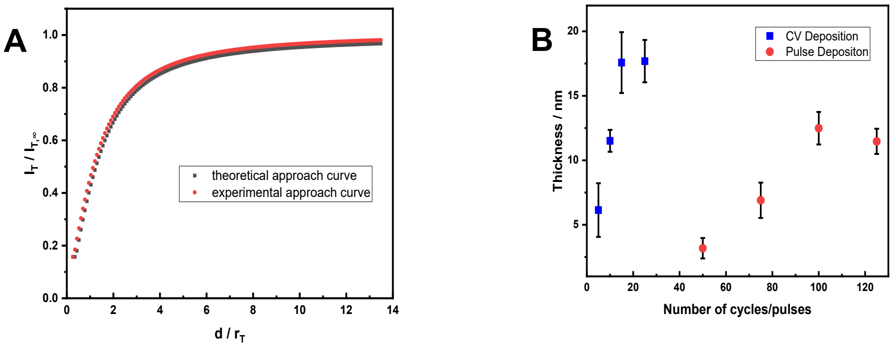

Fig. 1. **A** CV recorded in 5 mM hexaammineruthenium (III) chloride and 0.1 M KCl. **B** Thickness of the PDA films in dependence of number of cycles/pulses obtained by contact mode AFM.

Introduction

For the low-carbon society, the hydrogen production using the renewable energy is essential technology. The proton exchange membrane water electrolysis (PEMWE) is one of the candidate methods in several water electrolysis. In the development of PEMWE, the performance evaluation of synthesized catalyst is indispensable factor. The precise performance evaluation of membrane electrode assembly (MEA) and the anode and cathode polarization measurement using the reference electrode is the essential factor for the catalyst evaluation. In this study, the small-size electrode electrolyzer was developed, which can precisely control the pressure to the electrode area, and measure the anode and cathode polarizations by the equipment of two reference electrodes for the anode and cathode side surface of PEM. The electrochemical measurements using these functions were performed.

Experimental

The electrode size of developed electrolyzer was 1×1 cm^2. The first feature was that this electrolyzer has the precise pressure control structure to the only electrode area, and the second future was that the two reference electrodes, which connected at the faces of anode and cathode sides on PEM, was equipped in the electrolyzer as shown in Figure 1. The MEA was fabricated by the transcription method. The anode and cathode catalysts and PEM used IrO_x (ELC-0110, TKK), Pt/C (TEC10E50E, TKK) and Nafion®117 (DuPont), respectively. The electrochemical measurements performed for the chronoamperometry (CA, 1.3-2.5 V), the electrochemical impedance spectroscopy (EIS, frequency; 10 k-1 Hz, amplitude; 10 mV) and the linear sweep voltammetry (LSV, 1.0-2.5 V, scan rate; 4 mV s^{-1}).

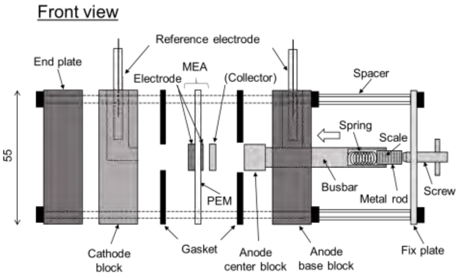

Figure 1 The structure of developed compact PEM water electrolyzer.

Results and discussion

The developed 1 cm^2 electrolyzer was compared with the conventional 16cm^2 electrolyzer, and the difference of performance was 1.6 % for the cell voltage at 1.0 A cm^{-2}. The optimized electrode-pressure as the specific value for developed electrolyzer-component was 0.52 MPa. Figure 1 shows the polarization measurement using two reference electrodes. The sheet resistivity of Nafion 117 using this method showed a 0.26 Ω cm^2, which was close to the reported-value [1]. The anode and cathode polarization curves, which were *iR*-corrected by PEM sheet resistivity, showed the linear tendency in Tafel plot. As a result, it was showed that this polarization measurement was the reasonable method as the polarization measurement of the anode and cathode reactions.

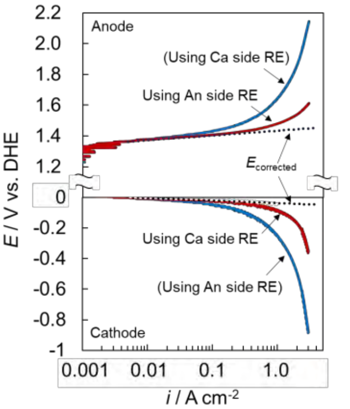

Figure 2 The anode and cathode polarization carves using two reference electrodes.

The oxygen evolution reaction is one of the major factors that limit economically feasible water electrolysis on a large scale. Not only it necessitates a substantially higher overpotential than the hydrogen evolution reaction, but also produces already abundantly available oxygen, a not highly valuable product.[1]

Glycerol is a well-known non-poisonous reducing agent. An increasing demand for biodiesel has led to its excess supply and low price on the global market. It offers three possible oxidation sites and thus can be converted to a wide variety of products. Amongst them is lactic acid, whose bifunctionality as a hydroxycarboxylic acid makes it versatile for industrial application e.g. for production of biodegradable polymers and non-toxic esters. The substitution of water oxidation by glycerol oxidation (GOR) as the anode reaction in the water electrolysis process could hence make electrocatalytic hydrogen production more profitable in the future. In order to be competitive, electrocatalysts for GOR do not only need to be active and made from earth-abundant materials, but also be selective and stable.[2-3]

In this work mixed cobalt nickel borides were synthesized via wet chemical reduction of nickel and cobalt precursor salts by sodium borohydride and subsequent annealing at different temperatures in an inert gas atmosphere. To further improve catalyst stability and provide additional adsorption sites during glycerol oxidation, the catalyst was mixed with benzoxazine monomers (BO) in different mass ratios prior to the annealing step. The resulting cobalt nickel borides embedded in a N-doped carbon matrix were evaluated as electrocatalysts for glycerol electrooxidation using rotating disk electrode voltammetry in alkaline electrolyte. $(Co_{0.5}Ni_{0.5})_2B$/BO - with a catalyst:monomer ratio of 7:1, annealed at 500 °C - revealed increased activity as compared to the corresponding catalyst in absence of the benzoxazine-derived carbon matrix. Investigations on the catalyst selectivity and stability were performed using a flow-through cell set-up for up to 18 hours. The analysis of the reaction products by liquid chromatography indicated the presence of lactate in addition to other oxygenates from glycerol. Future experiments aim on further improving the selectivity towards lactic acid.[4-6]

The electrochemical CO_2 reduction reaction (CO_2RR) is a crucial technology for the formation of gaseous and liquid fuels and chemicals feed stock. So far Cu is one of the few catalysts able to perform C-C coupling at significant rates leading to longer chain carbon molecules. However, it requires high overpotentials and lacks selectivity. Bimetallic nanoparticles have shown improvement in selectivity for CO_2 to $C_{\geq 2}$ products taking the advantages of the two spatially closely located independent active sites. A first reduction of CO_2 to CO takes place at Ag and then this intermediate diffuses towards Cu, where the final products are formed, enabling the formation of $C_{>2}$ products at comparatively low overpotentials. The sequential transfer of intermediates across different sites in close proximity is called spillover catalysis.[1]

The Ag-Cu nanozyme (Fig. 1a) is one step forward in the design of catalysts enabling confined spillover catalysis. Its structure does not only place two different active centres in close proximity, but also creates a nano-confinement to increase the turnover on Cu. The nanozyme was designed to first produce CO at the Ag-core surface from where it is diffused into the porous Cu shell for further reduction. This tailored structure allows the formation of up to C_3 products at -0.6 V *vs.* RHE.[2] These results were achieved in an H-type cell, in which the formation rate of CO_2RR products are limited by CO_2 depletion, low current densities and competition with the hydrogen evolution reaction.[3]

Previous studies showed an improvement in the current density and the production rate of $C_{>2}$ when the same catalyst is introduced to a gas diffusion electrode (GDE) with CO_2 flow.[3,4] We herein present a strategy to combine these two advantages for an improved CO_2RR selectivity and current density. By dispersing Ag-Cu nanozymes into a GDE a double confinement environment is established. This is a result of placing the nanozyme catalyst at the gas-solid-liquid (three-phase) interface, allowing locally high CO_2 concentrations with minimal diffusional loss. By keeping the CO_2 concentration constant allows for an increased conversion rate and enhanced currents densities leading ultimately to an increased $C_{\geq 2}$ products formation rate alongside with a lower overpotential.

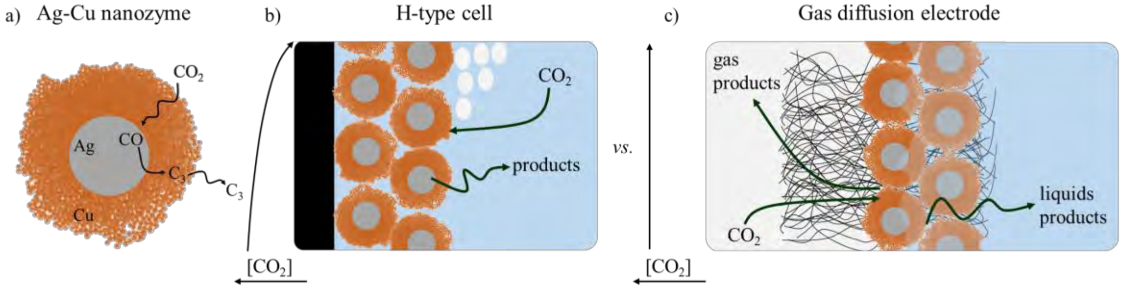

Figure 1. Schematic of the Ag-Cu nanozyme catalyst (a), H-type cell design (b) and the GDE electrode (c).

The main aim of our research is to couple electrochemistry with spectroscopic methods in a novel system made of a microcavity in an optical fiber (Fig. 1.)

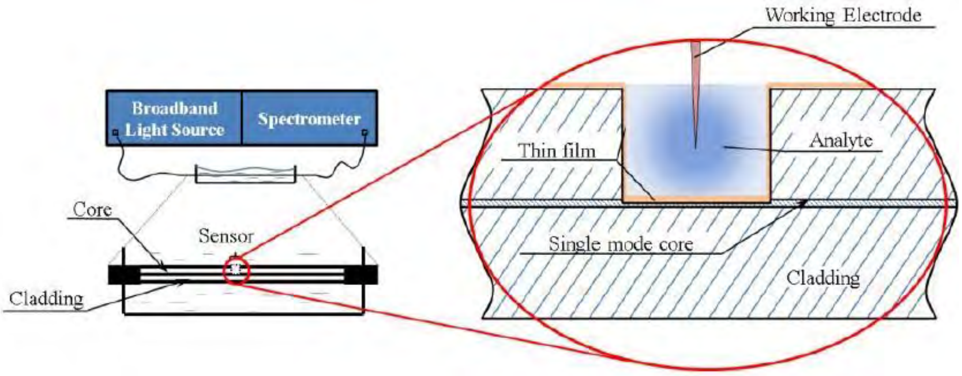

Fig. 1. Scheme of experimental setup – microcavity fabricated in an optical fiber

A microcavity fabricated in an optical fiber with the use of femtosecond laser has dimensions around 60 µm (length and depth) and acts as an electrochemical cell, in which picoliter volumes of solution can be analyzed, and simultaneously as an inline Mach-Zender interferometer.

We are preparing platinum microelectrodes, which put into microcavity play the role of working electrode. At their surface, electrochemical oxidation and reduction processes of studied analyte are carried out. The optical response to these processes is then examined, which gives more information about possible products.

We will compare the electrochemical response of the electrode inside the cavity with calculations in Comsol. We also present measurements of the optical response from the microcavity inline Mach-Zehnder interferometer recorded during electrochemical measurements.

Electrochemical fabrication of a LiZn-alloy – A two-step approach to reduce the volume expansion of alloy anodes

The current state-of-the-art electrochemical energy storage systems, i.e., lithium-ion batteries (LIB), reach almost their theoretical limit in energy density (584 Wh kg^{-1}).[1] Thus, the aim of current research is to increase the theoretical energy density. Especially the use of pure lithium anodes would lead to an immense increase in energy density due to the high specific capacity of lithium (3870 mAh g^{-1}). However, a lot of challenges hinder the commercialisation of pure metal anodes, *e.g.*, the growth of dendrites during metal deposition, which pose high safety risks.[2]

In order to build a bridge between safe and high capacity anodes, lithium-metal alloys are moving more in the focus of research.[3–5] In addition to the benefits, a number of challenges still need to be addressed, *e.g.*, the volume expansion and the contraction during lithiation and delithiation that can lead to cracking / deformation of the electrode.

Within this work we aim to reduce the negative effects of the volume effects using the example of a LiZn alloy. We thereby apply the alloy to a 3D-host structure (carbon mesh) over two steps (Figure 1 a). First, a porous ZnO-film is electrodeposited onto the carbon fibres of a carbon mesh. Afterwards, the ZnO-film is electrochemically converted into LiZn by reaction R 1.

$$\mathrm{ZnO} + 3\,\mathrm{Li}^+ + 3\,\mathrm{e}^- \rightarrow \mathrm{LiZn} + \mathrm{Li_2O} \qquad \textit{R 1}$$

First results indicate that ZnO is electrochemically converted into LiZn as intended. In the next steps, the LiZn@C-mesh is used as anode material in a LIB and the electrochemical reversibility is investigated by means of operando XRD. However, small cracks are still formed in the anode material (Figure 1 f). In order to decrease the negative effects of these cracks even further, ZnO nanorods[6] will be used in future experiments.

Development of innovative electrolytes for potassium-ion batteries

Lukas Medenbach, Siqi Liu, Lars H. Heß, Christian Leibing and Andrea Balducci
Centre for Energy and Environmental Chemistry, Jena (CEEC, Jena)
Philosophenweg 7a, 07743 Jena, Germany
Lukas.Medenbach@uni-jena.de

As one very promising post-lithium-ion battery candidate, potassium-ion batteries (KIBs) attracted the interest of researchers in recent years. Although potassium is much heavier than lithium or sodium, potassium-based batteries would reveal a number of advantages towards the lighter alkali-metal analogues. First, the half-cell potential of K^+/K can be even lower than the one of Li^+/Li depending on the used electrolyte composition [1]. Second, K^+ has usually a higher transference number within the electrolyte phase compared with Li^+ or Na^+ [1]. Third, potassium salts like KPF_6 are much less hygroscopic and can be produced at lower cost. And, in contrast to sodium ions, graphite is able to intercalate K^+ reversibly with a stoichiometric composition of C_8K (279 mAh g^{-1}) [2].

In this work we investigated the use of electrolytes based on 3-cyanopropionic acid methyl ester (CPAME) [3], tetraethoxy glyoxal (TEG) and tetramethoxy glyoxal (TMG) [4] for KIBs. From former studies, it is known that electrolytes based on these solvents display large electrochemical stability and are suitable candidates for the application in supercapacitors [3] as well as Li-ion batteries [4]. To the best of our knowledge, however, till now they have not considered in KIBs. The conductivity, viscosity, density, electrochemical and thermal stability of these electrolytes have been investigated in detail and compared to that of the frequently investigated electrolyte based on KPF_6 dissolved in ethylene carbonate/ diethyl carbonate (EC/DEC). Furthermore, the use of these electrolytes in combination with $K_2Fe[Fe(CN)_6]$ (prussian white) based cathodes and with graphite or soft carbon based anodes have been considered. The results showed that these unconventional electrolytes are promising in view of the realization of high performance KIBs.

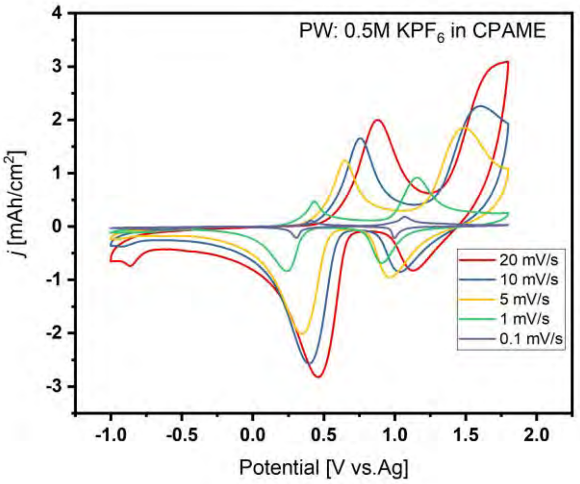

Figure: Cyclic voltammograms of $K_2Fe[Fe(CN)_6]$ at different scan rates. 3-cyanopropionic acid methyl ester (CPAME) was used as electrolyte solvent.

Over hundred years, so many oxidation technologies have been developed in environmental engineering fields. Mostly, chemical and biological oxidation processes have been enough to treat organic and/or inorganic pollutants to meet the legal emission targets. However, recent wastewater including non-degradable organic compounds demands the development of advanced oxidation technology since non-degradable organic compounds are hardly decomposed by chemical and/or biological treatment technology. Particularly, discharge of toxic or highly concentrated industrial wastewater has been significantly increased due to rapid industrial development to be a serious water pollution. To overcome this problem, various water treatment technologies such as chemical oxidation, precipitation, adsorption, capacitive deionization, electrochemical oxidation and so on have been recently developed and introduced to industry. Among them, electrochemical oxidation of the compounds at anode is environmentally friendly, easily operated and maintained compared to conventional treatment processes. Nonetheless, cost reduction and enhancement of performance/durability of anodic electrodes are highly necessary for commercialization. In this study, $TiO_2/IrO_2/RuO_2$ electrodes that IrO_2 and RuO_2 coated on anodized Ti substrate were prepared and investigated in terms of various electrochemical properties.

Most of electrochemically driven energy conversion devices consist of a pair of electrochemical reactions at electrodes and ion movement through electrolytes to complete full electrochemical cells. Ions move from anode to cathode or vice versa for electron exchanges. Pathway for ions is normally in an aqueous phase. Regardless, the introduction of any aqueous phase in energy conversion devices causes many problems during fabrication, operation, maintenance, and so on. Thus, much efforts have been devoted to develop quasi-solid electrolytes such as gel polymer, ion exchangeable polymers, impregnation of ions in porous matrix and so on. An approach to minimize areal resistance of film-type polymeric electrolytes is to make membrane thickness as thin as possible. Thus composite membranes have been highlighted as a new type of electrolytes. Composite membranes are made by impregnating polymeric electrolytes into thin porous substrates. However, hydrophilic ionomer is hardly impregnated into hydrophobic substrates. In this study, three-layered (electrolyte-skeleton/electrolyte-electrolyte) composite membranes with the thickness of 20-50 μm were prepared using porous substrates of various thicknesses. A technique to impregnate ionomer into hydrophilically treated porous substrates were developed so as to prepare void-free composite membranes. Characterization in terms of ion conductivity, ion exchange capacity, water uptake, dimensional stability, mechanical strength was carried out.

Energy conversion devices such as water electrolyzers or fuel cells require the movement of ions generated and consumed at two electrodes, i.e., anode and cathode. Ions should be transported inside electrodes to participate in anodic and cathodic reactions. Ion pathway is normally in liquid electrolyte. Regardless, the introduction of any aqueous phase in energy conversion devices causes many problems during fabrication, operation, maintenance, and so on. In addition, if gas penetration or gas evolution is one of phenomena taking place at electrodes, the electrodes should be porous. Thus, much efforts have been devoted to develop quasi-solid electrolytes such as gel polymer, ion exchangeable polymers, impregnation of ions in porous matrix and so on. Among the candidates, ion exchangeable polymers are quite often chosen as ion conducting media for energy conversion devices. The technique to introduce ion exchangeable polymers within electrodes for oxidation and reduction reactions is to solidify catalyst inks consisting of electrocatalyst, dispersion of ion exchangeable polymers, controlling solvents and additives by evaporation of all solvents in catalyst inks. Ion exchangeable polymers could be dispersed in various solvents. It causes different shapes of ion exchangeable polymers in solvents, for instance, cylindrical rods, a less-defined large particles, coils and so on. Such different types of ion exchangeable polymers form distinguished structure catalyst layers. In this study, the effect of solvents dispersing ion exchangeable polymers on the performance and durability of catalyst layers was investigated. Electrochemical characterization such as I-V polarization, cyclic voltammetry, impedance and so on and microscopic characterization such as SEM and TEM were carried out to evaluate the performance and durability of catalyst layers.

Understanding the Effect of Porosity in Biomass-derived Carbon Electrocatalysts for CO_2 Reduction

Shilong Fu, Marilia Pupo, Wiebren De Jong, Ruud Kortlever*
Large-Scale Energy Storage section, Department of Process & Energy

Electrochemical CO_2 conversion is a promising method to use renewable energy and waste CO_2, that otherwise would have been emitted into the atmosphere, and produce fuels and bulk chemicals.[1] Biomass-derived carbon electrocatalysts have triggered a considerable attention recently due to their excellent electrocatalytic performance, highly abundant resource, relatively low costs and good long–term durability.[2] Moreover, protein(heteroatoms), vascular bundle(tunnel), and inorganic salts(templates) present in the biomass source can modify the charge distribution and morphology of the carbon materials, resulting in enhanced electrocatalytic performance.

In a typical heterogeneous electrocatalytic reaction involving a gas reactant, the catalytic efficiency is limited by mass transport limitations of the reactant and the complexity of the reactions at the three-phase electrochemical interfaces (e.g., gas, solid, and liquid three-phase interfaces). In these cases, porous electrode structures with a high number of pore sites can promote a catalytic reaction at the interface, electrolyte ion diffusion and electron transport. Previous research has demonstrated that the optimization of the pore structure, including specific surface area, pore volume, pore size, and pore size distribution, is a highly effective approach to improve the electrocatalytic performance of biomass-derived carbon-based materials for CO2RR (CO_2 Reduction Reaction).[3] However, the difference in biomass sources, activators, preparation methods and conditions, bring different electrochemical performance, making it impossible to judge the specific functions of different porous structures in the electrochemical CO_2 reduction process.

Here, we designed a series of systematic experiments to explain the functions of porous structure in different bio-based carbon catalysts. The biomass-derived carbon catalysts were produced by a one-step method, using the same preparation procedure but altering activators. The textural analysis, such as: specific surface area, pore size distribution, degree of graphitization, etc. is combined with an analysis of the electrocatalytic performance (overpotential; product selectivity; current density and durability) towards CO2RR. From this study, we will show how the porous structure of biomass-derived carbon affects mass transfer during the electrochemical reduction of carbon dioxide. Finally, we will obtain an understanding of the role of different activators and the function of porosity in the CO2RR on biomass-derived carbon materials.

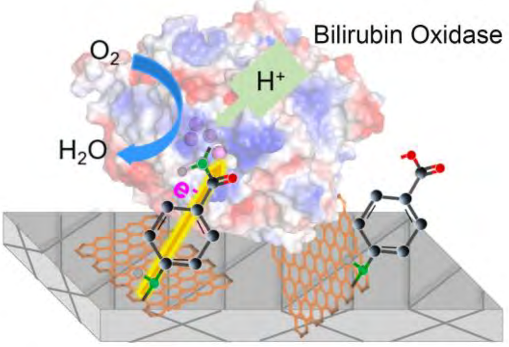
Aggregation of reduced graphene oxide (RGO) due to π-π stacking is a problem, as aggregation decreases the effective RGO working area.[1-2] Dispersing RGO on three-dimensional (3D) carbon paper electrode is one strategy towards relieving aggregation, but some aggregation still remains.[3] In this report we describe a study, where a negatively charged molecule 4-aminobenzoic acid (4-ABA) is grafted onto the graphene-based carbon paper electrode surface to induce orientation of the blue multi-copper enzyme *Myrothecium verrucaria* bilirubin oxidase (BOD) favourable for direct electron transfer (DET) for the oxygen reduction reaction (ORR) at neutral pH, Scheme 1. Simultaneous electroreduction of GO to RGO and surface grafting of 4-ABA are achieved by applying alternatingly negative and positive electrochemical potential pulses, resulting in very high catalytic current density (Δj_{cat}:193 ± 4 μA cm^{-2}) under static condition. Surprisingly we found that electrochemically grafted 4-ABA not only favours proper orientation of BOD validated by numerical model fitting to the electrocatalytic currents. RGO aggregation is also alleviated as disclosed by scanning electron microscopy, probably due to the electrostatic repulsion between the 4-ABA grafted graphene layers. Further, the bioelectrode shows outstanding operational stability with a half-lifetime of 55 h. Such a degree of stability has not been reported before. The bioelectrode is finally exploited in a gas diffusion configuration, offering great potential for applications for bioelectrochemical devices such as biofuel cells and biosensors.



Scheme 1. Schematic illustration of the prepared BOD on 4-ABA functionalized RGO-carbon paper electrode and its bioelectrocatalysis process. A possible orientation of MvBOD (PDB:2XXL), with surface charge distribution indicated with blue and red colour symbolizing positive and negative charges, respectively, is proposed (not drawn to scale). The left 4-ABA linker forms an amide bond with BOD, while the right 4-ABA with free –COO^- is still unreacted.

flisdat@th-wildau.de

Semiconductor nanoparticles (quantum dots - QDs) have become attractive tools in bioanalysis because of their optical and electrochemical properties. This is related to applications using fluorescence, electrochemiluminescence or photocurrent generation [1]. For photoelectrochemical systems QDs are immobilized on conductive electrodes. By illumination electron-hole-pairs are formed inside the nanoparticles which can be used for photocurrent generation. Signal chains can be constructed when suitable donor or acceptor molecules are present in solution. The special feature of such electrodes is that the response is triggered by illumination of the sensing surface [1]. In this study, a light-switchable photoelectrochemical sensor was built by coupling QDs with two different oxidases to detect the respective enzyme substrates in parallel.

For this purpose CdSe/ZnS QDs have been immobilised via a dithiol compound on gold electrodes. Two different enzymes, glucose oxidase (GOD) and sarcosine oxidase (SOD) have been deposited on this QDs-electrode at spatially well resolved places. Here small spots can be achieved. A laser beam is moved over these spots to allow photocurrent generation. Since oxygen can act as electron acceptor at the illuminated QDs the photocurrent is correlated to the oxygen concentration near the surface. By action of the enzymes in the presence of the corresponding substrate a competitive situation for oxygen is created in front of the QD layer and thus, the photocurrent decreases [2, 3]. Since this occurs in a concentration dependent manner, analysis of the enzyme substrate is feasible.

Due to the spatially separated immobilisation of two oxidases, an independent read-out of the two enzyme reactions is feasible. The experiments indicate good lateral resolution and selectivity of the multi-detection system without any crosstalk between the two sensing regions and without any response at regions, which are not modified with an enzyme [4].

Furthermore, the possibility of an imaging of the enzyme spot by photocurrent measurement has been investigated. When the laser is moved over the spot of GOD with a constant speed, the size of the spot can be determined from the photocurrent - time curve (with a defined moving speed). The photocurrent correlates to different local enzyme activities. Consequently, an imaging of the enzyme activity distribution on the surface has also been achieved by this method.

Electrochemiluminescence (ECL) is a light-emitting process and a powerful tool in analytical chemistry. This phenomenon is induced by the excited state of a luminophore, which is generated by an electrochemical reaction at an electrode surface.[1] Conversely, photoelectrochemistry on illuminated semiconductors is a process where an electrode absorbs light, and that can be used to decrease the potential required to trigger an electrochemical reaction.[2] In this communication, we will introduce the photo-induced electrochemiluminescence (P-ECL) of anodic ECL systems involving $[Ru(bpy)_3]^{2+}$ and a luminol analog (L-012). In this approach, the ECL emission is triggered by holes photogenerated in an *n*-type semiconductor electrode, which is normally highly challenging due to competing photocorrosion occurring at semiconductor electrodes in aqueous electrolytes.[3] In a first example, we will present the results we obtained on Si-based tunnel electrodes protected by a Ni stabilizing thin films and demonstrate that these photoanodes allow generating P-ECL in water. We will show that, in this case, P-ECL can be used as an upconversion process where light absorption at 810 nm induces ECL emission (635 nm) at a record low electrochemical potential of 0.5 V vs SCE.[4] Also, recent results obtained using a UV incident light to induce simultaneously L-012 fluorescence and the formation of oxidizing holes in the photoanode suggest that P-ECL leads to a stronger emission than fluorescence and that this phenomenon can be employed to finely tune the overall luminescence.[5]

In context of the growing need for a more sustainable energy sector, catalyst materials research to improve water electrolysis and fuel cell (FC) electrodes plays a significant role in the transition to a green energy production. *In-situ* studies of promising electrocatalysts in conditions close to real operation is of crucial importance to understand the limiting mechanisms occurring in catalytic reactions. The combination of soft x-ray absorption (XAS) and emission (XES) spectroscopies is an established method that can probe the (local) chemical and electronic structure of solid, liquid, and gaseous samples from an atom-specific perspective, providing insights into their catalytic activity.

For this purpose, in the Energy Materials In-situ Laboratory Berlin (EMIL) at the BESSY II synchrotron facility, we have developed an infrastructure that allows XAS, XES, and RIXS (resonant inelastic x-ray scattering) studies of electrocatalysts under operating conditions. This setup is based on a 3-electrode electrochemical flow-cell attached to an ultra-high vacuum chamber (UHV) dedicated for *in-situ*/*operando* studies. The modular design of the electrochemical cell ensures project-specific upgrades besides the standard use with liquid electrolyte; for instance, the implementation of a microfluidic gas system that allows membrane-based designs for acidic water oxidation electrocatalysts or proton-exchange-membranes for FC applications. The system is installed at a two *undulator*-based beamline covering a probing energy range from the extreme ultraviolet (~80 eV) up to the hard x-ray regime (~10 keV). In combination with the high detection efficiency and (moderately) high energy resolution of the newly developed high-transmission soft x-ray emission spectrometer (HiTS), high-quality XES and RIXS spectra of all relevant elements can be collected at appropriately fast timescales i.e. several minutes, enabling measurements during normal operation of a myriad of electrocatalysts.

We present the current status of the instrumentation dedicated for *in-situ* characterization of real-world electrocatalysts under operating conditions at EMIL@BESSY II and the first *operando* experimental results on highly active iridium oxide-based oxygen evolution reaction catalyst.

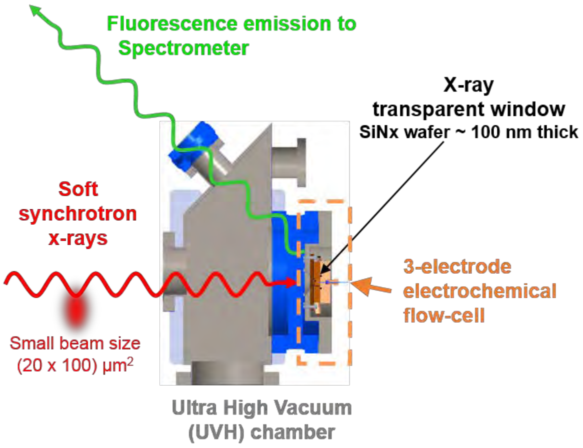

Figure: Schematics of the *operando* x-ray spectroscopy infrastructure at EMIL@BESSY II. The incoming x-rays generated at the synchrotron source impinge into the material through a thin membrane that separates the UHV environment from the examined material in the liquid electrolyte. The emitted fluorescence photons are collected with the energy dispersive spectrometer.

Towards *Operando* Studies of Electrolyte/Catalyst Interfaces in HT-PEMFC: Reference Materials Probed by X-ray Spectroscopies

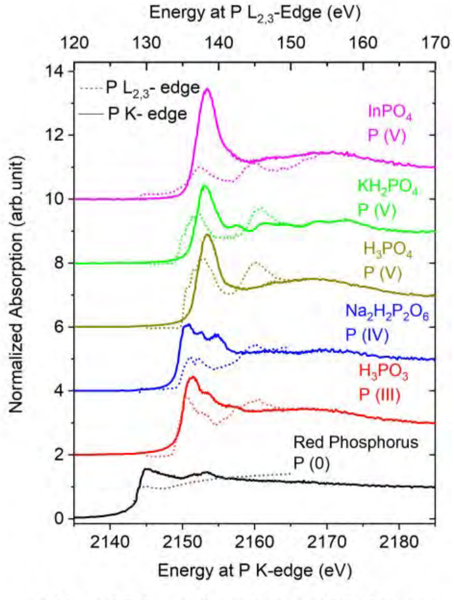
High-temperature polymer electrolyte membrane fuel cells (HT-PEMFCs) using polybenzimidazole (PBI) membrane doped with concentrated phosphoric acid are a promising candidate for a sustainable stationary energy source due to the promising combined heat and power efficiency[1]. However, long-term durability remains an issue and further optimization is needed to push HT-PEMFCs further into the market. By investigating the phenomena at the electrolyte/catalyst interface, light can be shed on the degradation mechanisms governing the lifetime of these devices. Several (*ex-situ*) studies have reported on the interaction between phosphoric acid-based electrolyte and Pt catalyst[2], but investigations dedicated to the reactions occurring at the electrolyte/catalyst interface under operating conditions are scarce.

We aim to elucidate the crucial interactions at the interface between H_3PO_4-based electrolyte and Pt catalyst by using *operando* absorption (XAS) and emission (XES) x-ray spectroscopy at the phosphorus K- and $L_{2,3}$-edge. Photon-in/photon-out x-ray spectroscopies are powerful tools to investigate the electrolyte/catalyst interface due to the detailed, element-specific information on oxidation state and local chemical structure that they can provide[3,4]. However, the interpretation of x-ray spectra can prove very intricate, since several phosphorus oxoacids might be generated when electric potential is applied to the Pt surface in contact with H_3PO_4[5], resulting in multiple and superposed contributions to the spectroscopic signal.

In order to pave the way towards *operando* investigations, a fundamental XAS and XES study on relevant phosphorus-containing compounds with different oxidation states and chemical environments has been performed at the P K- and $L_{2,3}$-edges. Complementary hard x-ray photoelectron spectroscopy (HAXPES) measurements have also been performed, and this unique dataset will facilitate the identification of the species emerging under operation conditions. Moreover, as an intermediate step towards real *operando* studies, differently prepared pellets containing Pt catalyst were immersed in aqueous phosphoric and phosphorus acid electrolyte and afterwards were probed at the P K-edge in order to gain insights into the electrolyte/Pt interaction at open circuit voltage (OCV).



P K- and P $L_{2,3}$- edge spectra of Reference Phosphorus Containing Compounds

As shown in the figure, both P K-edge and $L_{2,3}$- spectra are highly sensitive to the oxidation state and chemical environment of the different reference compounds, allowing use as speciation tools in the *operando* study.

Simulation of Electrochemical Time-of-Flight Experiments in a Scanning Electrochemical Microscope for the Investigation of Electron-Transfer Reactions

Sebastian Pleis, Gunther Wittstock
Carl von Ossietzky University of Oldenburg
Ammerländer Heerstraße 114-118, D-26129 Oldenburg, Germany
sebastian.pleis@uol.de

Reaction mechanisms in homogeneous catalysis using transition metal complexes often involve the formation of short-lived intermediates. To detect these intermediates, it is necessary to choose a technique with a short time-window relative to the lifetime of the investigated species. It has been shown that a scanning electrochemical microscope (SECM) can be employed to detect electrochemically active intermediates with short lifetimes and to investigate their electron-transfer kinetics [1-3].

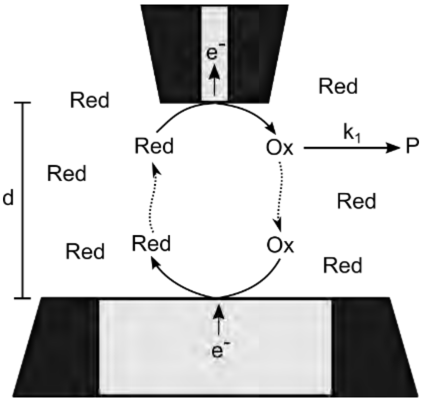

Figure 1: Schematic representation of the tip-generation substrate-collection (TG/SC) mode for the investigation of an E_rC_i-mechanism

In this contribution COMSOL Multiphysics was used to simulate electrochemical time-of-flight experiments using the tip-generation substrate-collection mode (TG/SC). A simple reaction mechanism of the E_rC_i-type was chosen as the basis of the simulation. As shown in figure 1 the oxidized species is generated at the tip-electrode via a heterogeneous electron-transfer and diffuses to the substrate-electrode where it is collected by electrochemical reduction. The collection efficiency depends on the distance *d* between the electrodes and the rate constant *k* of the coupled homogenous reaction. The simulation was used to explore the redox behavior of the species for varying tip-substrate distances and rate constants.

Formic acid is a valuable feedstock chemical that is utilized in broad industrial fields and is promising to be used in fuel cells.[1] The production of HCOOH or HCOO$^-$ via renewable energy driven electrochemical reduction of CO$_2$ is a promising strategy which combines renewable chemical synthesis, CO$_2$ emissions mitigation, and energy storage. Various materials have been investigated as promising electrocatalyst materials for selective and efficient CO$_2$ conversion into HCOOH (e.g., Sn, Pb, In and Cu$_x$S).[2,3] Among them, copper sulfide based electrocatalysts (Cu$_{2\text{-}x}$S) are promising candidates due to their activity, non-toxicity, and chemical abundance.[4] Moreover, the properties of Cu sulfides can be tuned by adjusting the stoichiometry, morphology, structure, and Cu valence state. Synthesis of Cu$_{2\text{-}x}$S particles with defined shape, particle size distribution, hierarchical organization, controlled stoichiometry, and defined crystal structure via a simple, low cost, and scalable process is still a challenge. Herein, we propose a simple, novel and inexpensive route for synthesis of digenite/roxbyite mixed phase cuprous sulfides via a direct reaction between elemental copper and sulfur dissolved in CS$_2$ and PhCH$_3$ at room temperature. The as-synthesized materials were characterized using variety of techniques including SEM, XRD, TGA/DSC and XPS. Electrochemically, the as-prepared materials showed that HCOOH is the only CO$_2$ER product (at < -1 V vs RHE in aqueous 0.1 M KHCO$_3$) and is produced with promising selectivity (55% FE). Additionally, we will provide our insight into the nature of the active site and the role of sulfur, and the subsequent mechanistic implications with reference to the conventionally described shift from carbophilic to oxophilic binding which characterizes the HCOOH production pathway.[4]

Electron-Hopping Governed Redox-Active Vertically-Aligned Mesoporous Silica Thin Films as Transparent Surfaces for Energy Storage Applications

Jianren Wang, Neus Vilà, Alain Walcarius
Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l'Environnement (LCPME), UMR 7564 CNRS – Université de Lorraine, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France.
jianren.wang@univ-lorraine.fr

The slow redox reaction rates always restrict the power densities of faradic materials. Different from the conventional electron transfer mechanism, electron-hopping, namely charge transfer between close but isolated redox molecules, may have the potential to accelerate redox reactions.[1] However, large-scale spatial assembly of redox molecules to increase the energy density remains difficult, and few studies systematically evaluate the value of electron-hopping mechanism in the energy storage field. Therefore, organic-inorganic hybrid membranes made of a high density of redox active moieties covalently bonded to the internal surfaces of vertically-aligned mesoporous silica thin films have been prepared from the combination of an electrochemically-induced self-assembly method[2] (to generate azide functionalized silica) and a copper-catalyzed azide-alkyne click reaction[3] (to derivatize the material with electroactive groups such as ferrocene). In such rigid and insulating porous membranes, the charge transfer reactions take place through a pure electron-hopping mechanism between adjacent redox sites, which are favored by the ordered and oriented mesostructure containing large amounts of uniformly distributed ferrocene functions. The density of ferrocene molecules in the mesochannels can be controlled by adjusting the ratio of organosilane in the precursor solution and the relationships among the energy storage behavior, ferrocene density, and materials structure are analyzed in detail. The most effective system is the ferrocene-functionalized silica film prepared from 40% organosilane due to both high charge transfer rates (electron-hopping) and easy mass transport (fast diffusion of counter ions), which is able to deliver a capacity of 175 F cm^{-3} at the current density of 0.4 A cm^{-3}. (with up to 48% capacity retention achieved at a charging time as short as 2.8 s). Moreover, the very small thickness (105 nm) and the uniformly distributed vertical mesochannels with ultranarrow diameter (2 nm) also deliver 82% transparency at 550 nm, making the hybrid films promising energy storage materials for transparent devices.

Biomarker discovery is an active research area, especially in oncology. Cancer diagnosis still relies on invasive tumor biopsies that are not exempt from risks. In recent decades, the search for specific biomarkers which assist clinicians in diagnosing cancer and enable disease monitoring, selection of the appropriate treatment and early detection of recurrence, has enormously increased. Unfortunately, pancreatic ductal adenocarcinoma (PDAC) lacks suitable biomarkers that help improve the devastating survival rate due to a late diagnosis. In this disease, the stroma plays a relevant role as a physical barrier against drugs and as a promoter of the tumor formation, invasion and metastasis. Therefore, abnormal components of the extracellular matrix are regarded as potential targets for therapy and diagnosis. With the aim of identifying these components, specific receptors are needed and aptamers possess features that make them ideal for this task.

In this study, we were able to select DNA aptamers against a potential extracellular matrix component by designing a 4-round SELEX protocol on magnetic beads. Several sequences were selected for detailed characterization based on their sequence homology and secondary structure. Electrochemical bioassays on magnetic beads were used to estimate the binding constant of the aptamer-target complex formation. The best sequences showed dissociation constants in the nanomolar range similarly to other tumor biomarkers. Likewise, electrochemical inhibition experiments supported the affinity of the aptamer for its target in solution. Selectivity was assessed by aptahistochemistry in healthy and PDAC tissues, and by aptacytochemistry using different tumor cell lines with and without target expression.

The generation of renewable energy fluctuates due to the intermittence of wind and sun. To have a stable energy grid, this energy has to be stored during highly productive days and released as needed. Electrochemical water splitting is attractive to store electricity in the form of hydrogen but limited by the slow kinetics of the oxygen evolution reaction (OER).[1,2] To understand this limitation, a mechanistic insight of the reaction is needed and can be gained using in situ spectroscopic studies on model electrodes. However, thin film model electrodes are difficult to integrate with commercially available electroanalytical instruments such as the well-established rotating ring disk electrode (RRDE) setup.[3] Furthermore, interfacing spectrometers with RRDEs is challenging. Therefore, we design a modular flow cell assembly that uses planar 5×10 mm electrodes and offers a simple interface with different spectroscopic systems. Our system can be adapted to various target reactions by changing the position, geometry and material of the electrodes as well as the flow geometry. The working and detector electrodes can be easily removed for post-mortem analysis. To validate our system, the redox behavior and mass-transport limitation were investigated using the ferri-/ferrocyanide redox couple in different electrolytes. Figure 1 shows the transport limitation as constant currents for both electrodes below ca. 0 V vs. SCE. The collection efficiency of the system in the mass-transport limiting case was simulated using multiphysics models in COMSOL®. The collection efficiency was found to be nearly independent of the flow rate at a value of around 35 %, which agrees with that calculated analytically.[4] The independence of the collection efficiency on the flow rate was also observed in cyclic voltammetry experiments using ferri-/ferrocyanide, where the collection efficiency was around 33(1) %, i.e. within 10% of the calculated value. The simulations have shown that products from the working and counter electrodes do not mix at experimentally used flow rates between 0.5 and 8 ml/min. In comparison to the RRDE system, we found that large flow rates are needed to produce the limiting current densities of typical RRDE experiments and that the time delay between production of the species and detection is larger in our flow cell. In conclusion, we find that our modular flow cell is a suitable alternative or addition to the common RRDE setups due to its flexible design and easy integration with further analysis systems to increase the information density of the measurement in future work.

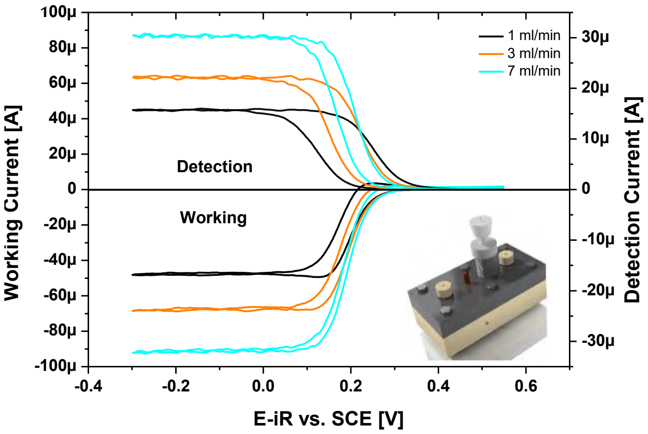

Figure 1. Collection efficiency measurements of the modular flow cell.

Membraneless microfluidic fuel cells with increased power density by passive flow control

Wiebke Rösing, Jörg König, Christian Cierpka
Institute of Thermodynamics and Fluid Mechanics, Technische Universität Ilmenau, Germany
Am Helmholtzring 1, 98693 Ilmenau, Germany
Wiebke.Roesing@tu-ilmenau.de

Microfluidic fuel cells are considered as the most promising candidates for power sources in portable electronic devices [1-3]. In membraneless microfluidic fuel cells, fuel and oxidant flow in parallel at low Reynolds number without convective mixing. The membraneless architecture eliminates many of the problems encountered with PEMFCs. However, it is still difficult to commercialize microfluidic fuel cells, because at practical flow rates and useful cell voltages poor fuel utilizations below 10% and low power densities persist problematic [4]. This is mostly caused by the formation of concentration boundary layers at the electrodes. A possibility to reduce the thickness of the concentration boundary layers is to increase the flow rate. However, this results in a further decrease in fuel utilization. A simple alternative method for the suppression of the concentration boundary layer expansion is a passive flow control by using a curved microchannel, which induces a transversal secondary flow as sketched in Fig. 1b) [5]. The generated counter rotating vortices enhance the transport of fresh reactant from the center of the channel to the concentration boundary layers. In order to investigate the correlation between the current density and the transversal secondary flow, a fuel cell with a U-shaped microchannel was fabricated (Fig. 1a). Segmented electrodes on the top and bottom of the microchannel enabled an electrochemical characterization of the fuel cell within the straight and curved channel part. In addition, optical flow measurements were conducted using astigmatic particle tracking velocimetry (APTV) [6]. Besides the experiments, numerical simulations demonstrate that, using a curved microfluidic fuel cell the current density increases compared to a fuel cell with only a straight section, due to the induced counter rotating vortices (Fig. 1c) [5]. The higher the flow rate, the higher the current density. At a flow rate of 30 ml/h the current density increases about 8%, while at a flow rate of 100 ml/h an increase of more than 30% is achieved. Further results, including measured polarisation curves and APTV flow measurements will be presented and discussed at the conference to emphasize the correlation between fuel cell efficiency and the flow physics based on our experimental findings.

Combining transition metal oxides and nanostructured carbon materials is considered as one of the best strategy to achieve high performance supercapacitors electrodes [1]. Here is reported a novel way to increase energy densities while maintaining high power densities of supercapacitors exploiting pseudocapacitance and nanostructuration of electrode materials.

MoO_3 has been recently reported as an appropriate pseudocapacitive anode material with a high capacitance [2]. Carbon nanotubes are used for their high electrical conductivity and rapid charge storage kinetics. The challenge is to assemble both material in a homogeneous nanostructured electrode with controlled composition and structuration aiming to create a synergetic effect between both charge storage mechanisms to improve electrochemical performances.

First, MWCNTs are deposited directly onto a current collector by dynamic spray-gun deposition. This deposition method used for nanostructuration of thin films insures the formation of homogeneous mats with tunable thickness [3]. This method is reproducible, easily scalable and low-cost considering that it is compatible with large surfaces. Then, molybdenum trioxide is deposited by a cathodic electrodeposition method directly onto the nanostructured carbon framework formed by the carbon nanotubes. Electrodeposition is very versatile and allows a good control of the composition of the hybrid material and of the morphology of the metal oxide, both impacting the final electrochemical performances of the hybrid material. The mechanism of growth of this specific metal oxide is quite complex with several possible intermediates presenting different oxidation states depending on the environment [4]. We study the influence of deposition conditions (such as pH, concentration in Mo^{6+} ions, current density) on the physicochemical and electrochemical properties of the resulting composite material.

The composition and structure of this electrode material is characterized by SEM, XPS, Raman spectroscopy, and microporosity analysis. Influence of an additional heat treatment after the electrochemical growth on the performances of the material is studied as well. A great amelioration of electrochemical performances after treatment under air at 350°C can be noted and the capacitance of the final material can reach up to 220 F/g for this hybrid negative electrode in an organic electrolyte (LiTFSI at 0.5M in γ-Butyrolactone). Indeed solubility of the deposited MoO_3 has been found to be a major issue in aqueous electrolytes.

Finally a full asymmetric supercapacitor with two different metal oxide based hybrid materials using this particular organic electrolyte was developed, as can be shown in the figure below. A hybrid MnO_2-rGO-CNTs material presented in one of our previous publications [5] is used as the positive electrode. Performances of this hybrid system compared to a symmetric system based on carbon nanomaterials developed at our laboratory show a great gain in terms of energy densities from 5 to 25 Wh/kg with a power density of 100 W/kg when pseudocapacitive materials are added.

Electrodeposition of Copper from Deep Eutectic Solvents – Influence of Composition

Tanja Geng[1], Maximilian Ceblin[1,2,3], Timo Jacob[1,2,3]

tanja.geng@uni-ulm.de

Recently, there has been an increasing interest in the deposition of various metals from Deep Eutectic Solvents (DES) as an alternative to other non-aqueous electrolytes such as ionic liquids. DES typically consist of an organic (DES type III) or inorganic (DES type IV) salt in combination with a hydrogen bond donor.[1,2] If mixed in the eutectic ratio, they form a liquid due to freezing-point depression. Advantageous characteristics of DES include but are not limited to a rather low viscosity compared to ionic liquids, high conductivity, and a broad electrochemical stability window. Further, the two components are usually inexpensive and can be purified separately.[1-3]

Despite the extensive research in the field of DES performed over the last years, there is little knowledge about their thermal behavior.[4] This holds especially true for the impact of composition on the freezing point and the resulting freezing-point depression. However, this can influence the conductivity as well as the complexes present in the electrolyte, and thus the electrochemical behavior. In this study, we investigated the thermal and electrochemical characteristics of different DES as a function of their composition. The influence of the hydrogen bond donor, the salt, and their ratio is studied systematically.

Differential scanning calorimetry is applied to generate phase diagrams of DES type III and to determine the eutectic composition and eutectic temperature of the respective mixtures. The focus of the subsequent electrochemical characterization is on copper deposition as a model system. Investigated electrolytes are combinations of choline chloride or choline nitrate with hydrogen bond donors such as ethylene glycol or trifluoroacetamide. As a copper source, Cu(I) or Cu(II) species are added to the mixtures. An Au(111) single crystal is employed as a model electrode to study the initial stages of the copper deposition. Cyclic voltammetry, chronoamperometry, and the electrochemical quartz crystal microbalance are applied to elucidate the nucleation mechanism of copper on Au(111) from DES type III. Literature believes that high chloride concentrations influence the deposition.[5] Our study with choline nitrate suggests, however, that a high concentration of anions in general is crucial. The reaction mechanism of copper deposition also depends on the hydrogen bond donor, its ratio to the salt, and the copper species involved. In all media, deposition follows a nucleation and three-dimensional growth mechanism controlled by diffusion. The bulk deposition is probably preceded by underpotential deposition at more positive potentials.

Furthermore, we are applying these methods to copper-based DES type IV. Analogous to DES type III, these show a freezing-point depression and can be used as electrolytes in metal deposition. Because of the high concentration of copper salt, their deposition behavior in terms of the nucleation mechanism is different.

Degradation of OER Based Reversal Tolerant PEFC Anodes – Innovative Characterization Methods and Further Insights

D. Bentele[1,2]*, K. Aylar[2], K. Olsen[2], E. Klemm[1], S. H. Eberhardt[2]

Durability is a major lever for cost competitiveness of polymer electrolyte fuel cells (PEFCs) with respect to combustion engines for automotive and stationary applications.[1] The occurrence of cell reversal events due to gross fuel starvation in one or more membrane electrode assemblies (MEAs) can significantly reduce fuel cell lifetime. In this case, the increase in anode potential during cell reversals causes irreversible damage to the anode catalyst layer (ACL) and other PEFC components.[2,3]

The introduction of an oxygen evolution reaction (OER) catalyst, such as IrO_x, constitutes a material based mitigation strategy to reduce cell reversal induced degradation.[2–6] By lowering the activation energy of the water splitting reaction, the OER catalysts significantly reduces carbon corrosion during cell reversal.[7] To achieve increased lifetime and cost reduction, comprehensive understanding of degradation processes within reversal tolerant anodes (RTAs) is crucial for MEA manufacturing and material development.

In this work, a supported IrO_x catalyst is combined with a state of the art carbon supported platinum hydrogen oxidation reaction (HOR) catalyst. To facilitate fast and cost-efficient research, innovative characterization methods and procedures are developed for single cell ($< 50\ cm^2$) testing. A major focus is set on a cyclic combination of cell reversal and normal operation to characterize HOR and OER performance and interaction. The use of such a combination is still comparatively low [4], whereas state of the art accelerated stress tests (ASTs) focus on uninterrupted cell reversal testing. Therefore, focusing more on OER lifetime rather than normal operation lifetime estimation during repetitive, short-term reversal events occurring within automotive application.

Combining the developed AST procedure with advanced performance characterizations, such as hydrogen pump experiments, the individual contribution of mass transport, ohmic and HOR activation overpotential can further be quantified.

Besides the significant impact of using different HOR catalysts, a strong ACL structure dependency regarding the reversal tolerance was found (cf. Fig. 1). Using identical components and catalyst loadings, varying the ACL structure reveals a reversal tolerance increase by a factor of nine.

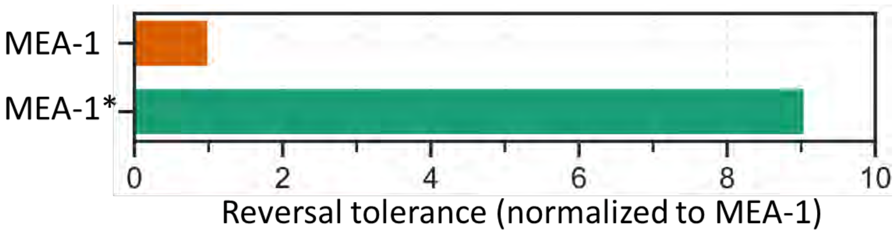

Figure 1: Reversal tolerance investigated by the developed cell reversal AST procedure for two different MEAs. Their ACLs differ regarding their structure whereas used components and catalyst loadings are identical.

A Novel Multi-Functional Electrolyte Additive for Ni-Rich Cathode Materials

Hieu Quang Pham, Sigita Trabesinger
Battery Electrodes and Cells, Electrochemistry Laboratory, Paul Scherrer Institute,
Forschungsstrasse 111, 5232 Villigen PSI, Switzerland
quang.pham@psi.ch

Ni-rich layer oxides $Li[Ni_xCo_yMn_{1-x-y}]O_2$ ($x \geq 0.8$, NCMs) are promising advanced cathode materials for high-energy Li-ion batteries because of their high specific capacity (≥ 200 mAh g^{-1}) with an average discharge voltage of 3.8 V vs Li^+/Li, as compared to the commercialized cathode materials (e.g. $LiCoO_2$, $LiFePO_4$).[1] However, the instability of cathode–electrolyte interface causes the structural degradation of cathode active material and the electrolyte consumption, as well as gas evolution due to oxidative decomposition of electrolyte, resulting in a rapid capacity fading.[2]

Thus, improvement in the stability of cathode–electrolyte interphase is a key requirement to inhibit their structural degradation and enhance their electrochemical properties. The formation of a protective surface film *via* electrolyte additives is considered a cost-effective and reliable way to improve the cathode–electrolyte interfacial stability, as the stable surface film, uniformly distributed over the entire cathode surface, would prevent direct contact of oxide with the electrolyte, still allowing Li^+ transport between the cathode and electrolyte.[3] In this work, we report the high-performance NCM cathode through interfacial stabilization using a novel electrolyte additive. The details of surface film stability and formation mechanism, and their relation to gas evolution as well as cycling performance would be discussed.

Pitfalls in Lithium Metal Battery Characterisation

Eric Winter[a], Thomas J. Schmidt[b], Sigita Trabesinger[a]
[a]Battery Electrodes and Cells, Electrochemistry Laboratory,
Paul Scherrer Institute, 5232 Villigen PSI, Switzerland
[b]Energy and Environment Division, Paul Scherrer Institute, 5232 Villigen PSI, Switzerland
E-mail: eric.winter@psi.ch

Since the early days of rechargeable battery research,[1,2] metallic lithium as an anode material has been considered a “holy grail” due to its highly negative potential (-3.04 V vs. SHE) and high theoretical capacity (3860 mAh·g^{-1}).[3] In the age of electro-mobility, exploiting the resulting high energy density of lithium metal has become even more desirable.[4]

However, even after intensive efforts in the last decade, lithium metal batteries (LMBs) still suffer from severe problems such as low cycling stability and low coulombic efficiency.[5] These performance shortcomings are mainly due to the high reactivity of the lithium metal towards electrolytes and dendrite formation during cycling. Major concern they cause is the safety of the LMB cells.

In order to tackle these issues, there has been growing consensus in the scientific community to aim for common reporting standards and testing conditions.[6] However, before these are established, it is necessary to understand the impact of the different experimental parameters on the trustworthiness of the testing results.

The aim of this study therefore was to investigate the influence of different experimental parameters, such as current density, amount of lithium metal moved, type, and quantity of electrolyte, in symmetric and asymmetric lithium metal cells. To better understand the morphology changes happening during lithium plating and stripping, complimentary techniques, such as *operando* dilatometry and *post-mortem* scanning electron microscopy, were used. We will discuss why potentially neglected parameters could have a significant impact on the outcome of measurements and in what way the findings of this study could be used to establish a reliable baseline for future LMB tests.

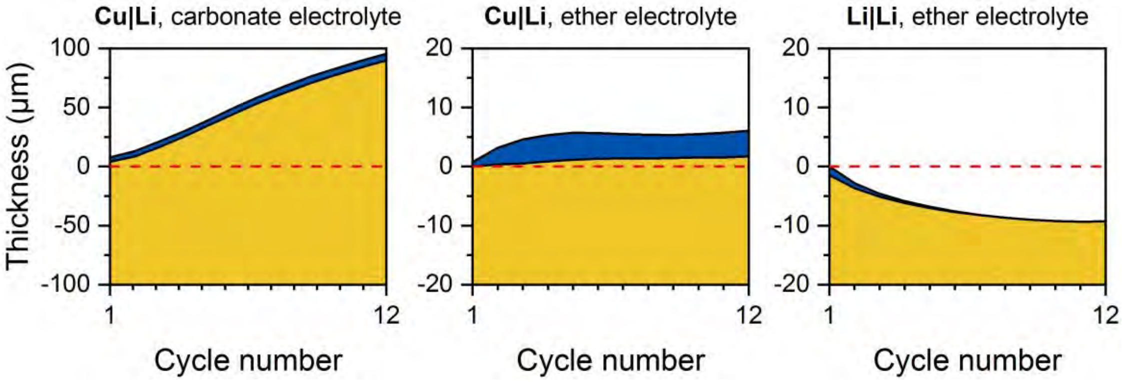

Figure 1: The thickness change of the working electrode (d = 7.5 mm) during cycling (2 mAh·cm^{-2}, 2 mA·cm^{-2}) can be positive or negative depending on cell configuration and electrolyte.

Capturing and converting CO_2 to easily storable fuels has become a hot research topic, in the last few years, due to its potential contribution to obtaining carbon neutral energy cycles. Among all the metals used for CO_2 electrochemical conversion, copper takes a special place; the main reason is related to its unique capacity of generating a wide range of CO_2 reduction products like HCOOH, CH_4, CO and promoting carbon–carbon coupling to obtain ethylene and ethanol. Copper electrodes have been extensively studied as electrodes for electrochemical CO_2 reduction reaction (CO_2RR)[1]. Nanoparticles, in particular, were reported to improve selectivity and increase energy efficiency. However, the choice of nanostructured supporting materials received only limited attention. Our aim was to study the effect of a graphene-based supporting material on copper nanoparticles stability and on products distribution.

We studied copper nanoparticle supported on two types of graphenide compounds. The first material was prepared from a graphenide solution obtained dissolving a nanocarbon intercalation compound of formula KC_8 in THF [2]; this solution act as a reducing agent for $CuCl_2$ salt, resulting in the precipitation of copper oxides nanoparticles over graphene sheets (Fig.1). The other material was an intercalation compound where copper nanoparticles are entrapped in between graphene sheets of larger dimension. XPS analysis confirmed the presence of copper (I) and copper (II), in agreement with what we found with the XRD analyses that showed reflections due to $Cu(OH)_2$ and Cu_2O phases.

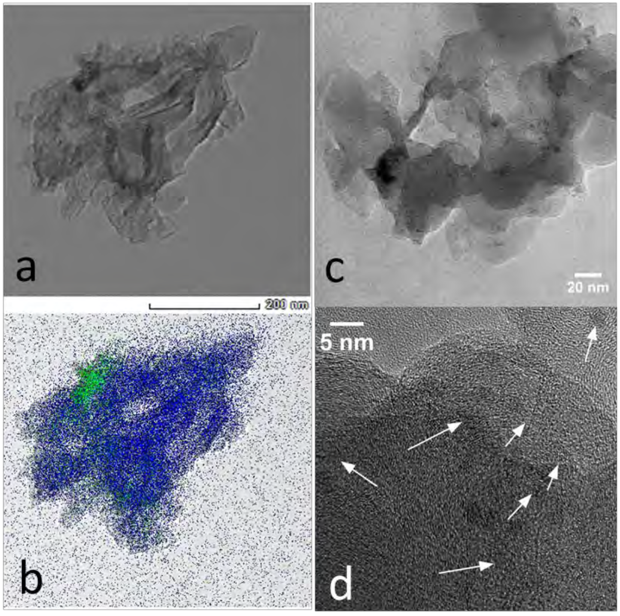

Fig. 1. (a) Lower magnification HR-TEM image of an aggregate of the CuOx(NP)/nC composite; (b) the corresponding EDX map; (c, d) Respectively lower and higher magnification HR-TEM image of the Cu(nP)/nC.

Powders were first suspended in an appropriate solvent, then dropcasted onto a glassy carbon disc and electrochemically reduced to metallic copper in situ before performing electrolysis.

Preliminary results showed that electrochemical reduction of CO_2 in a carbonate buffer at CuO_x(NP)/nC electrodes gave a formate yield close to 50%; higher than what reported for polycrystalline copper [3], to confirm the efficiency of nanostructures. The graphene intercalated copper oxide nanoparticles compared to surface anchored nanoparticles exhibit a very small activity but a better current stability for prolonged electrolysis (20 h). Using oxidation/reduction charge of copper oxides, obtained from cyclic voltammetries, we verified that we had negligible loss of material after prolonged polarization, even at potential where gas evolution on the electrode was massive.

This work aims at the preparation of Pt-coated Ti-based electrodes and their testing in the hydrogen evolution reaction (HER). Metallic Ti and black TiO_2 nanotubes (b-TNTs) were used as substrates. TNTs were annealed at 500°C in a vacuum quartz ampule, in the presence of CaH_2 powder to form anatase b-TNTs, which show high electronic conductivity [1]. Both substrates were pretreated before surface Pt loading; metallic Ti was etched in an acidic solution, whereas b-TNTs were subjected to electrochemical reduction-cathodization. Galvanic deposition [2,3] of Pt on both pretreated materials took place spontaneously in a $PtCl_6^{2-}$ ion solution; Pt(IV) complex ions were reduced-deposited as metallic particles on the pretreated Ti metal and b-TNT surfaces, while the freshly reduced substrate (etched Ti or cathodized b-TNTs) was partially re-oxidized. XRD measurements of the b-TNTs confirmed the preferred [001] orientation, which is highly desirable for improved electronic conductivity of the oxide. Top and cross sectional SEM/EDS observations show the distribution of the precious metal particles on the surface of both the metallic Ti and the b-TNTs. In both cases, cyclic voltamograms revealed Pt surface electrochemistry (*Figure 1a*), proving that the galvanic deposition method can also be applied to a partially reduced conductive oxide. Finally, HER in acid was studied by means of near steady state linear sweep voltammetry with a potential sweep rate of 5 mVs^{-1} (*Figure 1b*). Results at Pt/b-TNTs electrodes were compared to those of Pt/Ti electrodes and proved the latter to be more efficient HER cathodes.

Winery wastewater (WW) contains various organic and inorganic contaminants and its environmental impact is notable, mainly due to the large volumes produced and its seasonal variability **[1]**. The biological process requires large spaces and produces high quantities of sludge. In this context, electrochemical technologies represent a potential way to reach efficient elimination of organics from industrial wastewater. Anodic oxidation (AO) stands out among these processes. In this process, organic pollutants are completely mineralized to CO_2, water and inorganic salts by means of physisorbed hydroxyl radicals ($^{\bullet}OH$) **[2]**. The objective of this work was to compare the effect of three electrodes on the AO of the WW from a Chilean industry without the addition of salts (supporting electrolyte), at room temperature 25.0 ± 1.0ºC and at the original pH value (pH = 4). The electrolysis was carried out in an undivided 0.10 L open cell with always vigorously stirred to ensure the mass transfer. A Boron Doped Diamond (BDD) electrode, and dimensionally active anodes, one of chlorine and the other oxygen (DSA-Cl_2 and DSA-O_2) were used as anode. A stainless-steel cathode was used for each electrolysis. All the experiments were performed applying a current density of 30 mA/cm^2. The degradation of the organic compounds present in the wastewater was followed by spectrophotometric techniques and the mineralization was studied by removal total organic carbon (TOC).

Table 1. Parameters of WW treated by industrial biologic digestion and anodic oxidation

Parameters	Final industry effluent	AO (BDD)	AO (DSA Cl_2)	AO (DSA O_2)
Color	Uncolored	Uncolored	Uncolored	Uncolored
Total organic carbon (mg/L)	605 ± 41	225 ± 35	1610 ± 68	1300 ± 30
pH	7.30 ± 0.11	8.15 ± 0.10	4.22 ± 0.12	4.58 ± 0.20
Turbidity (NTU)	22 ± 0.20	12.80 ± 0.23	4.85 ± 0.20	6.73 ± 0.30
Abs. at 280 nm (U.A)	0.10 ± 0.08	0.37 ± 0.01	0.25 ± 0.13	0.25 ± 0.01
Conductivity (mS)	2.10 ± 0.30	2.73 ± 0.21	2.42 ± 0.32	2.82 ± 0.15
Mineralization energy (kW h/m^3)	-	279 ± 7.64	75 ± 0.01	134 ± 0.95
Mineralization cost by liter of solution ($USD)	-	48.90 ± 1.34	13.13 ± 0.01	23.51 ± 0.17

Table 1 shows that when working with the BDD electrode, the greatest degradation is achieved (86%). In addition, it is possible to achieve a degradation approximately 2.7 times greater than when the aerobic treatment is applied. However, it presents the highest mineralization energy. On the other hand, it is observed that the decolorization of the solution is dependent on the anode material used. In this context, absorbance decay reaches about 77% with DSA Cl_2 and DSA O_2 electrodes and 65% with BDD. However, in all cases an uncolored solution was obtained, these results are in concordance with the turbidity decay. This work demonstrated that AO can be successfully applied without the addition of supporting electrolyte, without adjusting the pH and at room temperature to remove the organic matter from wastewater produced by the wine industry.

Since the consumption of fossil fuels increases as well as the deforestation, the level of CO_2 in the atmosphere is growing. Furthermore, it is well known that CO_2 is causing the expand of global warming effect and ocean acidification. Therefore, many efforts are undertaken to recycle carbon dioxide into carbon-containing fuels that can help solve both above-mentioned problems. The electrochemical reduction of CO_2 supported by solar radiation, seems to be an promising solution [1, 2]. Among others, such metals like gold, silver, copper or platinum were studied to obtain methane or methanol out of CO_2. Nevertheless, the combination of two metals can be an interesting alternative, especially when it comes to gold and copper. On one hand, Au is one of the most efficient catalyst for CO_2 reduction [3]; on the other one, Cu is selective towards production of hydrocarbons at relatively low overpotential [4]. Following that, in this work we present the unique approach resulting in the formation of stable bimetallic structure, namely Au-Cu nanomosaic.

Fabrication of nanomosaic onto structured titanium foil is based on the sequential procedure including: anodization, chemical etching of as-formed nanotubes, magnetron sputtering of thin metal layers and finally rapid thermal treatment. SEM inspection performed after chemical etching reveals the creation of regularly distributed dimples in Ti substrate that can act as host wells for guest metal species. As also confirmed by SEM analysis, Au-Cu nanoparticles or coatings are formed depending on the temperature of thermal annealing. UV-Vis absorption measurements show over 400 nm shift of the band maximum towards red as well as its broadening for bimetallic materials in comparison to the monometallic ones. The chemical nature of prepared electrodes were checked by XPS and the presence of diverse Cu species (Au-Cu alloy, CuO, $Cu(OH)_2$) was noticed. Moreover, the electrochemical activity of samples was characterized in dark and under electrode illumination in 0.1M $NaHCO_3$ saturated with Ar and CO_2. Obtained results strongly suggest that proposed in here material can be used for CO_2 photoreduction and since applied techniques are already available in industry, the facile scaling up of the whole fabrication process is reasonable.

Electrocatalysis plays an important role in the future transition to sustainable energy. The state-of-the-art electrolyzer catalysts for oxygen evolution reaction (OER) are based on iridium and its oxides, since they exhibit the optimal ratio between activity and stability. Because of the scarcity of this critical metal, a lot of efforts are invested in the development of new electrocatalysts materials, which would either be intrinsically more active with at least the same stability as Ir or would have improved utilization of Ir. Achieving the latter is directly related to the development of sufficiently stable and conductive supports. To increase the utilization, Ir has been supported on oxides, such as antimony tin oxide (ATO), indium tin oxide (ITO) and titanium oxynitride (TiON$_x$).[1]

Here we present a new Ir-based high-performance electrocatalytic nanocomposite for OER, consisting of Ir nanoparticles with an average size of 3–4 nm, effectively anchored on a titanium oxynitride support (TiON$_x$), which is distributed across a high-surface-area Ketjen Black carbon (Ir/TiON$_x$/C). We note that direct physical contact between iridium and carbon has been omitted in order to avoid carbon corrosion. Additionally, new variations of the material have been developed, where prior to the addition of Ir, various amounts of Cu were added to the support (Ir/Cu-TiON$_x$/C).

One of the unresolved questions in the OER community is how to adequately and reliably measure the activity of the new catalysts and compare them with the literature data. This is obviously due to the lack of unified benchmarking protocol. To study the effects of different parameters on the activity measurement, an investigation was made on a benchmark catalyst Ir black (Alfa Aesar). The impact of parameters, such as loading, activation protocol, backing electrode and catalyst ink composition was systematically evaluated.

Our findings present guidelines on how to measure intrinsic OER mass activity. By appropriate benchmarking of OER activity via reproducible measurements and with meaningful normalization, we can now accurately compare Ir black to our new Ir/TiON$_x$/C electrocatalytic composite and justly proclaim its superior activity.
The new Cu-doped Ir/Cu-TiON$_x$/C materials exhibited even higher activities. The effect of the amount of the added non-noble metal was studied. It was shown that the increasing amounts of Cu enhances the activity of the catalyst, however, exhibits some stability issues.

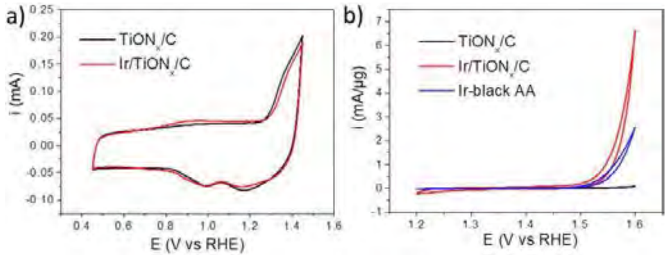

Figure 1: (a) Activation of TiON$_x$/C and Ir/TiON$_x$/C on Au electrode; (b) Activity for OER. Activation protocol: 0.45–1.45 V versus RHE, ink: 5 mlMQ + 3 ml Isop.[1]

Nowadays diabetes is one of the most dangerous civilization diseases. Above 400 million people are sick and additionally, that value is still growing [1]. The reason for this is an increased insulin level in the human body caused by a high carbohydrate diet in particular. Therefore, there is a need for sensors that can monitor the level of glucose especially in body fluids other than blood.

This work is intended to show the preparation method of the enzymatic biosensor as well as the characterization of its electrochemical properties. The electrode material was prepared starting from the anodization process of Ti foil. As a result, the TiO_2 nanotubes were created (Fig.1a). Then after the chemical etching, the Ti nanodimples(TiND) hidden underneath NTs were exposed (Fig.1b). Finally, the nanodimples were covered by Au film by magnetron sputtering (Fig.1c) and thermally treated in furnace (Fig.1d) and AuNPs-TiND was received.

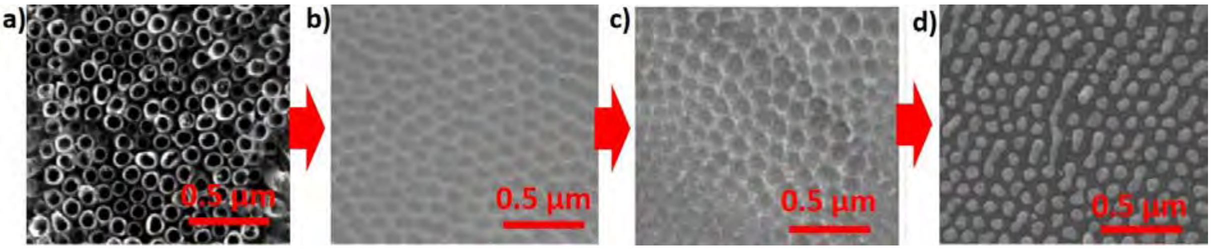

Fig. 1 The SEM images show all stages of material preparation: a) TiO_2 nanotubes, b) Ti nanodimples, c) Ti nanodimples covered by thin Au film, d) Ti nanodimples covered by Au nanoparticles.

Afterwards, the AuNPs-TiND material was modified by the enzyme [2]. The modification mixture consisted of three components: glucose oxidase (GOx), glutaraldehyde (GA) and bovine serum albumin (BSA). The chemical nature of functionalized material was characterized using X-ray photoelectron spectroscopy (XPS). Additionally, the complete coverage of the enzyme layer onto AuNPs-TiND was confirmed. The obtained electrodes were tested in 0.1 M PBS with an addition of glucose using cyclic voltammetry (CV). Basing on the series of CV measurements, the sensitivity of 25.74 $\mu A/cm^2 mM$, the linear range of 0.051-3.05 mM and the limit of detection equal to 7.61 µM were determined. These parameters ensures the successful glucose detection in human body fluids and therefore fabricated material can potentially find its application in developing fully operating sensor.

This work was financed by National Center for Research and Development under grant no LIDER/2/0003/L-8/16/NCBR/2017.

$LiMn_2O_4$ – a model catalyst for the oxygen evolution reaction: the origin of the total current and the impact of oxidation on the OER in aqueous solution

Max Baumung,[1] Florian Schönewald,[1] Cynthia A. Volkert[1], Marcel Risch [1,2]
1) Institute of Materials Physics, University of Goettingen, Friedrich-Hund-Platz 1, 37077 Göttingen, Germany
2) Nachwuchsgruppe Gestaltung des Sauerstoffentwicklungsmechanismus, Helmholtz-Zentrum Berlin, Hahn-Meitner-Platz 1,14109 Berlin, Germany

max.baumung@uni-goettingen.de

Controlling the oxygen evolution reaction (OER) is a crucial step for the long-time storage of electricity from renewables in chemical energy carriers.[1] Using $LiMn_2O_4$ as a model catalyst for this multi-electron transfer reaction, we aim to unravel the influence of bulk manganese valence state on the performance of catalytic water oxidation.

Using nano-size $LiMn_2O_4$ particles in a rotating ring-disk electrode (RRDE) setup, we identified the detection potentials of oxygen and manganese in separate calibration experiments to evaluate the catalytic performance and activation of our catalyst in a sodium hydroxide electrolyte (pH 13). Our analysis confirmed that total current per electrochemical surface area (ECSA) is the sum of the oxygen evolution and manganese loss at the investigated reference voltage. Additionally, we calculated an average Faradic efficiency of 75% after the electrode reached steady state after five cycles. The initial decay of disk current was assigned to manganese loss, while fairly constant oxygen evolution is detected at the ring (Fig. 1).[2]

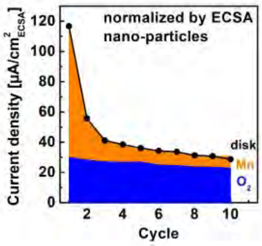

Figure 1. Calculated assignment of the currents due to Mn loss (orange) and catalysis (blue) to the measured disk current in NaOH for nano sized particles.[2]

The $LiMn_2O_4$ behaved differently in LiOH[3] electrolytes than in NaOH.[2,4] Definite redox peaks in the LiOH electrolytes with a concentration below pH 14 indicate manganese oxidation during rotating ring-disk electrode (RRDE) experiments that is more distinct at lower pH and Li^+ concentration. This pH-dependent oxidation of the active material was confirmed by X-ray absorption spectroscopy (XAS) of post mortem electrodes and has a disastrous effect on the onset of the OER causing an increase of the overpotential in less concentrated LiOH electrolytes and an unexpected non-zero Nernst slope (dE/dpH) of -40(4) mV/pH.[3] A E^{RHE}-pH diagram based on a thermodynamic model of $Li_xMn_2O_4$ lithiation and delithiation (Fig. 2) agrees with the experimental data and gives the same Nernst slope of delithiation of 116(25) mV/pH.[3] Thus, we believe that the observed oxidation is due to delithiation of the catalyst in aqueous solution. Our conclusions and the graphical representation of stability against redox changes may be useful for other battery materials that are increasingly used as electrocatalysts. It is crucial to get a better understanding of catalyst stability in different pH as it can change its catalytic properties.

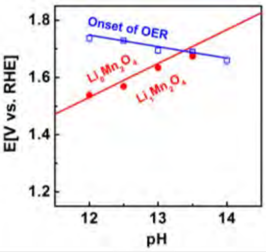

Figure 2. E^{RHE}-pH diagram of $LiMn_2O_4$ showing the boundary line of delithiation and the onset of the OER in LiOH.[3]

Electrocatalysis at the Liquid/Gas Interface: The Gas Accessible Membrane Electrode (GAME) for High-rate Reactions and In-Situ/Operando Characterisation

Guohui Zhang, Anthony Kucernak
Department of Chemistry, Imperial College London
South Kensington, London SW7 2AZ, United Kingdom
g.zhang@imperial.ac.uk

Electrocatalysis plays a significant role in energy storage devices, such as fuel cells and water electrolyzers. However, the study of gas-involving electrocatalytic processes is currently associated with several issues, including slow mass transport of gases to the reaction interface and lack of analytical tools that facilitate the online and immediate analysis of the product distribution. Although some methods have been developed to alleviate these barriers, such as the rotating disc and rotating ring-disk electrodes (RDE and RRDE) and thin-layer flow cells,[1-2] the mass transport is still intrinsically limited by the low solubility of gases and they are also not suitable for real time and in situ characterisation of complex (gaseous) products. These limitations have adversely hindered the assessment of reaction kinetics on electrocatalysts, and the appropriate understanding of reaction mechanisms and dynamics.

In this regard, we demonstrate the use of the gas accessible membrane electrode (GAME) as a versatile tool for electrocatalysis research. The GAME system takes the benefits of the previous floating electrode technique,[3] allowing low-loading (μg cm^{-2} scale) catalysts to be deposited. By employing an efficient gas-circulating loop, the GAME enables the gaseous reactants to be directly utilised from the gas phase, leading to higher current densities (~ hundreds of mA cm^{-2}) than conventional configurations. Moreover, the GAME can be merged with other techniques, such as mass spectroscopy and Fourier-transform infrared spectroscopy (FTIR), evolving into a series of correlative platforms for evaluating the products that are simultaneously collected from the reaction interface. As shown in Figure 1, these correlative platforms have a myriad of applications, and in situ/operando characterisation of reaction products can be carried out with high temporal resolution, providing mechanistic information about reactions involving multiple pathways (i.e. CO_2 reduction).[4] This work contributes to high-throughput screening of electrocatalysts and further offers promising strategies for the rational design of electrode structures and reactors for practical implementation.

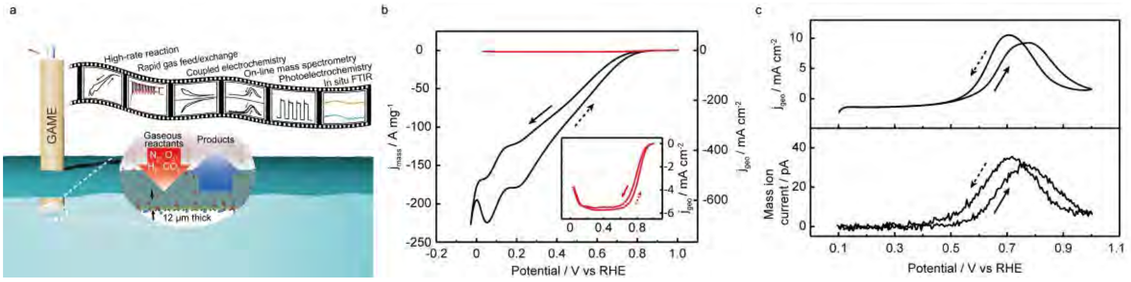

Figure 1. (a) Schematic of the GAME and possible applications. (b) Comparison of cyclic voltammograms for oxygen reduction reaction obtained from the GAME (black) and RDE (red). (c) Representative cyclic voltammogram and mass spectrometric cyclic voltammogram of CO_2 (m/z=44) for methanol oxidation.

Crosslinked Polymer Electrolytes Encompassing Protic Ionic Liquids: A New Class of Solid Electrolytes for Energy Storage Devices

Timo Stettner[1], Gabriele Lingua[2], Marisa Falco[2], Claudio Gerbaldi[2], Andrea Balducci[1]
[1] *Friedrich Schiller University, Jena, Germany*
[2] *Politecnico di Torino, Turin, Italy*
timo.stettner@uni-jena.de

In the last years, the use of polymer-based electrolytes in electrochemical energy storage devices has been intensively investigated due their favorable properties in terms of electrochemical/chemical stability and safety (leakage free).[1] Although most of these studies have been dedicated to the use of polymer electrolytes in batteries, they have also been used in electrochemical double layer capacitors (EDLCs), as well as with fuel cells.[2]

Polymer electrolytes encompassing room temperature ionic liquids (RTILs) show interesting features in terms of enhanced ionic conductivity, wide electrochemical stability and successful utilization in high-performance lithium-ion batteries (LIBs) and EDLCs.[3] The large majority of these studies have been conducted employing aprotic ionic liquids (AILs), which are the most commonly used RTILs for energy storage applications. Protic ionic liquids (PILs), on the other hand, have only been used in fuel cells, so far.[4]

In this work, we present for the first time a protic ionic liquid-based polymer matrix, based on n-butyl pyrrolidinium bis(trifluromethylsulfonyl)imide ($PYR_{H4}TFSI$) and soft crosslinked polyethylene oxide (PEO) that shows remarkable cycling stability as electrolyte and separator in lab-scale EDLCs as well as Li-metal cells. The innovative polymer electrolytes are produced by UV-induced polymerization, which is easily scalable, rapid, highly efficient and green.[5] Crosslinking allows the incorporation of high amount of RTIL and lithium salt, leading to polymer electrolytes with remarkable homogeneity and robustness. The thermal and transport properties, as well as the reactivity with elemental lithium of this innovative electrolyte have been investigated. Furthermore, its use in combination with activated carbons (AC) in addition to lithium iron phosphate (LFP) and lithium nickel manganese cobalt (NMC) cathodes has been studied and successfully demonstrated for the first time. The results of these studies indicate that protic ionic liquid-based polymer electrolytes can be considered as a novel and very interesting class of electrolytes for the development of safe and high performance EDLCs and even Li-metal based batteries.

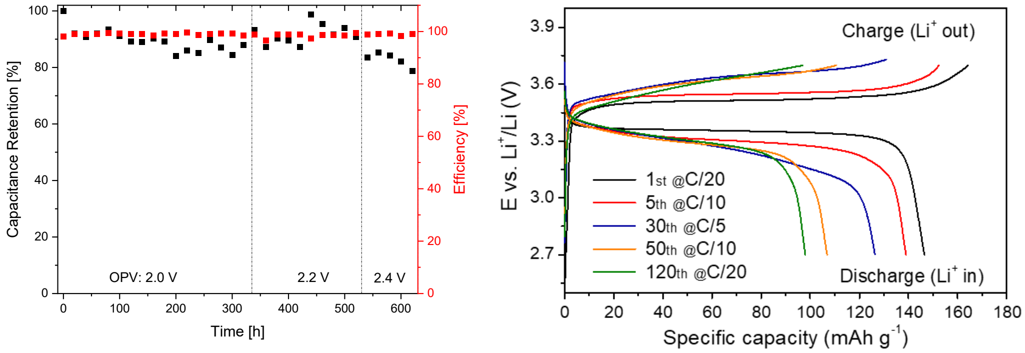

Figure 1 Stability investigations via float tests of an EDLC using the PIL based polymer electrolyte (left) as well as proof-of-concept rate tests via galvanostatic charge discharge measurements of a LFP based lithium metal polymer cell (right).

Three dimensional (3D) cultured cells such as spheroids are gaining much interest in drug screening and regenerative medicine as they express relevant characteristics to *in vivo* in comparison with two-dimensional (2D) cultured cells. However, engineering of thick 3D cell constructs is a challenging issue, because cells inside a large engineered construct lack sufficient supply of nutrients and oxygen, resulting in poor cellular viability. Incorporation of vascular structures in 3D cell constructs is one of the strategies to overcome this problem, expecting the endothelial cell (EC) networks to enhance mass transportation.
To support the elaboration of engineering tissue models, evaluation system for 3D cell constructs needs to be developed. Since electrochemical measurements provide label-free in situ analysis, we have been developing various electrochemical devices including probe electrodes and on-chip devices and adapted for evaluation of 3D cell constructs [1].

In this study, we fabricated fibroblast spheroids containing EC networks for the preliminary step of vascularized tissue models. With the incorporation of EC networks, the cellular activity as well as the capacity of drug penetration may differ. As oxygen consumption is one of the fundamental cellular functions of cells, we performed electrochemical measurement of respiratory activity for the spheroids with both non-treated and drug-treated conditions [2] (Fig. 1).

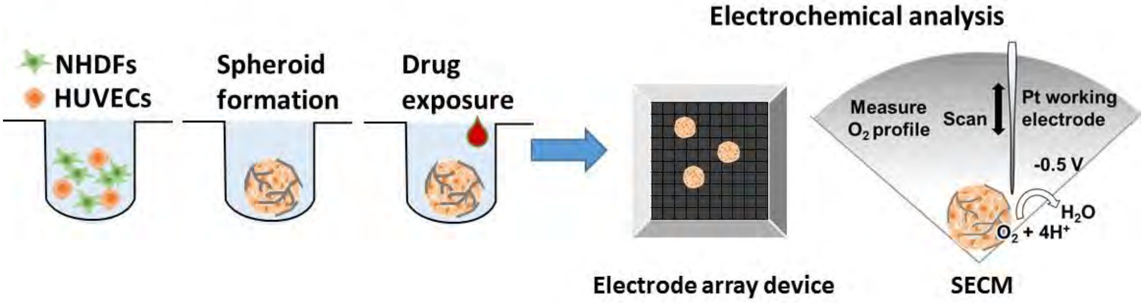

Fig. 1 Schematic illustration of electrochemical measurement of spheroids containing EC networks

For spheroid fabrication, human umbilical vein endothelial cells (HUVECs) and normal human dermal fibroblasts (NHDFs) were co-cultured at different seeding ratios (HUVEC concentrations of 0, 10, and 30%) in a hanging drop-based microwell plate. To investigate the drug sensitivity of the spheroids, doxorubicin (DOX) was added during the culture. The electrochemical measurement of respiratory activity was performed with scanning electrochemical microscopy (SECM) and an electrode array device.

During culture, HUVECs were partially connected to each other and formed networked structures. After DOX treatment, the respiratory activity of the spheroids with 10% HUVEC ratio was relatively small compared to those of 0% HUVEC, whereas, there was little difference between those in diameter. The incorporation of HUVEC networks in the spheroids promoted the penetration of DOX, resulting in lower respiratory activity in the spheroids with higher HUVEC ratio. Overall, respiratory activity may be a sensitive indicator for drug capacity of spheroids containing EC networks.

Scanning Gel Electrochemical Microscopy (SGECM): Local Electrochemistry with Flexible Spatial Resolution

Ning Dang, Mathieu Etienne, Alain Walcarius, Liang Liu
Université de Lorraine, CNRS, Laboratoire de Chimie Physique et Microbiologie pour les Matériaux et l’Environnement (LCPME), F-54000 Nancy, France
ning.dang@univ-lorraine.fr

Scanning gel electrochemical microscopy (SGECM) is a new scanning electrochemical probe technique that measures spatially localized electrochemistry based on gel probes in contact with the sample surface. So far, the gel probes are fabricated by electrodeposition of chitosan on micro-disk electrodes or etched metal wires and approached to the sample by current or shear force feedback. Proof-of-concept works have been published for topography, amperometric and potentiometric mapping [1, 2].

Like in any other scanning probe technique, spatial resolution is a key characteristic of SGECM, which determines the applications and the market. Especially considering the soft nature of gel, the contact area between the gel and the sample surface is tunable by pressing or stretching the gel. This offers an important feature of SGECM, that is, flexible resolution with the same probe, which is quantitatively analyzed from two aspects in this work: (1) marking single sampling points by locally oxidizing Ag to AgCl and measuring their size **(Figures 1 and 2)**; (2) line scan over reference samples with periodic topography and composition **(Figures 3 and 4)**. It is revealed that for an optimal gel probe based on 25 µm diameter Pt disk electrode of $R_g \approx 2$, the lateral physical resolution of SGECM at contact position is *ca.* 50 µm for current feedback and *ca.* 63 µm for shear force feedback. More importantly, it can be flexibly tuned in the range of 14 to 78 µm by pulling or pressing the gel probe after touching the sample. Current feedback is more sensitive to gel-sample contact than shear force feedback, but the latter is more versatile which is also applicable to non-conductive samples.

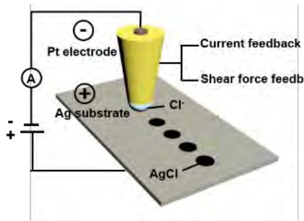

Fig.1 Scheme of SGECM patterning.

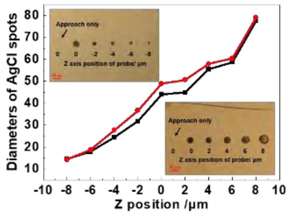

Fig.2 AgCl depositions on Ag substrate.

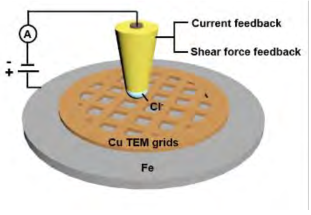

Fig.3 Scheme of SGECM line scan.

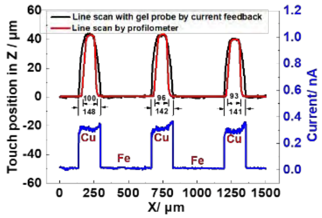

Fig.4 Line scan of profile and steady state current.

**e-mail: benyoav@bgu.ac.il*

Schizophrenia (SCZ) is a chronic mental disorder that affects 23 million people worldwide [1]. Clozapine (CLZ) is the most effective antipsychotic medication for treatment-resistant SCZ patients. Despite the superior efficacy of CLZ, it is dramatically underutilized due to the unavailable objective tests to measure CLZ efficacy [2]. Several redox biomarkers in the blood have been correlated to CLZ efficacy. Yet, existing analytical methods change the molecules levels, their redox state, and eventually destroy the sample. By bridging the analytical gap and profiling the redox biomarkers, rapid and accurate CLZ treatment efficacy monitoring can be provided. Our overall goal is to develop a novel intelligent electrochemical biosensor based on an array of microelectrodes for CLZ treatment efficacy analysis. Here, we present the fabrication of the microelectrodes array, modification of the array with diffusion-limiting films, and characterization of the film's effect on the generated electrochemical activity. The novelty of the biosensor lies within an array of microelectrodes modified with the positively charged biopolymer chitosan generating a set of complex electrochemical signals that are analyzed by using intelligent chemometric models. To achieve our goal, we microfabricated an array of 24 gold microelectrodes (100-µm-diameter working and 1,500-µm-diameter counter electrodes) by using photolithography and thin film deposition techniques (Fig. 1A). We used a 1.2% chitosan solution and applied cathodic current to electrodeposit thin films of chitosan onto the microelectrodes. To fabricate chitosan films with similar thicknesses and different densities, we measured the relationship between the thickness of the electrodeposited film and the applied electrodeposition current for 90s and 180s durations (Fig 1B). A similar wet chitosan thickness (57.6±0.8 µm) was successfully achieved with 510 nA for 90s and 950 nA for 180s durations. Moreover, different dry chitosan thicknesses were obtained for 90s (10.7±0.1 µm) and 180s (13.2±0.6 µm) durations. Therefore, we calculated the porosity of the electrodeposited films as the ratio between the thicknesses of the wet and the dry films (5.38±0.09 and 4.36±0.20 at 510 nA for 90s and 950 nA for 180s, respectively). Furthermore, we used cyclic voltammetry to characterize the permeability of the modified films by measuring the ratio of the electrochemical signals generated from differently charged redox molecules (negatively charged ferrocyanide, neutral ferrocene, and positively charged hexaammineruthenium) before and after the modification (Table 1). Statistical T-test analysis of the resulted permeabilities revealed significant differences for the charged molecules (P=0.85% for ferrocyanide; P=4.57% for hexaammineruthenium), while no significant difference was observed for the neutral molecule ferrocene. By providing a new way to analyze molecular profiles in blood, we anticipate establishing a new detection scheme for CLZ treatment efficacy that will help to transform schizophrenia management.

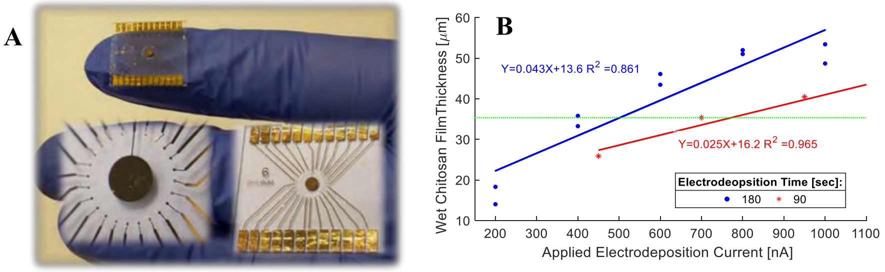

***Figure 1**: **(A)** Optical photos of the fabricated microelectrodes array. **(B)** The relationship between the wet chitosan thickness and the applied electrodeposition current for 90s (red stars) and 180s (blue circles) durations. The resulted calibration curves enabled calculating the conditions required to achieve chitosan films with similar thicknesses and different porosities (horizontal green line).*

Based on the equimolar High Entropy Alloy (HEA) composition CrFeNiCoMn [1-3], multi-component thin films about 500nm in thickness were deposited by means of dc magnetron sputtering on a Si substrate. Different amounts of carbon corresponding to 0 to 10 at. % were added to the films, which simultaneously increased the film ductility and hardness as well as changed the structure of the material [4]. The films were studied regarding their electrochemical corrosion properties in acidic environments such as 0.05 M H_2SO_4 and 0.05 M HCl aqueous solutions and the results were compared with those obtained for a CrFeNiCoMn bulk sample. The results indicate improved corrosion properties of the thin films due to their more homogeneous elemental distribution. The role of the carbon in terms of corrosion was studied using SEM/EDS, XRD, XPS/HAXPES, ICP-MS and electrochemical experiments, such as cyclic voltammetry, polarization curves and impedance spectroscopy (EIS). A beneficial influence of carbon was observed below 0.8 V vs. Ag/AgCl in H_2SO_4 and at potentials above 0.8 V vs. Ag/AgCl in HCl. The latter indicates a decreased pitting corrosion tendency in the presence of carbon.

The study of the interactions between per- and polyfluroalkyl substances (PFAS), a class of ubiquitous global contaminants, and serum proteins can improve the design of protein-based electrochemical biosensors for the on-site monitoring of these perfluorinated compounds in natural and industrial waters [1]. In the last decade, the affinity of PFAS for serum proteins (particularly albumins and globins) was subjected to extensive toxicological studies to explain their accumulation patterns, elimination rates and toxicity [2]. To transpose these findings in the design of bioreceptors, human serum albumin (hSA) was first considered. Untreated and delipidated hSA performances towards perfluorooctanoic acid (PFOA) binding were characterized with a multi-analytical approach. Isothermal titration calorimetry measurements allowed to define the stoichiometry and the affinity constants of the complexes showing a higher reproducibility of the binding event with the delipidated hSA. The stability of this latter was confirmed also by collision induced unfolding analysis performed by native nano-electrospray ionization mass spectrometry. Moreover, the molecular basis of PFOA interactions were clarified by the X-rays crystallography. Delipidated hSA was confirmed to be a more suitable bioreceptor than untreated hSA and so further applied in a proof-of-concept study for the development of an impedimetric biosensor. Aiming to design a portable device, the bioreceptor was immobilized at graphite screen-printed electrodes previously modified with pyrrole-2-carboxylic acid (Fig.1). This step was instrumental to obtain carboxylic acid groups on the surface to immobilize the protein via EDC/NHS coupling and to improve the conductivity of the working electrode. The impedimetric data interpretation was supported by the small-angle X-ray scattering analysis of the bioreceptor-target complex. A parallel investigation of PFAS impact on globins activity was performed following the changes in the heme electroactivity in presence of perfluorooctane sulfonic acid (PFOS) and PFOA. The results suggested the potential of serum protein-PFAS interactions monitoring for sensing, toxicological as well as precision medicine applications.

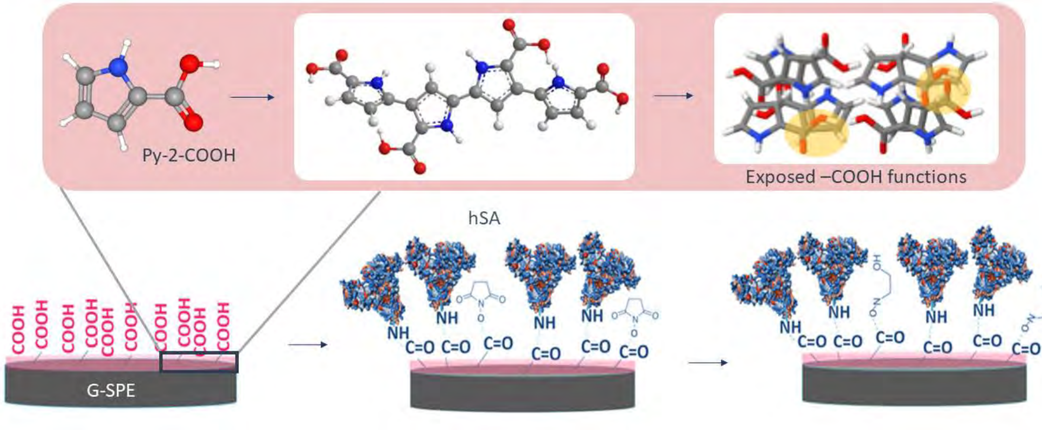

Fig. 1. Schematic illustration of the procedure optimized for human serum albumin immobilization at graphite screen-printed electrodes for the impedimetric biosensing of perfluorooctanoic acid.

Efficient electricity storage in chemical bonds is of vital importance for the replacement of fossil fuels with renewable energy sources. Hydrogen is a particularly suitable energy-rich molecule capable of renewable energy storage. Electrolytic hydrogen production is, however, limited by the sluggish kinetics of the electrocatalytic oxygen evolution reaction (OER) which is difficult to optimize. The state of the art OER catalysts are based on oxides of Ru and Ir the feasibility of which is compromised by the catalysts cost or stability. Hence, there is a great motivation to develop novel catalysts based on these elements which show increased stability with simultaneous reduction in the noble metal content.

This paper reports on synthesis and behavior of novel pyrochlore ($A_2B_2O_7$) catalysts simultaneously containing iridium and ruthenium in the B-site. Mixed Ru/Ir pyrochlores with a fraction of Ru in the B-site of x_{Ru} =0.2, 0.4, 0.6, 0.8 were synthesized by the spray-freeze freeze-dry approach The pyrochlores if stabilized with trivalent lanthanide in A site are single phase materials showing promising activity in oxygen evolution reaction (OER) in acid media. Increased catalytic activity of the pyrochlore based catalysts is achieved by the coexistence of Ir and Ru in the B-site of the pyrochlore structure. The observed activity is not, apparently, dependent on the size of the lanthanide (Yb, Gd, or Nd) cation in the A site and in this manner on the lattice constant of the prepared materials (see Fig. 1). All prepared mixed pyrochlore catalysts are surpassing the OER activity of the corresponding iridium and ruthenium analogs featuring no cation mixing as well as that of the benchmark IrO_2 catalyst. The synergy of Ir and Ru in the B-site of the pyrochlore structure suppresses the effect of the A-site cation radius on the OER activity. The observed OER activity scales with the Ir-Ru bond distance which represents the local structure of the prepared materials. The most active ytterbium containing catalysts also show significant stability improvement under OER operando conditions over the benchmark IrO_2.

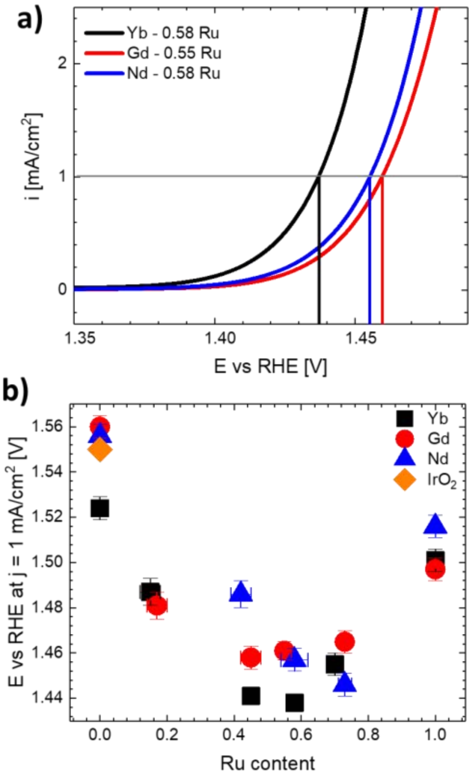

Figure 1 Typical linear sweep voltammograms of pyrochlore based catalyst samples of Ru/Ir mixed composition, measured in acidic media (0.1 M $HClO_4$, v = 10 mV/s) and b) potential in V vs RHE at a current density of 1 mA/cm² (in 0.1 M $HClO_4$) plotted versus the catalysts' ruthenium contents as determined by EDX, including the data for the pure lanthanide ruthenates and iridates.

Ageing induced exfoliation of $LaNiO_3$ perovskite OER catalysts using gelatin as a structure-directing agent

Rebecca Pittkowski,[1] Spyridon Divanis,[2] Mariana Klementova,[3] Jan Rossmeisl,[2] Petr Krtil[1]
[1]J. Heyrovsky Institute of Physical Chemistry, Dolejškova 3, 18223 Prague, Czech Republic

[3]Institute of Physics, Czech Academy of Sciences, Na Slovance 2, 182 21 Prague, Czech Republic
Rebecca.pittkowski@jh-inst.cas.cz

Electrochemical production of hydrogen is a key process to chemically store the energy of intermittent renewable sources. The bottle-neck of this process is the oxygen evolution reaction at the anode, a four-electron transfer process of sluggish kinetics. Optimization of the anodic oxygen evolution is thus necessary to make this process economically feasible.[1,2] Perovskites based on first-row transition metals have been studied as cheap catalysts of abundant elements with high catalytic activity in alkaline media.[3,4]

This report outlines $LaNiO_3$ perovskites as OER catalysts that were obtained *via* spray-freeze freeze-dry synthesis with gelatin as a structure-directing agent. Using a range of different concentrations of gelatin (0.3-7.5 g/L), $LaNiO_3$ perovskite powders were successfully synthesized. Nano-particles of 30-40 nm size were obtained after calcination at 700°C in air. The morphology of the obtained nanoparticles was analyzed with both SEM and HR-TEM and shows a tendency to form distorted cubic particles as a function of the gelatin concentration used in the synthesis. The HR-TEM reveals also a large number of planar defects in the crystal growth in gelatin containing samples (Figure 1a). X-ray absorption spectra were measured for all obtained samples. The EXAFS analysis unveils Ni-rich inclusions in the structure as a result of the gelatin-based synthesis (Figure 1b).

The electrochemical activity in oxygen evolution initially shows no dependence on the gelatin concentration in the synthesis. After ageing of the electrochemical ink, a dramatic increase in OER activity is observed for the nanoparticles synthesized with gelatin concentrations of 1.5 g/L and higher (Figure 1c). This can be rationalized as an acid-induced exfoliation process along the defects of crystallographic mismatch. In return, a more active surface area is formed exposing the Ni-rich inclusions.

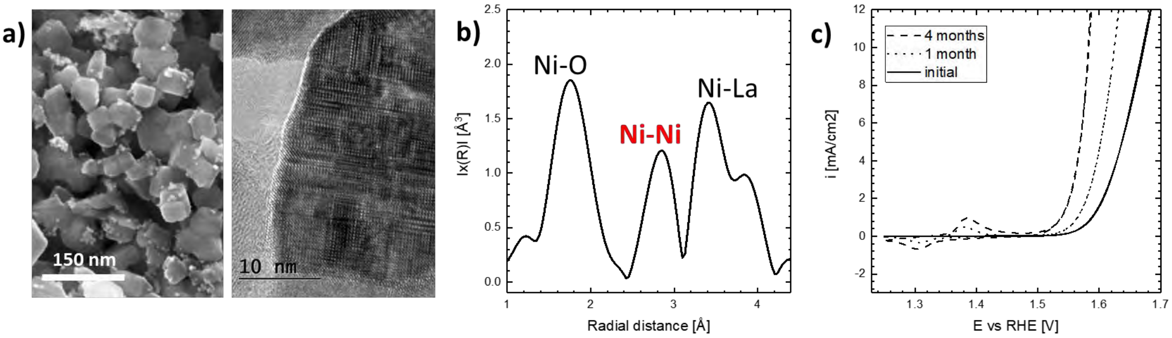

Figure 1a) SEM and HR-TEM micrographs **b)** Fourier transformed EXAFS functions measured at the Ni K-edge in R-space, weighed with k^2 **c)** cyclic voltammograms showing the OER activity of electrochemical inks initially and after ageing, all data are presented for the $LaNiO_3$ sample with 7.5 g/L gelatin concentration.

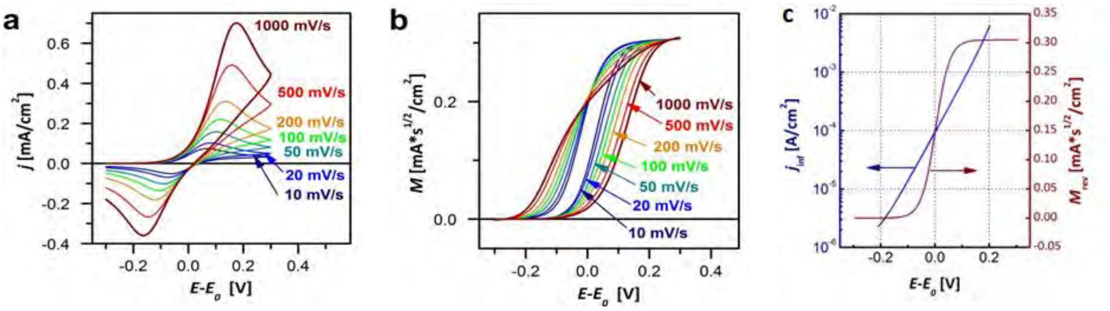
Analysis of quasi-reversible CVs and DEIS data: transformation to potential-program independent forms

Tamás Pajkossy
Institute of Materials and Environmental Chemistry, Research Centre for Natural Sciences,
Magyar tudósok körútja 2, Budapest, Hungary, H-1117
pajkossy.tamas@ttk.hu

Recently a numerical procedure has been suggested by which the $j(E)$ cyclic voltammograms, CVs, pertinent to partially diffusion controlled charge transfer reactions can be analyzed [1]. Using this procedure, from a set of "quasi-reversible" CVs taken at varied scan-rates v, two scan-rate independent, hysteresis-free functions can be calculated. One of them is the diffusion-free polarization curve, $j_{\mathrm{inf}}(E)$, the other is the semiintegrated form of the reversible CV, $M_{\mathrm{rev}}(E)$.

As this has been discussed in Ref. 2, the resulting $j(E) = j_{\mathrm{inf}}(E) - [j_{\mathrm{inf}}(E) / M_{\mathrm{rev}}(E)] \times M(E)$ equation is a general and exact solution to the problem of charge transfer coupled with semiinfinite diffusion. Various cases have been illustrated by numerical simulations; one is shown below.



Simulated CVs (a), their semiintegrals (b), and the calculated j_{inf} and M_{rev} functions (c). Simulation parameters: $D_{\mathrm{red}} = D_{\mathrm{ox}} = 10^{-5}$ cm²/s, $c_{\mathrm{red}} = 10^{-6}$ mol/cm³, $c_{\mathrm{ox}} = 0$ mol/cm³, $E_0 = 0$, $k_0 = 0.001$ cm/s, $\alpha = 0.5$.

Separating the contributions of charge transfer and diffusion to electrode kinetics can be done also by measuring and analyzing electrochemical impedance spectra (EIS). Parameters characterizing charge transfer and diffusion are R_{ct}, the charge transfer resistance and σ_{W}, the Warburg coefficient. These can be calculated from impedance spectra measured under *dc* conditions and also from spectra recorded during potential scans. This latter method, the combination of (sufficiently low scan-rate) CV and (sufficiently high frequency) EIS is called dynamic EIS (DEIS).

Both R_{ct} and σ_{W}, obtained from DEIS, depend on the scan-rate. However, the scan-rate dependence can be eliminated using the linear equations derived in [3]. As a result, we have the following set of equations connecting the measured j, M, R_{ct} and σ_{W}; the coupling parameter H $(= k_{\mathrm{ox}}/\sqrt{D_{\mathrm{red}}} + k_{\mathrm{red}}/\sqrt{D_{\mathrm{ox}}})$ is composed of rate and diffusion coefficients only. Note the simplicity and symmetry of the equations.

	charge transfer	coupling	diffusion
CV	$j = j_{\mathrm{inf}} - H \cdot M$	$H = j_{\mathrm{inf}}/M_{\mathrm{rev}}$	$M = M_{\mathrm{rev}} - 1/H \cdot j$
DEIS	$\frac{1}{R_{\mathrm{ct}}} = \frac{\mathrm{d}j_{\mathrm{inf}}}{\mathrm{d}E} - \frac{\mathrm{d}H}{\mathrm{d}E} \cdot M$	$H = \sigma_{\mathrm{W}}/R_{\mathrm{ct}}$	$\frac{1}{\sigma_{\mathrm{W}}} = \frac{\mathrm{d}M_{\mathrm{rev}}}{\mathrm{d}E} + \frac{1}{H^2}\frac{\mathrm{d}H}{\mathrm{d}E} \cdot j$

The theory opens a new route for the high-accuracy, fast determination of charge transfer rate coefficients of quasi-reversible redox systems by employing DEIS.

Effects of relative humidity at dry periods of wet and dry corrosion on hydrogen permeation behavior of steels

Masatoshi SAKAIRI[*], Xiaole HAN[**]
[*]*Faculty of Engineering, Hokkaido University*
[**]*Graduate School of Engineering, Hokakido University*
Kita-13, Nishi-8, Kita-ku, Sapporo, Hokkaido, Japan
msakairi@eng.hokudai.ac.jp

High strength steels are widely used in automobiles, trains and construction industry with the recent demands for increase in fuel efficiency and save natural resources [1-3]. It is, however, well known that increasing the strength of steels leads to increase susceptibility to hydrogen embrittlement. To reduce the susceptibility to hydrogen embrittlement of these steels is an important issue to ensure reliability in practical use of the steels. Therefore, the deleterious effects of hydrogen on high strength steels have attracted much attention recently[4-8].

Atmospheric corrosion plays an important role in the hydrogen generation for the practical use of steels and coated steels. Some studies have focused on the hydrogen generated by atmospheric corrosion inducing the hydrogen embrittlement of steels. There are reports that the permeation rate during a wet and dry corrosion cycle showed a maximum during the drying process[9], and temperature, relative humidity (RH) and amount of sea salt on the steel surface strongly affected hydrogen entry[10]. It is not fully elucidated relative humidity on the hydrogen permeation behavior during wet and dry cycle corrosion. The purpose of this study is to investigate the effects of different RH at dry period on hydrogen permeation behavior of steels during wet and dry corrosion cycles.

The steel sheets (20 mm × 15 mm × 1 mm) were used as specimens. Both sides of the specimen were mechanically polished with SiC papers up to 1200 grit under running water. One side of the sample used as hydrogen detection side was electroplated by Ni. Before the wet/dry corrosion cycles, sample was cleaned with purified water and ethanol. The hydrogen detection side was placed on the hydrogen detection cell with 1 kmol m^{-3} NaOH solution, and the cell was placed in a RH and temperature controlled chamber. The specimens were polarized at -30 mV vs Pt during the tests. After the current of the hydrogen detection cell reached lower than 40 nA cm^{-2}, 10 μL of 0.1 kmol m^{-3} NaCl solution was placed on the sample surface of hydrogen entry side. Wet (303K, 90 %RH) and dry (323 K) cycle corrosion tests were carried out in a chamber. The RH of dry period was controlled between 65 % and 20 %. Total 12 wet and dry cycles were carried out. The temperature dependent current was subtracted from the currents that were obtained during wet and dry corrosion tests. An optical microscope and SEM-EDS were used to observe the sample surface.

The amount of permeated hydrogen through the steel during the wet/dry corrosion tests decreased with the increase of the cycle number and the decrease of the RH at dry period. Fig. 1 shows hydrogen permeation current at 4th cycle. The hydrogen permeation current during dry period decreases with decreasing RH at drying period. A relatively larger permeation current was detected when the RH was controlled at 60 % and 65 %.

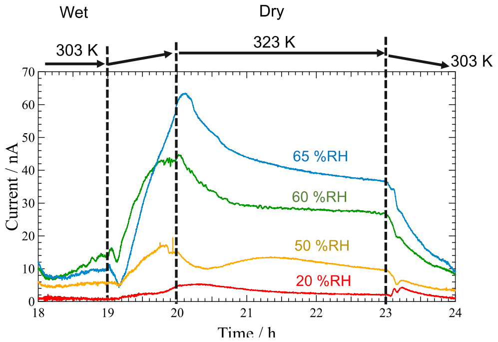

Fig. 1 Hydrogen permeation current at 4th cycle.

batyr.garlyyev@tum.de

One of the key factors limiting the widespread applications of fuel cell technologies is the cost of the electrocatalysts utilized in catalyzing the oxygen reduction reaction (ORR) at the cathode side. More specifically, only platinum based electrocatalysts have shown sufficient activity; however, due to the scarcity and cost of Pt, it is of a particular interest to increase their activity per mass. We tackle these challenge by optimizing the size,[1] shape[2] and composition[3,4] of Pt-based nanoparticles.

Results from Pt model catalyst surfaces have demonstrated that surface defects, in particular surface concavities, can improve the ORR kinetics. It is, however, a challenging task to synthesize nanostructured catalysts with such defective surfaces. Hence, we produced Pt/C catalyst with high density of surface concavities, which was confirmed by high-resolution transmission electron microscopy, 3D-tomography, high energy X-ray measurements and positron annihilation spectroscopy (**Figure 1**). The ORR activity of the developed catalyst exceeds that of commercial Pt/C catalyst, at least 2.7-times in terms of specific (~1.62 mA/cm^2 at 0.9V) and at least 1.7-times in terms of mass activity (~712 mA/mg$_{Pt}$), which can be correlated to the enhanced amount of surface defects.[2] In a separate study, we investigated the influence of the nanoparticle size on the ORR activity. ~1 nm sized Pt nanoparticles were produced by metal organic framework template approach. The produced electrocatalyst showed mass activity of 0.87 A/mg$_{Pt}$, which was in well agreement with computationally predicted values[1] (0.99 A/mg$_{Pt}$) (**Figure 2**). Furthermore, the alloyed Pt$_x$Pr nanoparticles were synthesized and their ORR activity was investigated.[3] The alloyed nanoparticles showed 4-fold enhancement in the specific activity and 1.5 times increase in mass activity in comparison to the commercial catalyst (**Figure 3**).

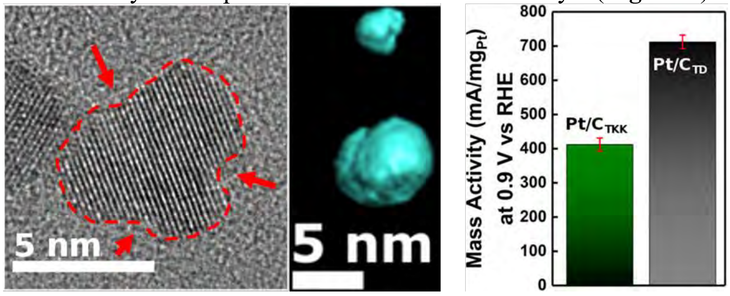

Figure 1. The ORR activity of Pt nanoparticles with high density of surface concavities. High resolution TEM and 3D Tomography images with mass activity of the Pt nanoparticles are shown in comparison to commercial Pt/C catalyst

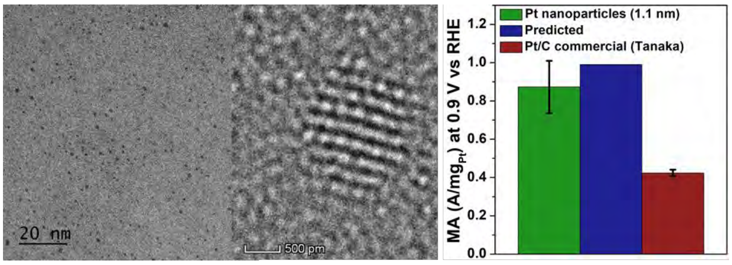

Figure 2. The ORR activity of ultra-small ~1 nm Pt nanoparticles. High resolution TEM and mass activity of the Pt nanoparticles are shown in comparison to theoretically predicted values.

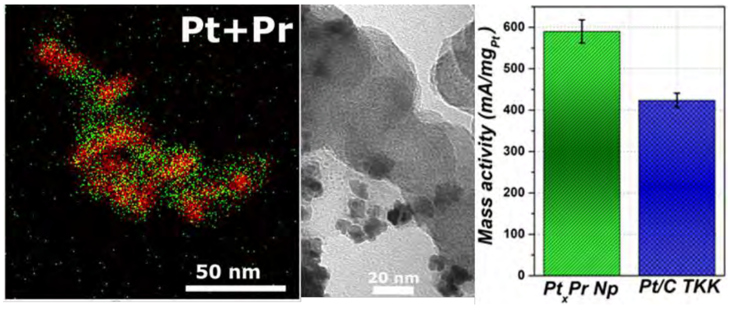

Figure 3. The ORR activity of alloyed Pt$_x$Pr nanoparticles. TEM and EDX mapping images with mass activity of the Pt$_x$Pr nanoparticles are shown in comparison to commercial Pt/C catalyst.

Ionic liquids are inevitable solutions for the recovery of metal-based materials in future environmentally friendly and energy efficient technologies [1]. The present processes of metal recoveries are based on hydrometallurgy, pyrometallurgy and/or cyanidation, i.e. either high temperature procedures that are closely followed with high energy consumption and release of carbon dioxide, or a toxic procedure. Besides, they are associated with large amounts of wastes, in gaseous, liquid or solid form that has to go through special treatments before being disposed, which requires additional energy. Designing adequate solutions for low cost clean metal recoveries is still a great challenge. Ionic liquids are powerful solvents that could be used as electrolytes for selective metal dissolution and recovery. Deep eutectic solutions (DES) are types of low cost environmentally friendly ionic liquids that are easily prepared at large scale and with potential of being suitable for metal recoveries. They offer the avoidance of water chemistry and all the drawbacks of aqueous electrolytes. However, in order to develop the DES based metal recovery technology, the experience on metal dissolution in these electrolytes has to be gained.

To overcome these challenges, the work aims to follow dissolution of a range of metals in differently formulated DESs. Namely, the dissolution of Fe, Zn, Al and Cu will be monitored in two deep eutectic solvents: reline (choline-chloride:urea, 1:2) and ethaline (choline-chloride:ethylene glycol, 1:2). The kinetics of metal degradation in DESs will be determined by inductively coupled plasma mass spectrometry and electrochemical measurements: potentiodynamic polarization and electrochemical impedance spectroscopy. The dissolution of various metals will be followed in their natural state, i.e. at the open circuit potential, providing data about metal dissolution, for example, from the waste dust. The other way to follow the metal dissolution is by applying positive voltage to metal electrode, thus inducing electrochemical dissolution at higher rate. This technique will be assessed as a suitable one for determining better solvent for anodic leaching of metallic waste in solid form.

Insights on the role of the copper electrode microstructure in CO_2RR

Simone Asperti,[a] Marilia Pupo,[a] Yaiza Gonzalez-Garcia,[b] Ruud Kortlever[a]

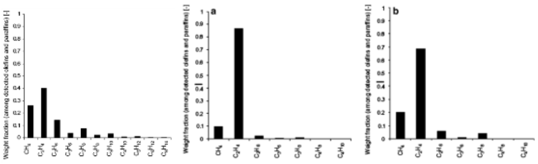
Many scientists nowadays are looking for alternative technologies to reduce the amount of CO_2 in atmosphere. Among them, one of the most promising technologies is the electrochemical conversion of CO_2 to highly-value carbon products (hydrocarbons, alcohols). This technique can be performed at atmospheric pressure and ambient temperatures. On the other hand, high overpotentials, limited stability, low selectivity and low yield are limiting the use of this technique[1].

In order to improve the CO_2 reduction reaction (CO2RR) and proceed to the upscaling on an industrial level as soon as possible, we aim to study the effect of compositional and morphological changes of copper electrodes during CO_2 reduction. We especially use copper electrodes, since they have proven to be the most efficient for the conversion of CO_2 to hydrocarbons such as methane and ethylene.

Here, we investigate the role of the manufacturing procedure of copper foils on their electrocatalytic performance for CO2RR. *Moulijn and coworkers* have previously compared the performances between Eurofysica® and Alfa Aesar® copper foils, demonstrating a clear difference in the product distribution for Eurofysica® copper electrodes before and after electropolishing procedure, in contrast with Alfa Aesar® copper electrodes that did not show any difference[2]:

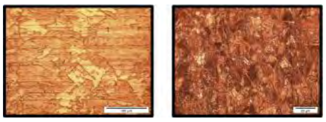


***Left image**: Eurofysica copper electrode before electropolishing, weight fraction**. Centre and right image**: Eurofysica® copper electrode after electropolishing. Product distribution after 360 min (A) and after 1160 min (B), product distribution.*

They claimed that the main parameter responsible for such difference is the difference in atoms orientation that, consequently, affects also the copper oxide amount on the copper electrode's surface, whereas the presence of impurities seems to be negligible.

Following this study, we compare commercial copper foils from multiple manufacturers, namely : Sigma Aldrich®, Alfa Aesar®, Goodfellow®, Mateck®. We link the difference in their electrocatalytic behavior for CO2RR to the surface and microstructure features:

1) Surface roughness
2) Grain sizes
3) Crystallographies and crystallite sizes
4) Different copper oxide amount



*Images after etching with HNO_3 / H_2O solution 1:1. **Left side**: Goodfellow® low purity. Variable grain size (20-50 µm). **Right side**: Eurofysica®. Average grain size: 10 µm. Magnification: 50 X.*

Silicon is an excellent candidate for negative electrode materials in Li-ion batteries because of its high theoretical capacity. However, it suffers from poorly resisting to charge/discharge cycles, due to the large volume variations associated with them. We have shown that amorphous methylated silicon a-Si$_{1-x}$(CH$_3$)$_x$:H has a better cyclability than amorphous silicon a-Si:H while keeping a very large capacity [1]. This was attributed to a lower density and stiffness of a-Si$_{1-x}$(CH$_3$)$_x$:H as compared to a-Si:H, allowing for better accommodating of the volume deformation upon Li loading/release. The presence of voids in the bulk material was observed by TEM imaging and the material mechanical stiffness was measured by AFM. The chemical changes during the first lithiation was investigated by Attenuated-Total-Reflection FTIR Spectroscopy (ATR-FTIR). For a-Si$_{1-x}$(CH$_3$)$_x$:H and a-Si:H, our results indicate a two-step process in which i) a heavily lithiated phase of constant composition progressively invades the materials and ii) after total invasion, the whole electrode is progressively enriched in Li [2].

Operando observations by optical microscopy were performed on thin layers (100 nm) during the first lithiation. Unlike a-Si:H, a-Si$_{1-x}$(CH$_3$)$_x$:H undergoes a first spatially non-homogeneous lithiation [3]: lithiated zones appear on the surface as colored spots (Fig.1), which grow circularly and progressively invade the active layer. These spots have a thickness greater than that of the initial layer, which can be estimated from their color change. The morphology of the lithiation spots and their evolution are accurately determined by ex situ AFM. The resistive character of the layer is responsible for this inhomogeneous behavior. A simple model has been worked out and is in semi-quantitative agreement with the combined electrochemical and microscopy measurements.

Using Raman spectroscopy, we investigated the properties of fully lithiated, semi-lithiated and non-lithiated layers, in and out of the lithiated areas (Fig.2). Our results give some insight into the structural and electrochemical changes during the first cycle. The Li-rich layer invading the material is "opaque", i.e., optically absorbing over a large wavelength range. After delithiation, the Raman peaks are better recovered in a-Si$_{1-x}$(CH$_3$)$_x$:H than in a-Si:H.

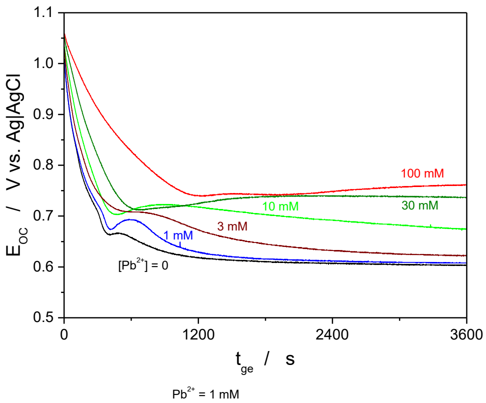
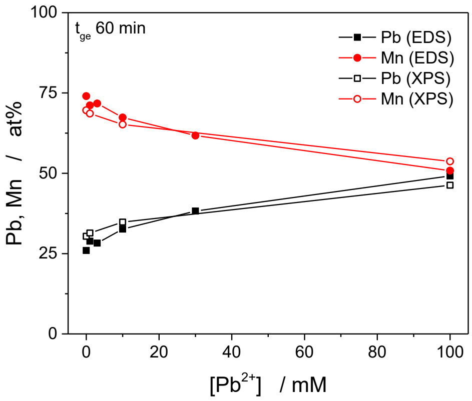
Galvanic displacement reactions between sacrificial oxides and metal cations have been used to produce secondary oxide nanoparticles [1, 2] and electrocatalytic layers [3]. Our group has investigated the mechanism of oxide-oxide galvanic displacement reactions, using PbO_2 layers and various cations (Mn^{2+}, Co^{2+}, Ni^{2+}, Sn^{2+}), reaching the following conclusions [4]: (i) There is no correlation between the thermodynamic driving force of the reaction and the secondary oxide growth rate which is controlled by solid-state diffusion of Pb species across secondary oxides. (ii) The growth occurs at the secondary oxide/solution interface; cations in solution need not to reach the sacrificial oxide to react with it. (iii) Secondary oxides contain significant amounts of the sacrificial oxide metal, i.e. they are mixed oxides.
We have collected new evidence about the effect of the concentration of Pb^{2+} ions in the solutions used in galvanic displacement reactions. In the figures we show data relevant to the reaction between PbO_2 (deposited on Au screen printed electrodes) and Mn^{2+} ions, performed with 0.02 M Mn^{2+} acetate solutions containing up to 0.1 M Pb^{2+}.





Chronoamperometric curves show that the open circuit potential (E_{OC}) declines progressively more slowly, and stabilizes at higher values, as $[Pb^{2+}]$ increases. Instead, in the absence of Mn^{2+} ions, the E_{OC} stabilizes soon after immersion of PbO_2 in the acetate solution and becomes lower when $[Pb^{2+}]$ increases, with a slope close to the theoretical value (29 mV per $[Pb^{2+}]$ decade).

By analyzing PbO_2/MnO_2 samples prepared with 1 h reaction time (t_{ge}), we found essentially identical compositions using EDS and XPS, whereas, for samples prepared with t_{ge} = 10 min, EDS yielded much higher Pb percentages than XPS. This shows that, using the thicker layers, EDS sampled only the secondary (mixed) oxide, which had a uniform bulk composition very close to the surface composition determined by XPS. By increasing the Pb^{2+} concentration in solution from zero to 0.1 M, the composition of the secondary mixed oxide changed approximately from $Mn_{0.75}Pb_{0.25}O_2$ to $Mn_{0.5}Pb_{0.5}O_2$. The larger Pb content in the secondary oxide explains the higher E_{OC} values observed at progressively higher $[Pb^{2+}]$. The marked influence of $[Pb^{2+}]$ on the secondary oxide composition shows that the reaction by which the Pb species leaves the oxide to enter the solution is reversible.

Valorization of waste gas CO_2 by means of electrochemical transformation is about to be realized in industrial plants. Yet fundamentals about the reaction are not understood to date. Landmark work from Hori and coworkers found that copper shows the unique capability to catalyze the formation of hydrocarbons such as methane or ethylene at high rates from CO_2.[1, 2] Later, more products of the electrochemical reduction of CO_2 such as alcohols, and aldehydes were identified.[3] Especially products containing two or three carbon atoms are interesting for a wide range of applications as fuels. Li and Kanan had success in finding a catalyst based on thermally annealed copper metal that promotes the C-C bond formation.[4, 5] Such oxide-derived catalysts show exceptionally low overpotential and high yield of liquid fuel. The product yield of such electrodes is typically quantified by established techniques such as gas chromatography, liquid chromatography, or nuclear magnetic resonance.[1-3, 6-8] Thereby, the time scale of characterization is minutes to hours. To accelerate the screening process of potential catalysts, to enable the detection of transient events and short-living products, we introduced the electrochemical real-time mass spectrometry (EC-RTMS).[9]

Herein, we present an unprecedented approach to quantify the liquid reaction products from carbon dioxide electroreduction short time after their formation on the electrode. By coupling mass spectrometry successfully to an electrochemical flow cell, we monitor seven different liquid products. By employing soft ionization, fragmentation of the compounds is suppressed. The partial currents of formation, and Faradaic efficiencies are resolved in one single potential sweep. Polycrystalline and oxide-derived copper catalysts are characterized and the role of reaction intermediates is discussed.

Under certain conditions, the liquid – liquid interface (LLI, e.g. water solution of the inorganic salt contacted to an organic and immiscible with water solution of hydrophobic salt) can be polarized and studied with the full scope of techniques offered by the electrochemical toolbox. Especially interesting are the systems where the polarized LLI is modified with functional materials. This can be achieved by means of (i) self-assembling molecules, micro- or nano-objects; (ii) polymeric or (iii) inorganic films or (iv) patterned membranes.[1] In either case the modifier brings new properties to the interfacial region that can be further harvested for sensing, energy conversion, catalysis, bio-interface development, molecular separation among many other examples.

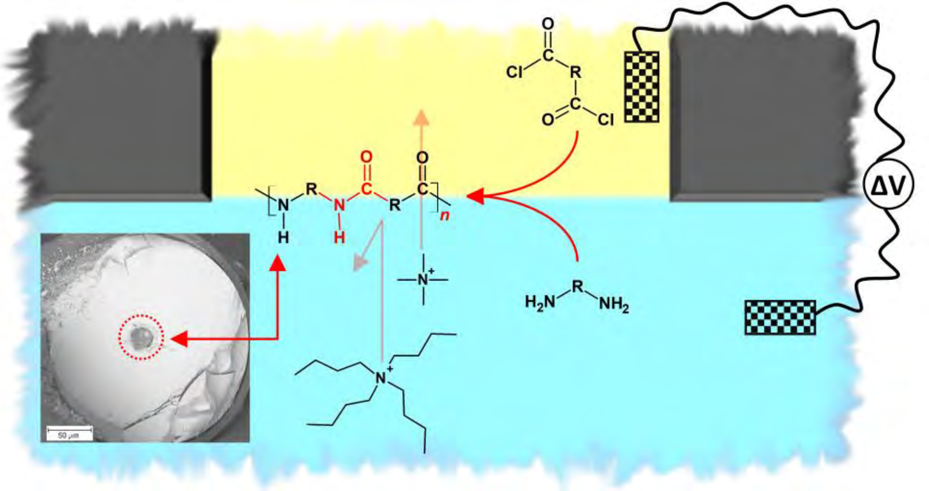

Figure 1. Schematic representation of the microscopic liquid – liquid interface modified with the nylon-6,6 and its size sieving properties.

In this work the interfacial polycondensation of polyamide (nylon-6,6,) was studied at the interface between two immiscible electrolyte solutions. The reaction between 1,6-diaminohexane initially dissolved in the water phase and adipoyl chloride dissolved in the organic phase was controlled and investigated in the presence of the potential difference applied to the soft junction from the external power source. The effect of a number of experimental conditions, this is (i) the concertation of the 1,6-diaminohexane; (ii) the concertation of adipoyl chloride and (iii) the pH of the aqueous phase on the electrochemical response of the system was studied. Optimized system was then applied for the miniaturized LLI modification (see Fig. 1). Fused silica capillaries having 25 µm in diameter were used in this respect.[2] Obtained films were then characterized with the ion transfer voltammetry showing partial and completer blockage of tetramethylammonium and teterabutylammonium cations interfacial ion transfer, respectively.

Electrified soft interphases, especially the interface between two immiscible electrolyte solutions - ITIES, hold a special place in electroanalysis. This is due to a unique detection mechanism that can arise from the ion(s) crossing the liquid – liquid interface. This means that the reactions occurring at the ITIES are not limited to an electron transfer reaction. The second point that is setting the ITIES apart is the detection selectivity which is governed by the molecular partitioning between two adjacent phases, or in other words, the analyte hydrophilicity/hydrophobicity. Since the liquid – liquid interface is flowing in nature it requires a support that can be used to control its geometrical dimensions. Microscopic apertures used as the ITIES supports are especially exciting in this respect, as these can be used to improve analytical performance of the concerned platforms: (i) smaller capacitive currents lower the limits of detection, (ii) ITIES gains mechanical stability and (iii) unique diffusion layer profiles established above the soft junction assures higher mass transfer which in turn improves detection sensitivity.[1]

In this work, a few of low cost and easy to prepare electrified liquid – liquid interface (LLI) supports fabrication protocols that are applied in electroanalysis will be presented. on the focus will be given to three platforms, that are based on: (i) fused silica capillaries with a pore diameter equal to 5, 10 or 25 µm;[2,3] (ii) array of apertures with micrometer dimensions that are micro-punched in an adhesive polyamide films and (iii) 3D printed supports with complex and pre-defined geometry. These platforms are comprehensively studied and described with the help of electrochemical (e.g. ion transfer voltammetry) and microscopy (optical and scanning electron microcopy) investigation techniques. The fully operational ITIES supports are then used to study the chemical species such as illicit drugs or antibiotics (e.g. detection of cocaine in street samples,[4] ephedrine in urine or pharmacochemical study of fluoroquinolones antibiotics[2,3]). In all cases, the effect of matrix and interfering chemical species (especially cocaine street samples adulterating additives) is comprehensively described.

Non-enzymatic glucose sensors are prominent alternatives to the commercially available glucometers. Their main advantages over enzyme–based devices are higher stability to changes of the environment such as pH and temperature and lack of complicated immobilization procedure [1]. However, non-enzymatic glucose sensitive materials are typically less selective, so there is a strong requirement for the development of proper coatings or membranes in order to minimize the negative influence of interferences. Therefore we present Au-Ti heterostructure covered with various coatings (e.g. Nafion, poly(sulfobetaine methacrylate)) and novel approach for analysis of interfering species influence onto electrode performance in neutral solution.

Fabrication procedure of material consists of the following steps: preparing structured titanium template (TiND) by anodization and etching of nanotubes, gold sputtering and subsequent dewetting. After those steps electrode morphology is investigated by scanning electron microscopy (SEM) and atomic force microscopy (AFM) [2] revealing the presence of gold nanoparticles (AuNPs) in every dimple of Ti foil. Lastly, as formed material is covered by protective coating. Electrochemical properties and catalytic activity towards glucose oxidation are determined by standard techniques - cyclic voltammetry (CV) and impedance spectroscopy (EIS). Examining interference phenomena of various compounds (such as ascorbic acid (AA), acetaminophen (AAp), urea and glycine) is realized by both CV and EIS techniques in certain configuration. Moreover, the influence of those species on the catalytic activity of the material is established. Obtained results confirm the high application potential of prepared electrodes for sensors towards noninvasive glucose detection in human body fluids.

The formation of a solid electrolyte interphase (SEI) on negative electrodes is a key requirement for the long-term durability and safety of Li-ion and Li metal batteries. The chemical composition of the SEI has been analyzed by several *ex-situ* techniques [1,2]. However, the complicated composition of the SEI may be altered during sample transfer procedures (rinsing, exposure to vacuum, mechanical changes due to bending or touching the delicate layer, unavoidable contact to even trace amounts of H_2O, CO_2 etc.) [3,4]. Therefore, *in-situ* electrochemical techniques such as electrochemical impedance spectroscopy (EIS) have widely been used to diagnose the development of interphases in battery cells [5]. Those techniques provide signals that are integrated over the entire electrode surface. Among a variety of scanning probe techniques, scanning electrochemical microscopy (SECM) has been applied to probe the *local* protective properties of the SEI against electron transfers from the negative electrode to electrolyte components [6,7]. However, these studies have been conducted either in a *post mortem* scheme or under current densities much lower than used in real cells. This allows for instance the observation of incipient formation of SEI on silicon electrodes [8].

Here we propose a new cell design for SECM cell in a thin layer configuration that allows charging and discharging of battery electrodes under realistic current densities immediately followed by SECM imaging or approach curves without manipulation of the sample under study nor the electrolyte used. Finite element simulation of the secondary current density distribution proved that the current distribution deviates only slightly in the area of the opening provided that the SECM microelectrode is retracted during the charging-discharging cycles.

As an example, lithium metal electrodes were cycled in 1 M $LiClO_4$ in propylene carbonate with different current densities. The local protecting properties of the solid electrolyte interphase (SEI) were probed by SECM in the feedback mode directly within the cell in between charging-discharging cycles. The development of lithium deposits was observed by SECM and can be linked to the used charging-discharging protocol. At higher current densities protruding Li deposits are formed. Approach curves prove that the Li metal of protruding deposits is significantly more active for electron transfer to the mediator than the remaining parts of the surface. The developed hardware and methodology can be directly applied to other electrolytes or other battery electrodes forming protective films.

The effect of naphthalene derivatives and ENSA on tin electrodeposition on gold

Diana Aranzales[1], Inandha Briliani[1], Jacques Wijenberg[2], Marc Koper[1]

Tin electrodeposition is a common electroplating process used in multiple applications: corrosion protection, electronics fabrication, packaging industry, and many others[1]; the process requires the addition of different compounds in order to have the desired chemical and physical properties of the deposit. Aromatic compounds are broadly used in tin electrodeposition and an extensive effort to understand their role during the initial stages and in the overall process has been done[2, 3]. Nonetheless, the chemical structure of the common additives is quite diverse and complex, which makes their understanding difficult.

In this work, we study the adsorption behavior of naphthalene derivatives: naphthalene (NPT), naphthalenesulfonate (NPTS) and hydroxynaphthalenesulfonate (HNPTS) on gold electrodes and their effect on the tin electrodeposition process, by means of in situ and ex situ surface analysis techniques. Experiments shown tin electrodeposition is strongly affected by the presence of NPT, NPTS and HNPTS films; tin bulk electrodeposition is inhibited in the presence of NPT and NPTS, but promoted in the presence of HNPTS. The tin deposit morphology is also remarkably modified by the presence of naphthalene derivatives. Tin deposits grown in the presence of NPT and NPTS seem to have the same morphology, but tin deposit grown in the presence of HNPTS exhibits markedly different features. Chemical composition studies revealed sulfur is incorporated in the deposit as a result of the reductive desulphonation of NPTS and HNPTS on the gold electrode.

Finally, the effect of ethoxlylatenapthalenesulfonic acid (ENSA), a commonly used additive in the tin electroplating industry, was studied on tin electrodeposition process. In good agreement with what has been shown, ENSA exhibited a similar behavior to NPT, NPTS and HNPTS during the tin deposition process in terms of the voltammetry. Nonetheless, SEM imaging shows that ENSA severely inhibits the tin bulk deposition.

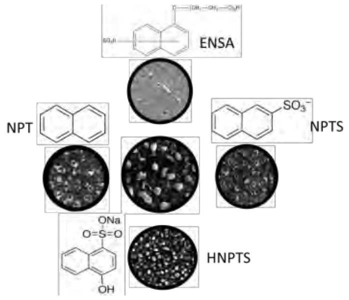

Figure 1. SEM micrographs of tin deposits morphology in the absence (center) and the presence of ENSA, NPT, NPTS and HNPTS.

Clarifying the Working Mechanism of Mg^{2+} Complexing Agents as Electrolyte Additives for Aqueous Mg-Air Battery

Linqian Wang[1a], Darya Snihirova[1b], Min Deng[1c], Bahram Vaghefinazari[1d], Sviatlana V. Lamaka[1e], Daniel Höche[1f], Mikhail L. Zheludkevich[1, 2g]

Aqueous primary Mg-air batteries have attracted much attention as promising alternative energy storage and conversion devices thanks to their high theoretical energy density, long shelf life and safety. Mg is a promising anode material. However, several drawbacks lower practical discharge potential and utilization efficiency of Mg anode. Low practical discharge potential is caused by the formation of insoluble discharge products (MgO and $Mg(OH)_2$), which reduce the active electrode surface. The low corrosion resistance of Mg anode leads to losses in utilization efficiency. One of the ways to improve the anode performance is to use the electrolyte additives that hinder formation of insoluble discharge products and keep the electrode surface clean. It has been already shown that complexing agents enhance the practical discharge performance of aqueous primary Mg-air batteries through changing the surface condition of Mg anode [1, 2]. The development of advanced Mg anode material also enhances the discharge performance of Mg-air battery. Low impurity content increase the corrosion resistance and suitable alloying elements improve the discharge activity of the Mg anodes, such as, Mg-Ca anode, Mg-Li anode, and Mg-Al anode [3-5].

In this work, we evaluate the ability of several Mg^{2+} complexing agents to improve the utilization efficiency and discharge performance by hindering the formation of insoluble discharge products and inducing uniform dissolution of Mg-Ca anode. The losses caused by chunk effect might be significant [6]. The reduction of the chunk effect by additives was also observed. The effect of the Mg^{2+} complexing agents as electrolyte additives on the discharge performance of Mg-air battery was determined via full cell discharge test. The results show that one of the Mg^{2+} complexing agents, 2,6-dihydroxybenzonate, simultaneously improves the utilization efficiency and discharge activity of Mg anode at a current density of 5 mA cm^{-2}. For a better understanding of the working mechanism of the Mg^{2+} complexing agents, the surface condition of the Mg anode in electrolyte was estimated by thermodynamic calculations to show the competition between soluble complex and insoluble $Mg(OH)_2$. Electrochemical impedance spectroscopy (EIS) measurements were performed to evaluate the surface film on Mg and to follow its evolution with time. The thickness of surface film and the resistance of discharge products were calculated based on the impedance data. Mg^{2+} complexing agents efficiently enhance the discharge performance of Mg-air battery via hindering the growth of surface film.

Since the commercialization of Li-ion batteries in 1991, lithium cobalt oxide ($LiCoO_2$, LCO) has been used as positive electrode material in them. Now, a few decades later, LCO is still one of the most used materials in Li-ion batteries for portable applications as it exhibits high operating potential, low self-discharge and high reversibility. As the result of three decades of investigation, several procedures to improve the performance of LCO have been proposed. These include e.g. different synthesis methods, particle morphology variation, doping and over-lithiation [1,2,3]. Several different dopants, such as Ti, Zr, Al, and Mg, have been reported to enhance the LCO performance. In addition, the synthesis methods and stages for adding the doping have been varied. However, it has not been investigated how the stage of doping affects the material properties. Therefore, in this work, the effect of the Mg addition at two different stages of synthesis on the electrochemical properties of Mg-doped LCO is investigated. In addition, the effect of Li/Co ratio of these materials on the electrochemical properties is reported as well.

The LCOs were synthesized *via* solid-state synthesis using Co_3O_4 and Li_2CO_3 as precursors. The Mg-doping was added either during the oxide precursor synthesis or during the lithiation i.e. mixing and heat-treating Co_3O_4 and Li_2CO_3. In addition, the investigated LCOs were synthesized with two different Li/Co ratios, 1.005 and 1.050.

The particle size and morphology of the LCO materials is investigated with scanning electron microscopy (SEM). Other structural characterization methods include X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and X-ray absorption spectroscopy (XAS). The electrochemical characterization of the materials is done with galvanostatic rate capability measurements in half cells and long-term cycling in LCO/graphite pouch cells. In addition, cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) measurements are done to further investigate the electrochemical properties.

One of the main mechanisms by which enzymes achieve their high catalytic efficiency and selectivity is through the isolation of their reactive centre from the bulk solution in which the substrate is found. This results in a solution environment adjacent to the active site that is chemically different from the bulk solution. When we exploit this nanoconfinement and molecular level control in faradaic electrochemical systems, reactant species are spatially constrained resulting in high concentrations near the active electrode surface for extended periods of time. We explore how the features of the nanoconfined substrate channel that enzymes exploit (constraining the reactants, altering the solution environment and actively transporting species in the substrate channel) can be translated into electrochemical reactions to give dramatically increased reaction rates and selectivities.

Previously, we have designed a “nanozyme”, which is a nanoparticle that mimics the three-dimensional geometry of enzymes for electrocatalysis as a way to increase specific activity for the oxygen reduction reaction (ORR). This is achieved by forming isolated substrate channels that penetrate into the centre of the nanoparticle with the exterior surface electrochemically passivated by a surfactant.[1] The electrochemical reaction is then restricted to occur within a nano-confined substrate channel allowing control over the solution environment. Kinetic current density is 3.3 times higher inside the nanochannels than at the surface outside and is among the highest specific activity reported for Pt-Ni nanoparticles.

In this work, ORR activity was measured for nanozymes with different substrate channel diameters with Koutecký-Levich plots being used to calculate kinetic current density over a range of potentials in the mixed kinetic-diffusion region. Our results showed that narrow channels are more active at low overpotentials (ca. 0.95 V (RHE)), while wider channels exhibit higher activity at higher overpotentials.[2]

Physicochemical modelling of the electrocatalytic system was then employed to help explain these results. Proton and oxygen concentration profiles inside isolated channels showed that nanoconfinement is an unforeseen double-edged sword. Proton concentration is higher within narrower channels, leading to high activity at low overpotentials. This high proton concentration is not depleted as overpotential is increased, likely from proton migration into the channel due to electrical double layer overlapping. As overpotential is increased, higher oxygen depletion within the smaller channels is detrimental to activity, resulting in the larger channel nanozymes becoming more active by comparison.

Electrocatalytic nanoconfinement has the potential to greatly enhance activity by controlling reactant mass transport. This can lead to greater reaction selectivity by controlling the chemistry inside substrate channels. Greater experimental control over parameters such as channel depth and width, coupled with molecular simulation modelling, will allow us to probe this phenomenon with more detail, and hence extend this concept to other reactions where entrapment and exclusion of species in solution is vital.

Proton exchange membrane fuel cells (PEMFCs) are a promising alternative technology for the replacement of combustion engines. The focus on the optimization of the catalyst activity in the past lead to the development of several types of highly active catalysts [1]. However, for practical applications the catalyst stability is equally important.

This work focuses on the investigation of the stability of different Pt-based catalysts to gain a better insight into the degradation mechanism of Pt nanoparticle catalysts under electrochemical conditions. [2] For this, accelerated stress tests (ASTs) are performed in a gas diffusion set-up to establishing conditions close to those in PEMFCs [3]. The applied AST protocol [4] is based on the load-cycles for an automobile proposed by the Fuel Cell Commercialization Conference of Japan (FCCJ) [5]. Applying small-angle X-ray scattering, the observed loss in active surface area upon application of the AST is correlated to different degradation mechanisms such as metal dissolution, particle detachment, Ostwald ripening or coalescence [6].

jfbrito@ymail.com

The chemical recycling of CO_2 minimizes the harmful environmental effect of excess greenhouse gases in the atmosphere and can be an interesting route for renewable fuel obtaining[1]. In that sense, $CuGaS_2$-based photocatalysts were studied for CO_2 reduction under photoelectrocatalysis (PEC) technique. The $CuGaS_2$ was modified with small amounts of In or Bi to analyze the interference of these metals in the products generation. The doped and non-doped $CuGaS_2$ were deposited by spray coating on Mo using inks comprised by the respective salts of each cations, and thiourea as the source of sulfur. A CdS and TiO_2 thin films were deposited by a chemical bath deposition method on the spray-coated $CuGaS_2$ films. The photoelectrodes were characterized by XRD, Raman, SEM, EDS, Diffuse Reflectance and XPS. The photoelectrocatalytic reductions of CO_2 were performed in a one-compartment glass reactor (50 mL) equipped with quartz window, at 20 °C, with three electrodes: Pt foil as a counter electrode, Ag/AgCl (KCl sat) as reference electrode, and the semiconductors as working electrode. The working electrode was immersed in 0.1 mol L^{-1} Na_2SO_4 saturated with CO_2, irradiated by a 150 W commercial solar simulator lamp (Newport 66902) and submitted to a controlled potential (potentiostat/galvanostat - Autolab model PGSTAT 302, Metrohm) for the experiments. Aliquots of the solution were taken at controlled times and products evaluated CG-FID[2]. The photoactivity of the semiconductors were evaluated along the potential applied in the cathodic region by linear sweep photovoltammogram. Comparing the photocurrent generated for the three semiconductors, the $CuGaS_2$ and $Cu(Ga,Bi)S_2$ semiconductors presented photoactivity quite similar, while $Cu(In,Ga)S_2$ presented smaller photocurrent along the applied potentials. Once the three electrodes presented photocurrent response under the potential of -0.7 V, a chronoamperometry under transient light was performed at this potential in order to evaluate the stability of the semiconductors. The higher photocurrent is obtained with the $Cu(Ga,Bi)S_2$ electrode (0.012 mA cm^{-2}), nevertheless its photocurrent decreases around 33% after 300 s, presenting at the end a photocurrent similar to $CuGaS_2$ semiconductor. The $CuGaS_2$ and $Cu(In,Ga)S_2$ electrodes presented a more stable photocurrent along the time analyzed, indicating a better stability of the material compared to $Cu(Ga,Bi)S_2$ electrode. The CO_2 reduction was performed under -0.7 V and light incidence (one sun) with the three electrodes. Comparing the amount of methanol (the main product for all the electrodes), this was higher employing $Cu(In,Ga)S_2$ electrode than under $CuGaS_2$ and $Cu(Ga,Bi)S_2$. However, the formation of other products that require a higher number of electrons and protons (ethanol and acetone) was higher under the $CuGaS_2$ catalyst. In addition, the stability and, consequently, repeatability of the products concentration formed using $CuGaS_2$ for consecutive reactions of CO_2 reduction is better than the observed for the catalysts modified with In or Bi. In fact, the Bi presence did not improve the $CuGaS_2$ activity for CO_2 reduction. After 240 min of CO_2 reduction using $CuGaS_2$ semiconductor under -0.7 V and light incidence (one sun) were quantified 1.30 mmol L^{-1} methanol, 0.45 mmol L^{-1} ethanol and 0.25 mmol L^{-1} acetone. So, despite the improvement for methanol production obtained in the first 4h of reaction with the addition of In in the semiconductor surface, the results obtained under $CuGaS_2$ electrode without further modification showed to be superior for CO_2 reduction using PEC technique.

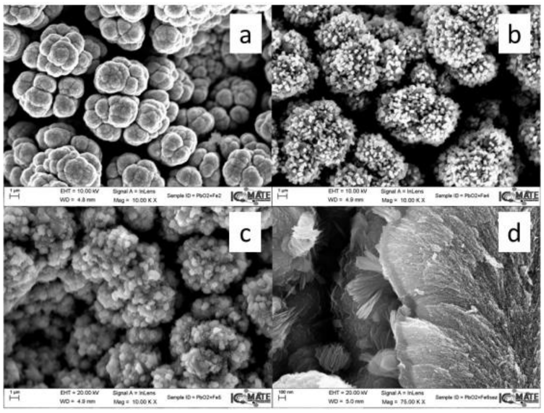
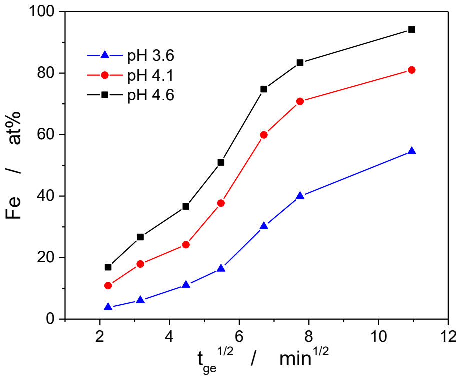
In the frame of a project aimed at the preparation of porous layers consisting of various (mixed) oxides potentially useful in electrocatalysis or energy storage, we have studied the galvanic displacement reactions between PbO_2 and Fe^{2+} ions. Following a well-established procedure developed in recent years, we have used oxygen bubble assisted anodic deposition to prepare porous PbO_2 sacrificial layers [1]. Then, we have exposed those layers to deaerated acetate buffer solutions containing 0.025 M $Fe(ClO_4)_2$, kept at 75°C, for variable reaction times (t_{ge}). The samples thus obtained have been submitted to SEM-EDS, XPS and XRD analyses, revealing a behavior significantly different from those of other previously described systems [2, 3].





SEM images recorded after different reaction times (from a to c, 10, 45 and 120 min, respectively) show distinct growth centers which progressively increase in size to completely cover the sacrificial oxide. However, the cross sectional SEM image (d) reveals that below the seemingly crystalline agglomerates, there is a continuous layer, ca. 100 nm thick, strongly adhering to PbO_2.

XPS analyses show that, at the surface of the secondary layer, iron is present as Fe(III), and that the oxygen peak is accurately fitted by two contributions with comparable intensity due to oxide and hydroxide environments, respectively. XRD analyses show the presence of crystalline γ-FeOOH (and minor amounts of α-FeOOH), in addition to the mixture of α-PbO_2 and β-PbO_2 already observed [1]. Thus, XPS and XRD data converge to suggest FeOOH to be the main component of the secondary layer, not excluding the presence of other amorphous compounds. As reported for secondary oxides of other metals [2,3], XPS reveals the presence of Pb, at variable percentage depending on the reaction duration. In the initial stages ($t_{ge} \leq 10$ min), corresponding to the formation of the continuous layer, the secondary oxide contains 5.5 at% Pb; for $t_{ge} = 1$ h, when the sample is covered by the crystalline material, the Pb content drops to 1.5 at%.

EDS analyses, as long as their sampling depth is larger than the secondary layer thickness, give qualitative information on the growth rate, although they are unable to provide the exact composition of the latter. The time dependence of Fe percentage shows that the growth rate is higher at higher pH value. It also shows different growth regimes which one might tentatively associate with the change in morphology shown in SEM images and with the variable Pb content in the secondary oxide layer.

Zirconium-based coatings are one among many attempts to replace coatings based on chromium(VI) compounds, which have been proven to cause bad effects on human's health and their surroundings, as less harmful and ecologically accepted alternatives [1,2]. On the other side, mechanisms for corrosion inhibition and suppression are subjected to myriad discussion of both academic and industrial researches. This research was carried out on an aluminum sample AA 7075 and the corrosion stability of zirconia (ZrO_2) as an inhibitor of corrosion was tested [3]. In order to prevent agglomeration of nanoparticles the stable colloidal dispersions (sols) of zirconia were used as a source for deposition of nanoparticles. Zirconia sols were synthesized by forced hydrolysis of aqueous solution of zirconium salt ($ZrOCl_2$), resulting in well dispersed particles with uniform size. Two sols were synthesized, diluted (0.4 wt.% solid phase content) and concentrated (0.8 wt.%). The particles size distribution (hydrodynamic diameters) was in the range 30-120 nm for both sols, with average particle size of about 60 nm. Zirconia nanoparticles were deposited on a metal surface by immersion in both diluted and concentrated ZrO_2 sol. Throughout the research, multiple methods were combined: scanning electron microscopy (SEM), electrochemical impedance spectroscopy (EIS) and open circuit potential (OCP). The OCP monitoring indicated a three-step process of zirconia deposition: initial short dissolution of Zn intermetallic particles from AA 7075, followed with native oxide layer dissolution and subsequent zirconia film deposition and thickening. It was shown that the inhibition effect of zirconia coatings depends on its two general characteristics: thickness and porosity. With the information collected by scanning electron microscope, it was established that the zirconia particles coated homogeneously the underlying surface and assembled into a porous deposit. The results indicated that the zirconia layers formed from the concentrated sol had pores penetrating deeper inwards the substrate, as compared to the one deposited from the diluted sol. This was confirmed by the EIS data in 0.05 mol dm^{-3} NaCl.

The total impedance of layer obtained from dilutted sol increased with time of immersion in NaCl solution and EIS response was characterized with two time constants. The resistance of coating deposited from concentrated sol was considerably smaller than of that deposited from diluted sol. Furthermore, the coating deposited from concentrated sol resembled the AA 7075 response, while the one obtained in diluted sol offered longer protection of the aluminum substrate.

Investigations of Reversible Voltage Losses and their Recovery after Dry Operation in PEMFCs: Some Mechanistic Insights

Fengmin Du[1,2]*, Tuan Anh Dao[1], Andreas Bauer[1], Kathrin Preuss[1], Alex Martinez Bonastre[3], Jonathan Sharman[3], Geoffrey Spikes[3], Markus Perchthaler[1], Thomas Justus Schmidt[2], Alin Orfanidi[1]

Over the last years, fuel cell electric vehicles (FCEVs) have been experiencing rapid development and are regarded as promising alternatives for battery electric vehicles with regard to their long driving range and low refueling time. However, cost and durability of polymer electrolyte membrane fuel cell (PEMFC) stacks remain the main obstacle for successful commercialization of FCEVs. Over the lifetime of a PEMFC in an FCEV, certain duration of dry operation and/or dry-wet cycling is hardly preventable. It is known that significant reversible voltage losses (several hundred mV) take place under these conditions [1].

In order to keep the cell performance high and prevent reversible losses from developing into irreversible ones [2], the standard approach is to apply proper recovery steps of certain frequency. In the literature, various recovery procedures could be found, such as increasing inlet gas humidity, lowering cell potential and switching cathode gas to nitrogen [1]. There are also reports about using air as cathode gas during recoveries [3]. One other possible way of mitigating or preventing the reversible voltage losses under these conditions is to develop catalyst layers that are less prone to the degradation phenomenon. For this purpose, a detailed understanding of the degradation mechanism is essential. In the literature, the reversible losses after dry operation are explained either by adsorption of ionomer sulfonic groups to the Pt surface and poisoning of the latter [1-2,4], or by degradation of Pt/ionomer interface in the catalyst layer [1].

In this work, we tackle the problem of reversible degradation by first evaluating the effectiveness of various recovery protocols found in the literature [1,3] or designed in-house. Comparing the mass activity regain after recovery steps, we conclude that the application of diluted air might be of significant advantage by showing its superior water management and relatively low cathode potential, both known to favor recovery from dry operations [1]. We then use the found recovery protocol and investigate whether catalyst components influence the reversible losses. Hereby, we focus on the effect of carbon surface modification [5-6] and the change in ionomer content in the catalyst layer. With electrochemical characterization methods (polarization curve, mass activity measurement, CO stripping, limiting current and electrochemical impedance spectra (EIS) under H_2/air and H_2/N_2) applied at various stages of degradation and recovery, we demonstrate some additional possible mechanisms of the losses after dry operation, including ionomer reconstruction and decrease in catalyst layer proton conductivity. These findings serve as input for future operation strategies as well as catalyst layer development to reduce the adverse effects of those reversible degradations during PEMFC lifetime to a minimum.

Thermal Investigation of Innovative Electrolytes for High Voltage Electrochemical Capacitors

Annika Bothe, Andrea Balducci
Institute for Technical Chemistry and Environmental Chemistry and Center for Energy and Environmental Chemistry (CEEC), Friedrich-Schiller University Jena, Philosophenweg 7a, 07743 Jena, Germany
annika.bothe@uni-jena.de

The development of innovative electrolytes is considered of key importance for the realization of Electrical Double Layer Capacitors (EDLCs) with higher energy than the state-of-the-art devices.[1-3] For this reason, several studies have been dedicated to novel solvents and conducting salts in the last years, including ionic liquids, suitable for the realization of EDLCs with operative voltages higher than 3 V. The conductivity, viscosity and electrochemical stability of these electrolytes have been investigated in detail.[1, 4-6] On the other hand, only few studies addressed the thermal stability of these electrolytic solutions. These kinds of studies, however, appear of importance to understand the temperature range of use of the devices.

In this study, we are reporting a detailed investigation on the thermal stability of four electrolytes based on the solvents propylene carbonate (PC), adiponitrile (ADN), butylene carbonate (BC), 3-cyanopropionic acid methyl ester (CPAME) and on the salt 1-butyl-1-methylpyrrolidinium tetrafluoroborate ($Pyr_{14}BF_4$). In all electrolytes, the salt concentration was set to 1 M. All these electrolytes are suitable for the realization of EDLCs with operative voltage higher than 3 V.[1, 4-5] The thermal behavior of these electrolytes during thermal ramp and isothermal experiments have been investigated. Furthermore, the effect of the confinement of these electrolytes on activated carbon has been addressed (see figure 1). Finally, the impact of the thermal stability of the electrolytes on the stability of EDLCs during float tests carried out at 60°C has been considered.

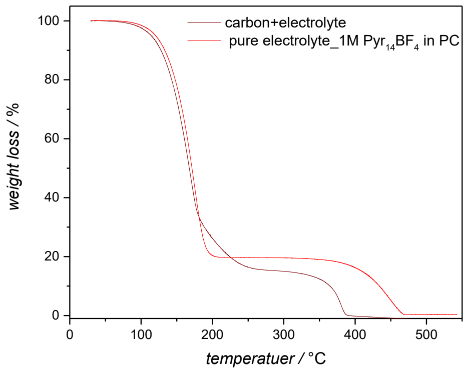

Figure 1: Thermogravimetric analysis in ramp mode of pure electrolyte (1 M $Pyr_{14}BF_4$ in PC) and carbon wetted with electrolyte. (scan rate 10°C min^{-1}).

Hybrid ion capacitors have made a tremendous impact in rising the energy density of high power energy storage devices, by integrating the battery and supercapacitor within a single device.[1-2] Amatucci et al.[3-4] first introduced the idea of combining a $Li_4Ti_5O_{12}$ (LTO) based electrode with an activated carbon (AC) based electrodes. After this pioneering work, several investigations focused on the replacement of LTO with graphite electrode, and nowadays devices based on graphite and AC are commercially available. These devices are indicated as lithium-ion capacitors (LICs) [5-6]

In this work we report an investigation about the electrochemical behavior of high voltage LICs, having an operative voltage of 4.5V, containing liquid as well as gel polymer electrolytes. We investigated the impact of the pre-lithiation of graphite electrode on the performance of these devices, and the influence of the SEI layer on their cycling stability. Furthermore, we analyzed in details the behavior of these high voltage LICs during float test at 4.5V and, also, their self-discharge. These two latter investigations, although are of high importance for high power devices, have not been systematically carried out in the past for this kind of devices, and especially for systems containing gel-polymer electrolytes. The results of these investigations are giving interesting and novel information about the operative limits of high voltage LICs and, also, about the advantages and limits related to the use of gel polymer electrolytes in these high power devices.

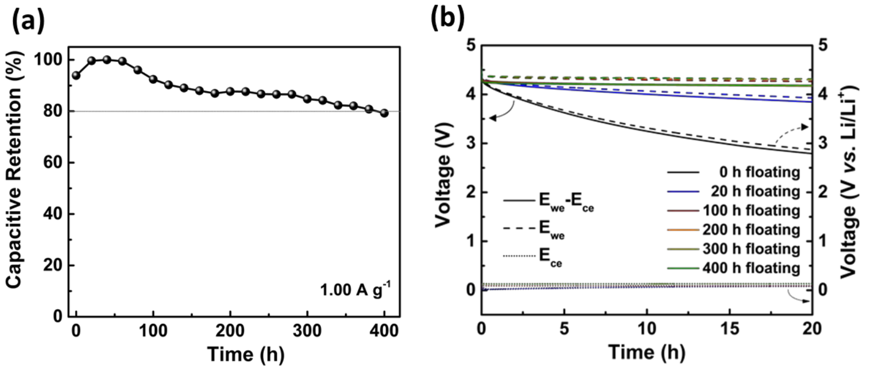

Figure 1: (a) Capacitive retention and (b) self- discharge profile of LIC at different floated hours.

Aluminium Electrodeposition in EMImCl-AlCl$_3$ Ionogels for Improved Aluminium Batteries

Oi Man Leung[a], Carlos Ponce de Leon[b], Theresa Schoetz[a], Themis Prodromakis[a]

Aluminium batteries are promising candidates for the next-generation of energy storage devices, given the natural occurrence of aluminium (third most abundant element) and the intrinsic safety characteristics of the electrolytes used. The specific capacity of an aluminium negative electrode (2980 mAh g^{-1}) is comparable to that of lithium (3860 mAh g^{-1}), while its volumetric capacity of 8040 mAh cm^{-3} far exceeds that of lithium (2060 mAh cm^{-3}), due to its ability to transfer three electrons[1]. Most non-aqueous aluminium batteries utilise electrolytes including inorganic molten salts, deep eutectic solvents, organic solvents and ionic liquids, and operate by the reversible deposition/dissolution of aluminium at the negative electrode and the intercalation of the chloroaluminate ions at the positive electrode.

This work studied the electrodeposition of aluminium from the 1-ethyl-3-methyl-imidazolium tetrachloroaluminate (EMImCl-AlCl$_3$) ionic liquid and its gel form- the *ionogel*. Ionogels have previously been shown improve thermal[2] and moisture stability[3]; here, the ionogel was introduced to widen the potential stability window and enable aluminium deposition from lightweight $AlCl_4^-$ anions in Lewis neutral ionogels. Generally, aluminium is deposited by the reduction of heavy $Al_2Cl_7^-$ ions present only in Lewis acidic ionic liquids, which is generally not possible in neutral and basic compositions as the reduction of the organic cation and subsequent ionic liquid decomposition occurs at a higher potential than the reduction of $AlCl_4^-$.

Lewis acidic and neutral ionogels of varying degrees of gelation were synthesised with polyethylene oxide and EMImCl-AlCl$_3$. The electrochemical behaviour of the electrolytes was investigated by cyclic voltammetry, and aluminium deposits from the Lewis neutral ionogel were confirmed by scanning electron microscopy and energy dispersive X-ray spectroscopy. The deposition of aluminium from a Lewis neutral EMImCl-AlCl$_3$ ionogel was demonstrated for the first time (Fig. 1)[4], serving as a basis for further investigation into the role of polymer additives in developing improved ionogel and semi-solid state electrolytes for aluminium batteries.

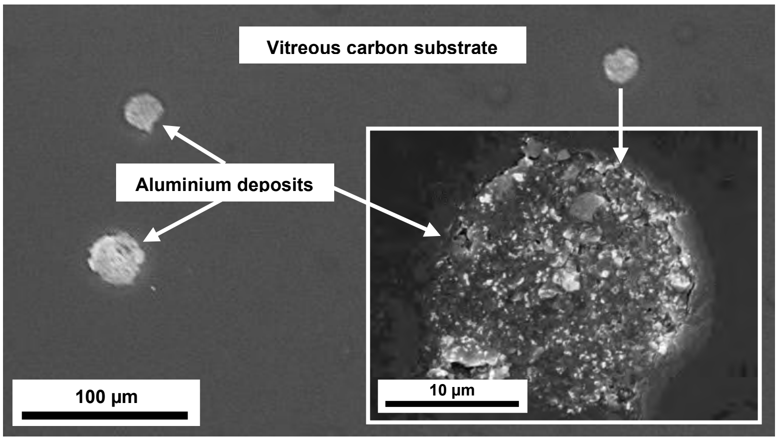

Fig. 1. Scanning electron micrographs of aluminium deposits on vitreous carbon obtained from a Lewis neutral EMImCl-AlCl$_3$ ionogel by applying a constant potential of -1.9 V *vs.* Al|Al(III) at 25ºC.

The use of Ni-rich Li[$Ni_{0.8}Co_{0.1}Mn_{0.1}$]O_2 (NCM_{811}) as cathode active material is considered the next big step towards advanced lithium batteries with even greater energy density[1]. However, its wide exploration in practical applications still requires to overcome several challenges, including improvable cycling performance due to parasitic side reactions with the electrolyte, structural degradation at the particle surface, very high sensitivity towards moisture, and poor thermal stability[2,3]. The application of coatings is an effective approach to stabilize the surface of sensitive cathode material particles and to suppress detrimental side reactions at the interface with the electrolyte and/or moist air thanks to the physically prevented contact[4].

Here, we propose a novel functional organic coating which acts as protective layer to prevent the NCM_{811} from detrimental side reactions with moist air and/or the electrolyte, especially at elevated temperatures. As a result, the surface-modified NCM_{811}–based cathodes revealed enhanced cycling performance and thermal stability. Moreover, this surface coating strategy could be extended to other cathode materials, highlighting its great potential for the development of high-performance cathodes for next-generation lithium batteries.

alex.r.silva@uol.de

Nanoporous gold (NPG) has emerged as interesting material in electrochemistry due to its interesting properties, such as high surface area,[1] electrocatalytic activity,[2] tunability of surface structure,[3] among others. Previous studies have shown that NPG acts as a good electrocatalyst for methanol oxidation (MOR),[2,4] but how this reaction take place on the surface is not very well understood yet. One of the main limitations to achieve systematic studies is the necessity of a new sample for each experiment introducing variability in the surface composition and surface structure. Electrochemical studies in electrodes with a high surface area represents a challenge due to mass transport limitations in the pore space of the material and distorsion of voltammograms due to the *IR* drop. In order to overcome these limitations, a small amount of powdered NPG within a cavity microelectrode was used as working electrode.[5] This allows the preparation of multiple samples from one NPG monolith, reduces the overall current and thus the IR drop and enhances the mass transport by hemispherical diffusion to the microelectrode. By means of under-potential deposition of lead ions in alkaline media, the NPG surface was characterized. Clear signals of basal planes are obtained. The surface undergoes restructuring when it is cycled in acidic media, whereas no or less restructuring was observed in alkaline media. More interesting, controlling the bulk concentration of Pb ions, it is possible to achieve a partial coverage of the NPG surface. The energetically most favorable places are occupied first. This allows to selectively block certain sites and observe their contribution to electrocatalytic reactions such as methanol oxidation in a potentiodynamic experiments (cyclic voltammetry). This finding allowed the evaluation of the different facets of the surface towards methanol oxidation, showing that the reaction is mainly performed on the {111} terraces, contrary to the stablished notion that claim the high-energy defects are the most reactive spots. In conclusion, using cavity microelectrodes and under-potential deposition as a tool, it was possible to characterize the structure of the surface structure of internal surfaces in NPG and the reactivity of the different facets, taking advantage of the partial coverage of the surface achieved by controlling the bulk concentration of the lead.

Hollow titania nanopillars as a flexible platform for encapsulation

Jakub Wawrzyniak, Piotr Kupracz, Jakub Karczewski,
Emerson Coy, Katarzyna Grochowska, Katarzyna Siuzdak
The Szewalski Institute of Fluid-Flow Machinery, Polish Academy of Sciences
Fiszera 14 st, 80-231 Gdańsk, Poland
jwawrzyniak@imp.gda.pl

The titania nanostructures are primarily known for their potential as photoactive materials, due to their stability, corrosion resistance and flexibility of their morphologies. Their main drawback, however, is the wide electron bandgap, which greatly limits their immediate usability in the light-driven processes. Therefore, various methods of their modification have been explored, focusing on improving their overall absorption and carrier separation. For example, doping with foreign atoms [1], creating defects and vacancies [2], and introducing rib-like photonic structures [3] have all shown promise in regards to improving photoactivity of the titania nanotubes.

Today, we present an alternative method of modification of laterally spaced titania nanotubes via laser irradiation. The presented approach allows for a fast and scalable encapsulation of the nanotubes, trapping any material previously embedded within their interior. The created tightly-sealed nanostructure can be used either as a way to separate and protect sensitive material from the harsh environment, or to enhance absorption through the introduction of an extra scattering medium, like plasmonic metal nanoparticles. Moreover, the distinct separation between nanopillars, enables them to be detached from the surface independently, allowing them to be used as self-standing capsules, rather than nanopillar arrays if the application calls for it.

The newly developed hollow titania nanostructures can find success not only in conventionally research applications but also, through the versatility and biocompatibility of the titania, in biomedical applications.

Fast Electron Transfer Kinetics in Deep Eutectic Solvents: Effect of Water Addition

Fangchen Zhen,[1] Corinne Lagrost,[1] Jia-Wei Yan[2], Bing-Wei Mao,[2] Philippe Hapiot[1]

[1]Univ Rennes, CNRS, ISCR-UMR 6226 Campus de Beaulieu, Bat 10C, 35042 Rennes Cedex, France

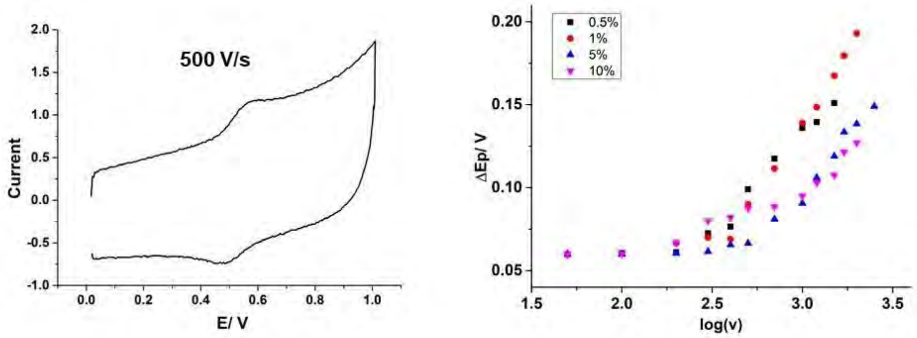
fangchen.zhen@univ-rennes1.fr

Deep eutectic solvents (DESs) are an emerging class of solvents, which is considered as sustainable and cheap alternatives to ionic liquids.(1) DESs generally consist of mixtures of salts and hydrogen bond donors producing eutectics at optimized ratio that are liquid at ambient temperature and have unusual solvent properties. Hydrogen bonding between hydrogen-donor and hydrogen-acceptor is supposed to cause the strong decrease in the melting point of the eutectics. Water amount in DESs strongly affects its physicochemical properties from density, viscosity, melting point, surface tension to conductivity,(2) while being part of DESs composition. Recent results from literature have shown that DESs' nanostructure is varied according to the amount of water present in DES.(3) It is known that DESs spontaneously absorb water when exposing in the air, to a certain extent depending on the hygroscopicity of its components. It is therefore interesting to analyze effects of water concentration on electron transfer kinetic rate constants. This point is not only a concern for fundamental molecular electrochemistry but is also meaningful for practical utility.

In a recent publication, we demonstrate that electron transfer kinetics rate constants involved in two classical oxidation reactions of ferrocene and ferrocyanide in ethaline were remarkably larger than those in ionic liquids while being comparable to values obtained in molecular solvents.(4) In this work, we will study the kinetics of oxidation of ferrocene and ferrocyanide in five DESs, including Ethaline, Reline, Glyceline, choline chloride (ChCl)-lactic acid and ChCl-malonic acid by varying the water amounts from 0.5 wt% to 10 wt% with a particular consideration of ohmic drop compensation. The extracted data in DESs shows that kinetic rate constants values considerably increase with the addition of water in DESs. Electron transfer kinetics increases much faster for the ferrocene/ferrocenium redox couple than for ferrocyanide/ferricyanide redox couple with the addition of water amount in all the five DESs.



Cyclic voltammogram and ΔEp-log(v) curve of ferrocene in Ethaline for different water additions.

luca.mattarozzi@cnr.it

Bimetallic alloys are attracting much interest for the production of efficient and cheap materials, applicable to many areas. In this context, Ag-Ni alloys are promising for applications in electric/magnetic devices and (electro)catalysis [1]. Ag and Ni have both face-centered cubic (fcc) structure, however due to large difference in atomic radii, they do not exhibit solubility at equilibrium in the solid state. Electrodeposition may generate materials of structure or composition far from thermodynamic equilibrium, made stable by their (very) slow rearrangement at room temperature [2]. However, the deposition of Ag-Ni films is complicated by a fairly large difference in standard reduction potentials, respectively 0.799 V for Ag and -0.25 V for Ni (vs NHE). Cyanide baths were used in the past to deposit Ag and Ag-based alloys, for their strong complexing action of Ag^+ ions, leading to deposition of compact films, but nowadays less dangerous solutions are preferred, both for safety and environmental concerns. Ag-Ni thin films were already electrodeposited from baths containing thiourea as complexing agent, obtaining quite compact films but also undesired sulfur inclusions up to 20% [3].

We propose here the electrodeposition of Ag-Ni alloys from concentrated chloride baths, already used in the past for deposition of Ag-Pt and Ag-Pd alloys [4]. Concentrated chloride media may dissolve various metal ions and, in the specific case, the Ag-chloride complexes $[Ag(Cl)_n]^{(1-n)-}$ are more stable than the Ni ones, bringing closer the reduction potentials and promoting co-electrodeposition.

Linear sweep voltammetries of Ag-Ni electrodeposition performed in 10 M chloride baths indicate that alloy formation occurs under transport-limited reduction of silver complexes, so that films of desired composition may be obtained by regulating the deposition current j_{dep}. The obtained films have good compactness, with globular morphology (Fig.1, left); moreover, microanalysis indicates that they are free from foreign species. XRD spectra indicate the presence of two crystalline phases, one Ag- rich and the other Ni-rich (only for Ni >50 at%) with minimal inclusions (few atoms %) of the minority species. Tests of nitrate reduction, based on linear sweep voltammetries (Fig. 1, right) and constant potential electrolyses, were performed on an alloy of approximate composition $Ag_{30}Ni_{70}$, with a significant yet limited Ag content. The main observations from these tests are: a) lower overvoltages for nitrate reduction with respect to pure Ni; b) marked increase of reduction current with respect to both Ag and Ni, in a broad potential region; c) better selectivity to NH_3 production and lower H_2 evolution.

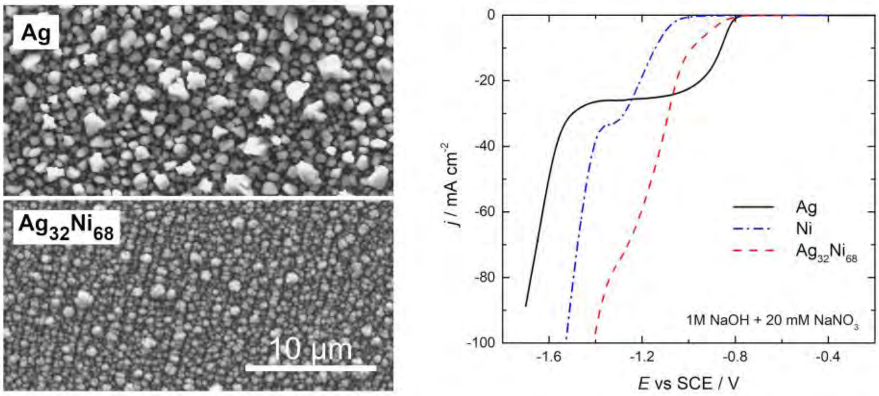

Fig. 1: SEM images of Ag and $Ag_{32}Ni_{68}$ samples from conc. chloride medium (left), and LSV of NO_3^- reduction on Ag, Ni and $Ag_{32}Ni_{68}$ cathodes in 1 M NaOH (right).

Effects of Melamine Adsorption on Activity of Pt/Pd/C Core-Shell Catalyst

Minoru Inaba,[1] Hideo Daimon,[1] Masafumi Asahi,[2] Shin-ichi Yamazaki,[2] Tsutomu Ioroi[2]
[1]*Dept. Molecular Chemistry and Biochemistry, Doshisha University, Kyotanabe, Kyoto 610-0321, Japan*

minaba@mail.doshisha.ac.jp

In a NEDO project "Advanced Technologies for Reduction in Pt Usage (FY2015-19), we have developed highly active catalysts based on the core-shell technique. We have so far developed a new preparation method (the direct displacement (DD) method), which is suitable for mass production of Pt/Pd/C core shell catalysts as well as an activation method (the H_2-O_2 gas-switching method) and polydopamine coating for improving the durability[1-4].

One of the problems in the DD method is the parasitic formation of large Pd particles, which spoils the activity of the resulting Pt/Pd/C [4]. We overcame this problem by the use of an improved Pd core particles (Ishifuku Metal Industry) that have much less fine Pd particles, and obtained a very high mass activity (1,685A/g-Pt, 775A/g-PGM) after activation using high activation protocol (HAP, rectangular wave, 0.05 V (300 sec)-1.0 V (300 sec), 80°C, 50 cycles). Furthermore, we increased the Pd core loading from 30 to 46 wt% using Ketjenblack EC-600JD (1600 m^2/g), and obtained good MEA performance (0.1 mg-Pt/cm^2, 80°C) shown in Fig. 1. The performance at 1.0 A/cm^2 was 3.7 times higher than that of Pt/C catalyst; that is, it is comparable to the performance of Pt/C at a loading of 0.37 mg/cm^2. The performance at high current densities are significantly improved (2.0 A/cm^2 at 0.6 V) as well.

We developed a novel activation method, in which Pt surface is modified with N-containing organic compounds [5-7]. One example is shown in Fig. 2, where melamine molecules [5] were adsorbed on the surface of Pt/Pd/C. Without melamine adsorption, the mass activity was 1,460 A/g-Pt. After melamine was adsorbed, it increased to 3,625 A/g-Pt (x 11 of Pt/C, 1,673 A/g-PGM). Water adsorption on Pt(111) is a strong inhibitor for the activity for ORR. Melamine is weakly adsorbed on Pt surface, and suppresses the adsorption of water, which resulting in the high ORR activity shown in Fig. 2.

Effects of $Ti_3C_2T_x$ Nanosheets (MXenes) in the Electrocatalytic Activity of SnO_2/Ti Anodes for the Degradation of Methyl Red

S. González-Poggini, Andreas Rosenkranz, M. Colet-Lagrille
Department of Chemical Engineering, Biotechnology and Materials, Faculty of Physical and Mathematical Sciences, Universidad de Chile
Beauchef 851, Santiago, Chile
sergio.gonzalez.p@ug.uchile.cl

In recent years, electrocatalytic advanced oxidation processes have received growing attention for wastewater treatment. In this context, various metal oxide-coated anodes have been studied for anodic oxidation of pollutants in wastewater exhibiting excellent electrocatalytic activity. Among them, SnO_2-coated anodes have shown a high electrocatalytic activity for the generation of hydroxyl radicals ($^{\bullet}OH$) and ease of fabrication [1].

In addition, $Ti_3C_2T_x$ nanosheets (MXenes) are a two-dimensional material which application seems promising in batteries, supercapacitors and catalysis due to their high surface area and metallic conductivity [2, 3].

The present work aims to fabricate stable MXenes-SnO_2 electrodes by spin coating of a precursors solution on Ti substrates and to study the effects of the MXenes and cerium incorporation on the electrodes microstructure, electrocatalytic activity for the oxygen evolution reaction and the catalytic activity for the electro-oxidation of methyl red. The precursors solution contains MXenes particles, $SnCl_2$, $CeCl_3$, citric acid and ethylene glycol and after spin coating the electrodes are thermally treated in the presence of air.

The obtained electrodes are characterized in terms of morphology, chemical composition and crystallinity by scanning electron microscopy (SEM), energy-dispersive x-ray spectroscopy (EDS), Raman spectroscopy and x-ray diffraction (XRD). The electrochemical behaviour and electrocatalytic activity are characterized by cyclic voltammetry (CV) and electro-oxidation of methyl red (MR) experiments.

Electrodes characterization indicates the formation of a SnO_2-TiO_2 film when MXenes nano-sheets were added to the precursor solution (MXenes-SnO_2/Ti electrode) and a Ce-doped SnO_2-TiO_2 film with additional cerium incorporation (MXenes-SnO_2-Ce/Ti electrode). Furthermore, the addition of MXenes nano-sheets led to the incorporation of Ti^{4+} ions into the lattice of SnO_2 crystals. CV curves demonstrated that the oxygen evolution reaction is restrained in the MXenes-SnO_2/Ti and MXenes-SnO_2-Ce/Ti electrodes. The maximum MR degradation rate was achieved using MXenes-SnO_2/Ti electrodes, whereas the minimum was obtained for the MXenes-SnO_2-Ce/Ti electrodes. The enhanced catalytic activity verified for the MXenes-SnO_2/Ti electrodes can be attributed to the generation of oxygen vacancies in the crystal lattice, which act as charge carriers and increase the electrical conductivity of SnO_2.

The anion exchange membrane fuel cell (AEMFC) is an attractive alternative to its acidic counterpart, the proton exchange membrane fuel cells (PEMFC), and has recently received increasing attention. In principle, they allow the use of non-precious metal catalysts thanks to the high pH of the electrolyte, which reduces significantly the cost in fuel cell systems. Through the development of new materials the performance of AEMFC has increased substantially enabling competition with PEMFC regarding begin of life performance. However, the long-term stability of AEMFC is one of the remaining challenges for this technology.[1-2]

The improvable stability under fuel cell operation is mainly related to the degradation of the anion exchange membrane (AEM) and the anion exchange ionomer (AEI), which were identified as crucial components in AEMFC. They are composed of nanostructured polymer backbones with positively charged functional groups, typically based on quaternary ammonium functionalities, distributed along the polymer chain. While their hydroxide (OH^-) conductivity has reached satisfying values, the most critical issue is that the molecular structure of the membrane itself decomposes due to the presence of the highly nucleophilic OH^-.[3] The nucleophilic attack is enhanced at low content of water coordinating the hydroxide ion which occur at high current density operation of AEMFCs.[4-5] These findings highlight the need of more stable polymer materials, characterisation techniques that enable stability studies under conditions simulating AEMFCs in operation and investigations of the long-term stability at single cell level.

In this contribution, the voltage decay over the operation time was investigated at the single cell level allowing the evaluation of the performance stability under fuel cell conditions. Membrane electrode assemblies (MEA) were prepared using different membrane materials and characterized by the application of developed test protocols. The degradation of polymer components was accelerated by the distinct application of harsh conditions. Possible degradation pathways of the MEA dependent on the applied parameters were enlightened by *in situ* electrochemical impedance spectroscopy and widespread *ex situ* testing at end of test conditions. Morphological changes were determined with µ-computed tomography and atomic force microscopy. Degradation products of the AEM and AEI were detected by ion chromatography of the exhaust water. Spectroscopic techniques were applied to investigate structural changes of the membrane. This combination of measurements under AEMFCs condition and distinguished analytical tools contributes to a more comprehensive understanding of AEMFC long-term stability.

a.trivino@icv.csic.es

Yttrium-doped barium zirconate (BZY) is one of the most promising materials for electrolytes in protonic ceramic fuel cells (PCFCs) in the intermediate temperature range (400-700ºC) due to its high proton conductivity in humid atmospheres and its good chemical stability against acid gases such as CO_2 in typical PCFC operation conditions. However, chemical stability may be further enhanced on incorporation of halogens, reducing the basicity of the perovskite-lattice. Employing conventional sintering techniques and powders, temperatures around 1700°C are required to obtain ceramic pellets with sufficient densification (> 95% relative density). Alternative methods such as sol-gel synthesis allow the preparation of the yttrium-doped barium zirconate powder at low temperature (700ºC) with higher reactivity. In this study, the $BaZr_{0.8}Y_{0.2}O_{2.9-x/2-\delta}M_x$ series (M = Cl, F and x = 0, 0.1) were prepared by a modified sol-gel method based on alkoxide routes in order to study the influence of the halogen dopant on both microstructural and electrical properties. Pellets and thin-films were obtained by a combination of dip-coating and sol-gel synthesis by low-temperature thermal annealing at 1000ºC, and single BZY phase without barium carbonate was obtained. The combination of sol-gel and dip-coating methods may be a promising alternative for the fabrication of BZY proton conductors.

Controlled electrodeposition of nanoscale n-Si/metal Schottky junctions for water dissociation

Kiseok Oh,[1] Olivier. de Sagazan,[2] Gabriel Loget[1]

kiseok.oh@univ-rennes1.fr

Silicon (Si) is an attractive electrode material for manufacturing photoelectrochemical cells (PECs) because it has a small bandgap, it is very abundant and widely used in the photovoltaic industry. Nevertheless, using Si as a photoanode for oxygen evolution reaction (OER) is highly challenging as Si surface is particularly prone to deactivation by spontaneous oxidation and chemical etching. In order to solve this matter, conformal surface protection methods have been applied by several processes (e.g. chemical vapor deposition, atomic layer deposition, sputtering or evaporation[2]).

Recently, ourselves and others have reported that transition metals (Ni[1a,b], Fe[2] and Co[3]), electrodeposited on n-type Si from aqueous solutions. In the form of isolated nanoparticles (NPs) to create nanoscale Schottky contacts enable to perform OER for several hours under simulated sunlight at pH 14. Actual knowledge suggest that these surfaces behave according to the pinch-off model, which predicts a strong dependence of the NPs size and their respective spacings on the photoelectrode property[4][5]. However, the typical electrodeposition procedures that were used so far led to randomly-dispersed arrays of metal NP onto n-Si. Using this methods, the geometrical parameters of individual Schottky junctions and their respective spacing cannot be accurately controlled.

The lithographically patterned nanowire electrodeposition (LPNE) method combines basic photolithography steps with electrodeposition. It allows to fabricate high aspect-ratio nanowires vertically aligned on a substrate[6]. In this work, we adapted this process to n-Si wafers in order to create a series of photoanodes with controlled nanoscale n-Si/metal contacts. In this presentation, we will present this method and discuss our last results which aim to provide a better general understanding of these outstanding junctions.

Preventing Thermal Runaway in Lithium-Ion Batteries through Functionalisation of Passive Materials and Components

Min Zhang [a], Andrew L. Hector [a], Nuria Garcia-Araez [a], Denis Kramer [b], John R. Owen [a]
[a] *Chemistry, University of Southampton, Southampton SO17 1BJ, United Kingdom*
[b] *Engineering, University of Southampton, Southampton SO17 1BJ, United Kingdom*
mz1e18@soton.ac.uk

Lithium-ion batteries are widely used in portable electronic devices, electric vehicles and distributed energy storage systems due to their high energy density, high power density and light weight.[1-3] The safety concern is the main obstacle that hinders the large-scale applications of lithium-ion batteries in electric vehicles and energy storage systems. The cascading thermal runaway is the most catastrophic safety failure of lithium-ion batteries. Thermal runaway can occur due to the electrical abuse such as short circuit and overcharge/over-discharge, thermal abuse like exposure to excessive temperatures, and mechanical abuse like crush or penetration of the battery pack. It can release toxic and flammable gases, generate heat, cause fire and even explosion. For large-scale applications of lithium-ion batteries, the thermal runaway of one failed battery can cause a thermal cascade throughout the battery pack.

To prevent the thermal runaway in lithium-ion batteries, we functionalised the passive materials and components instead of the active materials to maintain the full choice of active materials and obtain enhanced safety and lifetime without compromising on power density, energy density or cost. The positive temperature coefficient of resistivity (PTCR) additives were introduced into battery electrodes to replace the conductivity additive (e.g. carbon black) or as coatings on the active materials. PTCR material exhibits a raised electrical resistance as the temperature increases. When the electrode temperature passes a threshold value, the PTCR embedded electrodes become non-conducting to interrupt electron pathways, suppress all electrochemical reactions and impede further temperature increases, thus preventing thermal runaway in lithium-ion batteries.

NiO thin film electrodes were successfully prepared by magnetron sputtering (MS) deposition under an oblique angle configuration (OAD). Intercalation of Na ions in the nickel oxide layers has been studied using electrochemical techniques (cyclic voltammetry, galvanostatic discharge-charge cycles and electrochemical impedance spectroscopy). Sample characterization before and after sodium intercalation has been carried out by SEM, micro-Raman, XPS, RBS and XRD measurements. The porous structure of the films is confirmed by electron microscopy evaluation. The increasing of the cycle's number leads to a continuous reduction of the discharge capacities due to some amount of Ni^0 and Na_2O produced during the discharge process remains in the electrode and does not participate in the charge process. Sodium half cells have shown a discharge capacity of 465 mAh g^{-1} after 16 cycles at 400 mA g^{-1} between 0.01 and 3.00 V (vs. Na^+/Na).

High-Efficient Cathode Catalysts of Li-CO_2/O_2 Batteries

Peng-Fang Zhang[1], Jun-Tao Li[1], Shi-Gang Sun*[1,2]
[1]College of Energy and [2]College of Chemistry and Chemical Engineering,
Xiamen University, Xiamen 361005, China
e-mail address: sgsun@xmu.edu.cn

Li-O_2 battery and Li-CO_2 batteries hold high energy density of 3500 and 1876 Wh kg^{-1}, respectively, and are promising new generation of energy storage systems[1]. For the Li-O_2 battery, trace of CO_2 in air (environment) will result in inevitably the formation of side product Li_2CO_3, which leads to severe degradation of batteries and limits the cycleability. While the discharge products of Li-CO_2 battery are Li_2CO_3 and C[2]. Therefore, investigation of the properties of the Li_2CO_3 based on the Li-CO_2/O_2 batteries is significant for the rational design of cathode catalysts to enhance the cyclicity performance of of Li-CO_2 and Li-O_2 batteries. In this work, 3 different catalysts, Ru/NC，Ru/NiO@Ni/CNT and Pt/CNT were prepared based on consideration of the uniform distribution, the synergetic effect and the high activity of catalytic sites. The results demonstrated that the designed and prepared catalysts exhibit high activity for the decomposition of Li_2CO_3 and have significantly improved the cycleability.

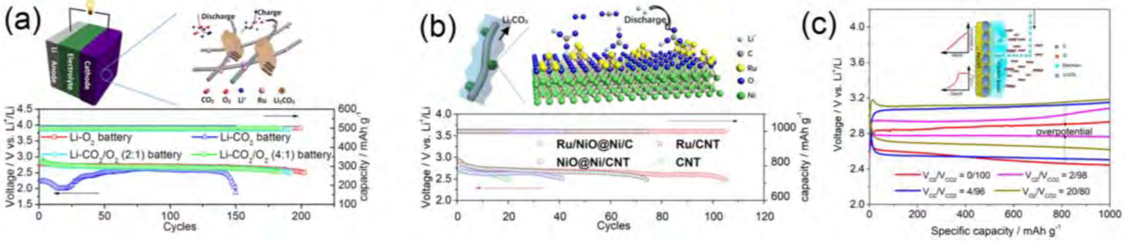

Figure 1 The performance of Li-CO_2/O_2 batteries with (a) Ru/NC, (b) Ru/NiO@Ni/CNT, Ru/NC, NiO@Ni/CNT, CNT and (c) Pt/CNT catalysts.

(1) Ru/N-doped carbon nanotube (Ru/NC) catalyst. It was prepared by solvothermal method. The Ru nanoparticles are uniformly distributed on the surface of NC (Figure 1a). The Li-CO_2/O_2 battery with this catalyst operated with $V_{CO2}:V_{O2}$= 4:1 presents an overpotential of 1.06 V and could be cycled smoothly for 184 cycles at 500 mAh g^{-1}. XRD and SEM characterizations reveal that the as-generated Li_2CO_3 can be effectively decomposed by the Ru/NC catalyst. Besides, with Ru/NC catalyst, the Li-CO_2/O_2 battery operate with different $V_{CO2}:V_{O2}$ ratios ($V_{CO2}:V_{O2}$= 0:1, 2:1 and 1:0) also show enhanced cycling stability of 200, 190 and 150 cycles, respectively.

(2) Carbon nanotube supported Ru/NiO@Ni catalyst (Ru/NiO@Ni/CNT). It was synthesized with Ru nanoparticles (~2.5 nm) anchored on the surface of core-shell structure NiO@Ni nanoparticles (~17 nm). The Li-CO_2/O_2 ($V:V$=4:1) batteries with Ru/NiO@Ni/CNT catalyst has delivered a long cycling life of 105 cycles at a cut-off capacity 1000 mAh g^{-1} with overpotential as low as 1.01 V, demonstrating a strong synergetic effect between the Ru and NiO species in electrocatalytic decomposition of Li_2CO_3 (Figure 1b). Density functional theory (DFT) calculations indicates that the formation O_2 is the rate determining step in RuO_2 promoted electrochemical decomposition of Li_2CO_3. Furthermore, the formation and decomposition process of Li_2CO_3 on Ru/NiO@Ni/CNT catalyst was illuminated at a molecule level by *in-situ* FTIRs spectroscopy.

(3) Pt/CNT catalyst. It was prepared by deposition of 2.5 nm Pt nanoparticles uniformly on CNT. DFT analysis indicates that the formation of O-O bond in Li-CO_2/O_2 battery and the generation of C-O bond in Li-CO_2 battery during Li_2CO_3 decomposition are the rate determining steps, respectively. When using Pt/CNT catalyst as cathode in the Li-CO_2/O_2 battery with 2% O_2 content, the ever lowest overpotential of 0.3 V and stability of 128 cycles at 1000 mAh g^{-1} have been achieved (Figure 1c). The formation (2.5 V) and decomposition (3.2 V) of Li_2CO_3 have been studied at molecular level using *in-situ* FTIR spectroscopy.

This study if of significance in development of highly efficient cathode catalysts of Li-O_2 batteries.

Novel single-ion conducting polymer electrolyte for lithium-metal batteries

Xu Dong, Zhen Chen, Xinpei Gao, Alexander Mayer, Haipeng Liang, Dominic Bresser, Stefano Passerini

Helmholtz Institute Ulm (HIU), Helmholtzstrasse 11, 89081 Ulm, Germany
Karlsruhe Institute of Technology (KIT), P.O. Box 3640, 76021 Karlsruhe, Germany

Email: xu.dong@kit.edu

Lithium-based batteries are now increasingly employed in portable electronic devices, (hybrid) electric vehicles (EVs) and stationary energy storage. This rapidly expanding list of potential applications and the consequent rise in number of battery cells needed demands for more efficient, safe and environmentally friendly battery systems. Among different battery technologies, polymer electrolytes are being intensively studied for use in solid-state lithium-metal batteries to power electronic devices, including EVs.[1-3]

In this work, the design of a new single-ion conducting polymer electrolyte is presented. The very facile synthesis is environmental-friendly and cost-efficient, involving only a very limited number of steps. The polymer electrolyte is based on a (commercial) polysulfone backbone with covalently tethered fluorinated side chains bearing the ionic function. The resulting single-ion conductor is blended with ethylene carbonate (EC). The chemical structure was confirmed by nuclear magnetic resonance (^{1}H-NMR and ^{19}F-NMR) spectroscopy. Following a comprehensive physicochemical and electrochemical characterization, revealing inter alia an electrochemical stability window of ca. 4.75 V and an ionic conductivity of $1.5*10^{-4}$ S cm^{-1} and $2.4*10^{-4}$ S cm^{-1} at 30 °C and 40 °C, respectively, the applicability of this electrolyte for high-energy Li/NMC$_{622}$ cells was evaluated. The cells provide a specific capacity of more than 160 mAh g^{-1} at C/20 and stable cycling at C/5, indicating that this new electrolyte may serve the realization of intrinsically safer, high-performance lithium-metal batteries.

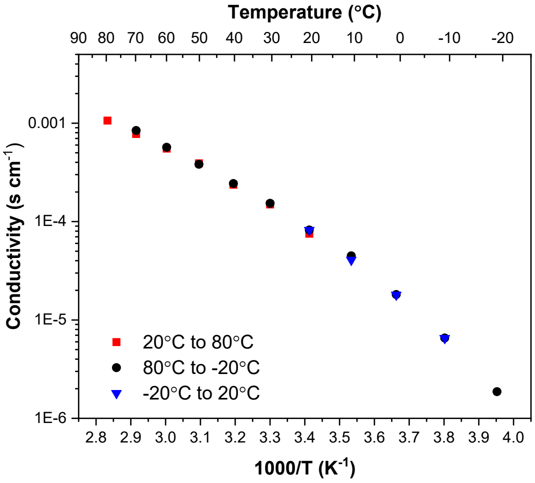

Fig. 1. *Ionic conductivity of the single-ion conducting polymer electrolyte comprising 37.5 wt% of EC as a function of temperature.*

New models for the Electrochemical Double Layer of the Pt(111)-Aqueous Electrolyte Interface

Kasinath Ojha* and Marc T.M. Koper

Leiden Institute of Chemistry, Leiden University, 2300 RA Leiden, The Netherlands.

* *email: kasi_chemistry@yahoo.com*

Atomic/molecular level understanding of the double layer, interfacial water structure such as organization and orientation, H-bonding network at the metal-electrolyte interface is of utmost importance for fundamental electrochemistry as well as for technological applications[1–3]. The interfacial water structure at the metal-electrolyte interface is the most important part of the double layer structure which governs all kind of interfacial physio-chemical properties and processes. Pt is the most studied and applied metal in energy conversion, electrocatalysis, and electroanalytical sensing. The double layer structure of Pt is still incompletely understood although it has been investigated for more than 50 years. Recently, we discovered the minimum of the Gouy-Chapman capacitance on Pt (111) for the first time and directly identify the potential of zero charge of Pt(111)[4], which is an important intrinsic property of an electrode material. Similar experiments were demonstrated to observe the GC capacitance and pzc of Au(111) which is in good agreement with the literature[5]. The inner layer and diffuse layer capacitance of Pt(111) are significantly higher than that of Au(111) and mercury. By comparing the diffuse layer capacitance of Pt(111), Au(111), Ag(111) and Hg, we understand that Pt(111) is better screened by the ions (electrolyte) at the interface (outer Helmholtz layer). This is due to the interfacial water-ion interactions following reverse Hofmeister series which is investigated by using non-specifically adsorbing anions (e.g. perchlorate, fluoride, methanesulfonate) and their concentration contributing to the double layer capacitance of Pt(111)[6]. The presentation will discuss these new data in detail and will suggest a new model of the Pt(111)-electrolyte interface.

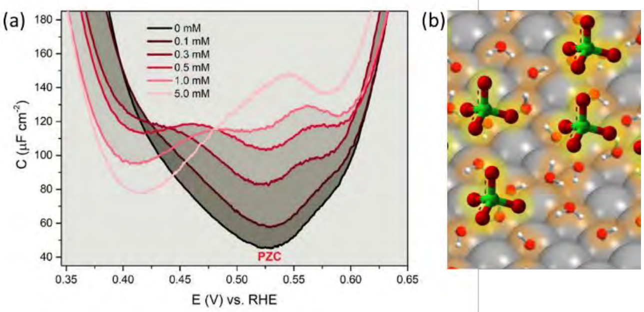

Figure 1. (a) Capacitance curves of Pt(111) in $HClO_4$ electrolyte (pH = 4) showing GC capacitance minimum at PZC (b) schematic of Anion-water (interfacial) interactions on Pt(111).

Voltammetry of cobalt(II) complexes with naturally present organic ligands in seawater

Anđela Bačinić and Marina Mlakar
Rudjer Boskovic Institute
Bijenička 54, 10 000 Zagreb
abacinic@irb.hr

Cobalt (II) as an essential element and important for biochemical processes in the marine environment, is bioavailable in its dissolved form. At present it is known that cobalt in seawater is partially, but strongly complexed to natural organic ligands (binding place for cobalt is very possible a nitrogen-containing functional group). Dissolved cobalt(II) is biologically important element for marine organisms (for their biochemical and physiological functioning). Despite its abudance in oceans, dissolved Co^{2+} is present in low concentrations, $<10^{-9}$ mol L^{-1}, mostly as soluble organic complex. [1,2] Electrochemical characterization of cobalt (II) complexes in model aqueous solution (0.55 mol dm^{-3} NaCl) was performed using square wave and cyclic voltammetry on mercury drop electrode.

Results on complexation and electrochemical reaction mechanisms of cobalt (II) complexes with 4-nitrocatechol, humic acid, glutathione and 1,10-phenanthroline, as ligands appearing in the marine system, will be presented. All used ligands are biologically important molecules. Catecholates, ortho-dihydroxybenzene and 4-nitro-dihydroxybenzene are present as a structural part of complex marine ligands (humic acid, siderophores, etc.). Humic substances as heterogeneous biomolecules are a characteristic component of the dissolved organic carbon (DOC) pool important for phytoplankton communities in seawater. [3] Glutathione is present in eukaryotes and some prokaryotes (cyanobacteria and purple bacteria) and makes up > 90 % of non-protein thiols in plants and algae [4], while 1,10-phenanthroline is an inhibitor of metallopeptidases. [5]

All of these Co(II) complexes are electroactive and give a reduction response on a voltammograms (square wave and cyclic) from E_p = -0.9 to -1.1 V.
Mechanisms and stability constants of complexes were determined. While reduction reactions with 4-nitrocatechol and humic acid were irreversible, reduction reactions with glutathione and 1,10-phenanthroline showed reversible/quasireversible behavior. Using CLE/ACSV method were calculated stability constants for Co(II)4NC and Co(II)HA_2 complexes, (log $K_{Co(II)\,(4NC)2}$ = 21.86 (pH = 8.2), log $K_{Co(II)\,(4NC)\,2}$ = 21.11 (pH)= 6.5), log $K_{Co(II)\,(HA)2}$ = 11.32 (pH = 8.2)). For other complexes calculations are in process.

Recently, application of advanced oxidation technologies (AOTs) for environmental purification have received growing attention [1]. Especially electrolysis with boron-doped diamond (BDD) electrodes make it possible to generate various highly active oxidants such as O_3 which can oxidize aqueous contaminants [2]. In this study, we introduce recent studies about environment-friendly "AOT-treatments" of textile by using of O_3-water with UV irradiation instead of conventional treatments (scouring and bleaching) with environmentally persistent reagents. Fig. 1 shows the photographs of cotton bleaching by AOT. Cotton fabrics were treated by O_3-water (1.0 ppm, 1.5 L/min, continuously generated from tap water) with UV irradiation (170 mW/cm^2 @310-380 nm). After treatments, the fabrics were dried under room temperature and analyzed by reflection spectra. Fig. 2 left shows the reflection spectra and photographs of cotton fabrics. After 60 min of AOT, the spectrum and whiteness of the cotton are almost the same with conventional chemical-bleached one. But the only problem is "color reversion" by ironing (heating around 200°C). Heating of oxidized cellulose generates conjugated systems and yellow color (Fig. 2 right, green line). However, we found that reduction of oxidized cellulose by rongalite can prevent color reversion (Fig. 2 right, red line). Therefore, AOT-treatment is attractive to reduce energy consumption and cut waste in the fabric processing.

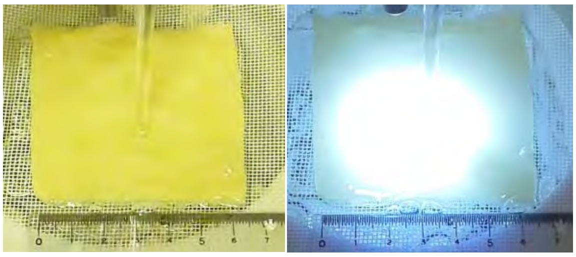

Fig. 1. Cotton bleaching by O_3-water treatment (left) and O_3-water with UV irradiation (AOT, right).

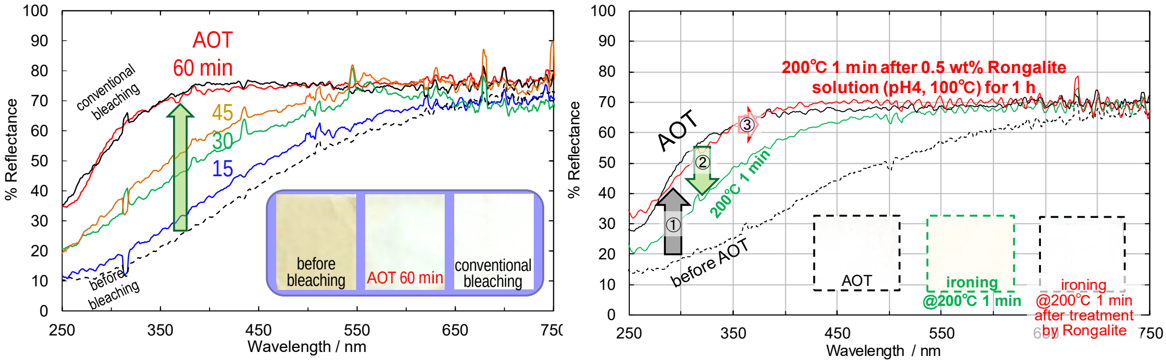

Fig. 2. Reflection spectra and photographs of cotton fabrics. (left) Comparison of AOT and conventional chemical bleaching. (right) Effects of rongalite-reduction for preventing of color-reversion by heating.

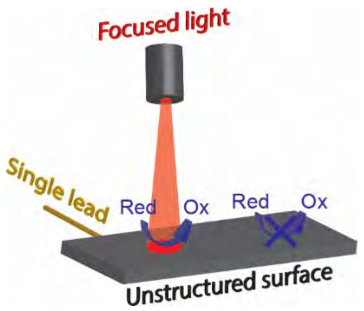
Spatiotemporal Confinement of Redox Reactivity at the Silicon–Electrolyte Interface by a Light Stimulus

Yan B. Vogel, Simone Ciampi
School of Molecular and Life Sciences, Curtin Institute of Functional Molecules and Interfaces, Curtin University, Bentley, Western Australia 6102, Australia.
yanboris.vogel@curtin.edu.au

Chemical reactivity is often discussed and studied in the context of mixing bulk reactants in a homogeneous media. However, specific applications require confining a chemical reaction, or a cascade of reactions, at a precise location and at a certain moment. For instance, localizing chemical reactivity is required to maintain life – a state of low entropy or high organization – and all biological systems rely on chemical triggers that are accurately addressed and confined in space and time. Mimicking such natural processes by triggering or stopping chemical reactions in precisely selected areas have answered everlasting questions of molecular and cell biology.[1] The spatiotemporal control of chemical reactions is also a central feature to man-made systems; many current technologies, ranging from biomedicine to photolithography pivots around means of spatiotemporally controlling chemical reactivity.[2] However, triggering transient chemical changes at a specific microscopic site over a macroscopic substrate remains challenging.



Focusing mainly on heterogeneous redox chemistry, we have shown that chemical reactions can be addressed with spatiotemporal control on a semiconductor surface without the need of physical probes or photochemical reactions.[3] For this, we take advantage of the property of semiconductors to generate charge carriers upon illumination. Driven by an electric field, the photogenerated charge carriers are transferred to redox species in the solution in contact with the semiconductor surface. A focused light stimulus is used to generate localized transient fluxes of charge carriers, hence triggering a chemical change in the species near the interface with spatiotemporal resolution. We developed an optical/electrochemical system to localize the light stimulus and hence the chemical reactivity.[4]

We demonstrate the versatility of this "light addressable" principle first by assembling patterns of nanoparticles with adjustable morphology and interparticle spacing over space.[5] Nanoparticle arrays are formed in a single-step, within seconds, with a resolution of few microns, and without the need of physical masks or templates. Furthermore, shining light on a semiconductor to localize a redox reaction was used to interrogate its surface activity.[4] The photocurrent recorded is linked to the local surface activity, and was used to construct redox chemical microscopy images. Driving and reading redox reactions over space using light was also explored in the context of chemical analysis. Analytical models were developed to interpret the photocurrent – voltage data acquired in photoelectrochemical systems.[6-7]

Our latest research focuses on the spatiotemporal control of chemiluminescent reactions. Unlike fluorescence, spatiotemporal control of chemiluminescence is an unmet challenge. As a result, fluorescence remains the dominant microscopy technique. However, major drawbacks of fluorescence are absent in chemiluminescence, potentially giving it a significant advantage over fluorescence in the field of microscopy. By means of a focused light stimulus delivered to the sample from the opposite side under analysis we provide a strategy for removing interference between excitation and emission lights, light-induced sample damages, photobleaching and autofluorescence, all commonly encountered in fluorescence microscopy.

The traditional Lithium Ion battery (LiB) technology has approached its maximum in energy and power density in the last years. Several emerging new generation material systems and technologies such as All-Solid-State Batteries (ASSB) have been proposed recently. The traditional liquid electrolytes of LiB are flammable, as they are based on organic solvents and do not provide mechanical strength to inhibit the growth of Lithium metal dendrites, which is the most important reason why the holy grail of battery technology, namely lithium metal anodes, have not been implemented in commercial systems. Pure lithium metal anodes have the highest theoretical energy density (3860mAh/g) and the lowest negative electrochemical potential of 3.04V (versus standard hydrogen electrode).

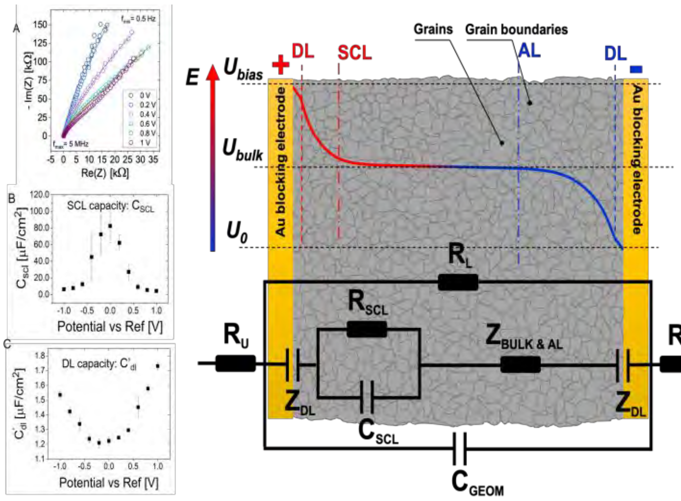

Fig 1: A) Impedance spectra for Au/LICGC[5]/Au cell under potential variation B) Space charge capacitances in the order of several dozens of microfarad. C) Double layer pseudo-capacitance with bias dependency. Right) Physical and Electrical Modell for a Solid Electrolyte showing the contributions of double (DL), accumulation (AL) and space charge layer (SCL) to the impedance equivalent circuit.

While stand-alone solid electrolytes, such as LATP and LAGP are stable in air, even with humidity and against metallic lithium a series of challenges are posed by the interface towards electrode materials. While highly planar interfaces of polished LAGTP glasses suffer from void formation upon cycling[1] and chemical decomposition is observed for sulfide solid electrolytes[2], a more underlying phenomena the so-called space charge layers have been theoretically predicted but not observed to date. A thermodynamic model[3], although neglecting direct coulomb interaction, suggest charge layers with a thickness of several hundred nanometers, while an electrochemical model[4] predicts a thickness of single nanometers. In this work, we present evidence of space charge layers in Ohara Glass[5] upon polarization in blocking conditions using Impedance Spectroscopy. An elaborated equivalent circuit, including two different charge accumulation (pseudo) capacitances, is used to fit impedance spectra to obtain the capacitances, and thus dielectric properties and thicknesses can be calculated. The space charge layer thickness is approx. 60nm leading to a non-negligible interface resistance.

Electro photo sensitive smart nanobiocomposit based on DNA super coil/metal/aptamer spiral lattice for early detection of CTC

Aboulfazl Mirzapoor[1]
[1]Department of Nanobiotechnology, Faculty of Biological Sciences, Tarbiat Modares University, P.O. Box 14115-175, Tehran, Iran
a.mirzapour@modares.ac.ir

Early detection of breast cancer is so much important to treatment of patient. Nano device with multiple application and special molecular properties have crucial role in developing of nanotechnology and nano biosensors. In this study, a new effective and conducive DNA super coil/metal/aptamer nanostructure and nanodevices designed and fabricated. DNA based nanospiral lattice fabricated with DNA super coil hybridized with Ag nanoparticles. This nanosubstrate immobilized with specific aptamer by non-covalent and covalent interaction. These self-assembled hybrid nanostructure could be used in nanowire, nanocapacitor and nanobiosensor fabrication. Hybrid and self-assembled nanostructure fabricated by region selective covalent combined between aptamer and DNA super coil/metal Nano structure. These hybrid nanostructures have different electrochemical properties compare of alone DNA super coil/metal and DNA super coil/metal/aptamer and also hierarchical DNA super coil/metal/aptamer/CTC. Electrochemical behavior of hierarchical hybrid DNA/nanostructures are studied by cyclic voltammetry and impedance spectroscopy technique. DNA super coil/metal/aptamer wire shaped nanostructure utilized for bio sensing of breast cancer CTC. Results showed DNA super coil/metal/aptamer hierarchical and self-assembled nanostructure is good candidate for biosensor fabrication. Exactly, DNA super coil/metal/aptamer wire shaped nanostructure used for BC CTC molecular biosensor.

Keywords: DNA based nanodevices, CTC biosensor, and DNA super coil/metal/aptamer.

Assessment of Electrochemical Reactors for the Removal of Sulphur Dioxide and Production of Sulphur from Synthetic Effluents

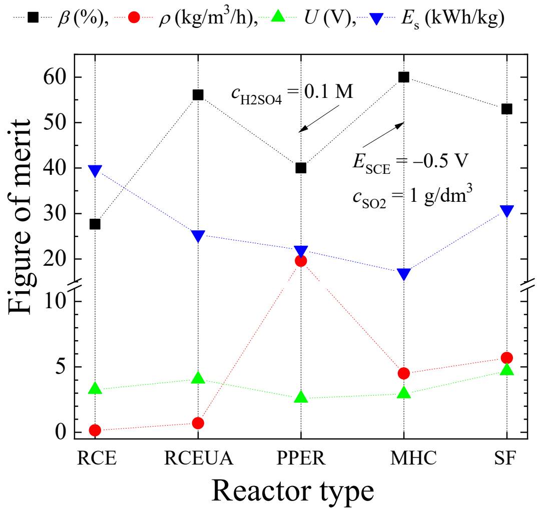
The combustion of fossil fuels for energy production and also several manufacturing processes produce sulphur dioxide as a gaseous effluent, which represents a deleterious agent for the environment requiring its treatment. Electrochemistry represents an interesting alternative for the abatement of the contaminant,[1] being desirable its transformation into useful species with commercial value. This concept can be achieved by electrochemical reduction of sulphur dioxide to colloidal sulphur, which is required for the fertilizer production and also in cosmetics, photographic, soap and dye industries. Additionally, the reduction of sulphur dioxide can also generate secondary compounds such as the polythionates, which present also practical applications.

The main issue for the electrochemical sulphur production is the passivation of the cathode due to its surface is covered with an insulating layer of sulphur which restricts the flow of current. Accounting that the reduction of sulphur dioxide in an acidic solution is mass-transfer controlled working under limiting current conditions in a narrow range of potentials,[2] it is inferred that the electrochemical reactor must have two-dimensional electrodes with good mass-transfer conditions. The reactors considered here are: rotating cylinder electrode, RCE, rotating cylinder electrode with ultrasound assistance, RCEUA, parallel-plate electrochemical reactor with a double convergent flow, PPER, modified hydrocyclone, MHC, and electrochemical reactor with decaying swirling flow, SF. The figure on the left-hand side compares parameters that characterise the performance of these reactors for the production of colloidal sulphur given by the mean values of: current efficiency, β, space time yield, ρ, cell potential difference, U, and specific energy consumption, E_s. One of the most relevant figures of merit is the space time yield showing the best value for the PPER. However, this reactor presents as a relevant problem the removal of the insulating layer of sulphur from the cathode surface. The rotating cylinder electrode shows a lower value of space time yield and the passivation can be avoided with application of ultrasound, improving the reactor performance. Reactors based on the modified hydrocyclone or swirling flow concepts present similar values of space time yield and specific energy consumption without cathode passivation in both cases due to the impingement effect of the helical flow. In the reactor SF it was used a large interelectrode gap, 24.15 mm, which contrasts with that for the MHC, 7.25 mm. In the design of the reactor with swirling flow, it has been privileged at the inlet an expansion swirl flow in order to improve the mass-transfer conditions. However, in counterpart the large interelectrode gap increases the reactor volume decreasing the space time yield and at the same time enlarges both the ohmic drop in the electrolyte and the cell potential difference, U, increasing the specific energy consumption. Thus, for the SF case the interelectrode gap can be further optimised for industrial applications. Then, it is concluded that the equipment with swirling flow represents the best option.



Working conditions: single phase flow, 5 g/dm^3 SO_2 in 0.5 mol/dm^3 H_2SO_4. E_{SCE} = –0.7 V. T = 30ºC. Unless otherwise is stated in the figure.

Novel cell design for operando pressure measurements of Li-ion battery materials

Niamh Ryall, J. Padmanabhan Vivek, Ben Rowden, Liam Lu and Nuria Garcia-Araez
University of Southampton
Highfield Campus, SO17 1BJ, Southampton, United Kingdom
n.garcia-araez@soton.ac.uk

Operando pressure monitoring of Li-ion batteries has been identified as one of the most important predictors of the cycle life of the battery [1,2]. This is because the formation of very small amounts of gases during the operation of Li-ion batteries, or irreversible changes in electrode volume, can have very detrimental effects in the battery performance. Unfortunately, highly sensitive monitoring of pressure changes in Li-ion batteries is only available for commercial or pouch cell configurations, which are not available in many research laboratories and require large amounts of materials to produce large electrode sheets for their fabrication.

Here, we present a novel cell design (Figure 1) that is cheap and readily available to any laboratory, and requires very small amounts of materials to fabricate the electrodes. The cell is simple and uses standard Swagelok parts that are commercially available, thus providing an advantage with respect to previous approaches [3,4]. The cell also provides unprecedented sensitivity for operando pressure measurements, which is achieved by minimizing the gas headspace volume. We illustrate the application of this novel cell design for the operando pressure measurements of $LiFePO_4$ and graphite in Li half-cell configurations, and we show that the results reveal the reversible changes in electrode volume associated to Li-ion insertion/extraction processes, as well as the amount of gases evolved during the formation of an SEI on graphite. Due to its simplicity and high sensitivity, we believe that this new cell design is ideally suited for screening novel materials/formulations for Li-ion battery applications.

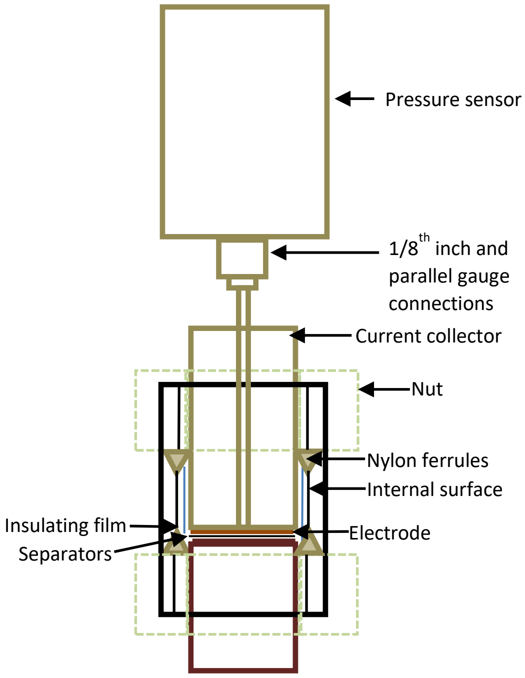

Figure 1. Sketch of novel and simple cell design for operando pressure measurements of Li-ion battery materials. By minimizing the connections between the cell and the pressure sensor, the gas headspace volume is kept at a minimum (1.9 ml in a one-inch diameter Swagelok cell).

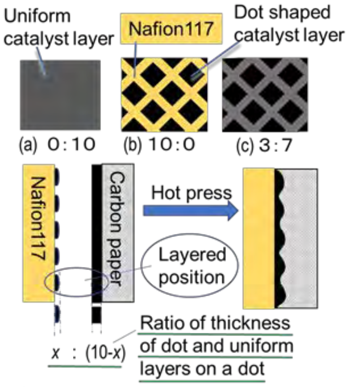
cel@ml.ynu.ac.jp

Introduction

Recently, the large-scale storage and transportation of hydrogen as secondary energy has been required for effective utilization of fluctuated and uneven distributed renewable energy. Toluene (TL)/ methylcyclohexane (MCH) organic hydride system is one of the candidates of hydrogen energy carrier. To improve the energy conversion efficiency for TL hydrogenation, we have studied direct hydrogenation of TL with water decomposition electrolyzer using proton exchange membrane.[1] To reduce the cell voltage and increase the current efficiency, we applied fine mesh anode based on ca 1.2 mm of strand width expanded metal. The ultrafine mesh anode based on sintered titanium fiber porous plate drastically reduced cell voltage. However, it decreased Faraday efficiency at the same tine. Uniform MCH layer, which was produced in the cathode catalyst layer with uniform structure of the anode, might block TL mass transfer into the catalyst layer. In this study, to improve TL mass transfer into the catalyst layer, the catalyst layer stacked for the dot shape and the uniform surface coating had been investigated.

Experimental

Figure 1 shows the structure of catalyst layer. The dot shape catalyst layer was formed on a proton exchange membrane (Nafion®117, DuPont), and uniform surface catalyst layer was formed on carbon paper (35BC, SGL carbon ltd.) using PtRu/C (TEC61E54, Tanaka Kikinzoku Kogyo). Catalyst metal loading was 0.75 mg cm^{-2} for the layered position. Thickness ratio of dot and uniform layers was indicated as *x*: (10-*x*). The anode was ultrafine mesh DSE® (De Nora Permelec, Ltd.). As a comparison, conventional fine mesh type DSE® was used. The anode and cathode compartments were circulated 1 mol dm^{-3} H_2SO_4 and 10% TL/MCH, respectively. The electrochemical measurements were conducted for the linear sweep voltammetry, the electrochemical impedance spectroscopy, the chronoamperometry to determine current efficiency at 60ºC.



(d) Cross-section of layered catalyst layer

Fig. 1 The structure of cathode catalyst layer.

Results and discussion

Figure 2 shows the cell voltage and current efficiency as a function of current density for various cathode structure. The low cell voltages with the ultrafine mesh anode are almost the same with various cathode catalyst layer structure compared with the cell voltage using the fine mesh anode. At this moment, the current efficiency improved with the dot layer structure, and 3:7 showed the highest in these structures. Cathode potential of 3:7 at a constant current efficiency was the lowest in these structures. From these results, the selectivity of hydrogenation should not be controlled by kinetics of charge transfer of the catalyst, but strongly affected by mass transfer process of TL in the catalyst layer. In this study, the optimized shape catalyst layer was 3:7.

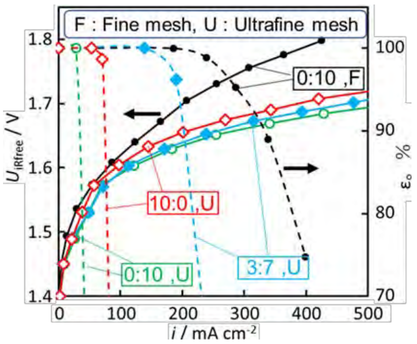


Fig. 2 Cell voltage (solid lines), and current efficiency (dashed lines) as a function of current density for x=0 (○, ●), and x=10 (◇) and x=3 (◆) shape cathode with each anode.

Bifunctional H-Bonding Cross-Linked Polymeric Binders for Silicon Anodes of Lithium-ion Batteries

Wen-Feng Ren[1], Jun-Tao Li[2], Yao Zhou[2], Ling Huang[1], Shi-Gang Sun*[1, 2]
[1] State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China
[2] College of Energy, Xiamen University, Xiamen 361005, China

Binders play a crucial role in the cohesion of active materials and conductive additives together onto the current collector.[1] The traditional PVDF binder with weak Van der Waals force could not maintain the electrode integrity of Si-based anodes. Therefore, strongly adhesive polymeric binders are required for enduring the severe mechanical stress derived from the large volume change. Basically, the optimal binder for Si-based anodes should have excellent bulk property, such as high chemical and electrochemical stability, suitable adhesiveness, strong ion/electron conductivity, functional group for self-healing, cost-effectiveness, and environmental friendliness.[1,2] Recent reports mainly focus on the bulk properties of binders to improve the mechanical characters and electrical conductivity of Si-based anodes. Nevertheless, the adhesion ability and functional mechanism of binders with Si active materials as well as with current collector are also important to maintain the electrode integrity and avoid the electric contact loss, whereas this problem is rarely investigated.

In the present study, we designed the H-bonding cross-linked polymeric binders (CMC-co-SN), through a consideration of the binders that should have excellent bonding interaction with Si active materials and copper (Cu) current collector while the preparation route is simple and low-cost. The preparation of the CMC-co-SN binders was carried out by in-situ thermopolymerization of chain-typed carboxymethylcellulose sodium (CMC) with sulfur-containing polymer (SN) during the drying processes of Si-based electrode disks. The obtained CMC-co-SN binders possess the bifunctional role (Fig. 1a) with Cu current collector and Si active materials through covalent bonding (-S-Cu-) and multi-hydrogen-bonding (-OH, -C=O, =S) forces, respectively. When served as binders to micro (1-5 μm) (M-Si) and nano (~50 nm) (N-Si) Si particles (Fig. 1b), the Si anodes exhibited high initial coulomb efficiency, 91.5% for M-Si and 83.3% for N-Si, and good cycle life, 1121 mAh g^{-1} for M-Si after 140 cycles and 1083 mAh g^{-1} for N-Si after 300 cycles, respectively. CMC-co-SN binders could be expanded to SiO and Si/C electrode materials, which also exhibited good electrochemical performance. The results demonstrated that the H-bonding cross-linked polymeric binders provide a novel strategy to improve the electrochemical performance of Si-based anodes through the bonding force of binders with active materials and current collector to maintain the electrode integrity and avoid the electric contact loss.

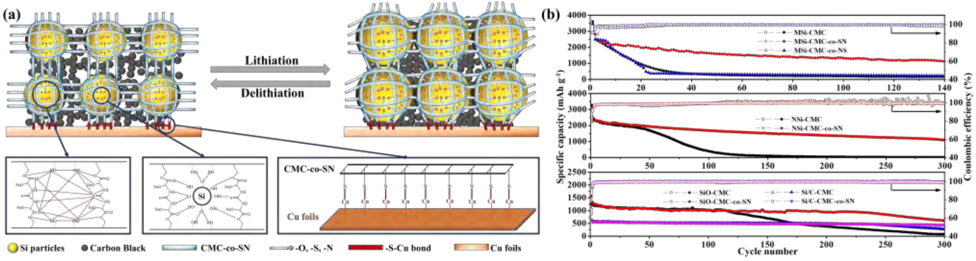

Fig. 1 (a) Schematic visualization of H-bonding cross-linked polymeric binders for Si anodes during cycling and the difunctional bonding effects with Si active materials and Cu current collector, (b) the corresponding cycling property and coulombic efficiency of M-Si and N-Si anodes.

valentin.briega@ua.es

Chemical modification of electrode surfaces can strongly influence their electrocatalytic activity and the charge-transfer processes at electrified interfaces, and therefore it is one of the most common methods for the design of new electrocatalysts for different applications. In relation to the oxygen reduction reaction (ORR), an approach based on molecular patterning of platinum surfaces with cyanide adsorbates that can efficiently block the sites for adsorption of spectator anions with the ORR remaining unhindered was used for the rational design of cathode electrocatalysts with potential use in any environments containing strongly adsorbing anions [1]. In this work, it has been observed for the first time a similar enhancing effect towards the ORR by Pt(111) surfaces modified with different coverages of Te adatoms. In addition, the surface charge modification by the Te adlayer and its effect on the ORR electrocatalytic behavior can provide useful information about the mechanism of this reaction.

The ORR on Te-modified Pt(111) electrodes has been studied in $HClO_4$, H_2SO_4 and H_3PO_4 acidic solutions by using hanging meniscus rotating disc electrode configuration. Te was irreversibly adsorbed on Pt(111) [2]. While adsorption of Te-adatoms on Pt(111) progressively shifts towards less positive values the ORR reaction onset for $0 < \theta_{Te} < 0.25$ in 0.1 M $HClO_4$ solution (Fig. 1A), in 0.05 M H_3PO_4 and 0.05 M H_2SO_4 solutions a positive catalytic effect has been pointed out (Fig. 1B), interpreted in terms of a competitive adsorption-desorption mechanism involving replacement of adsorbed sulfate or phosphate species by Te adatoms. In addition, a displacement towards more positive values of the inhibition potential of the ORR is observed when increasing Te coverage (Fig. 1A), which is related to the modification of the surface charge and suggests that H_2O_2 intermediate is participating in the mechanism [3]. Measurements at higher pH values supply more information about the ORR bifurcation mechanism.

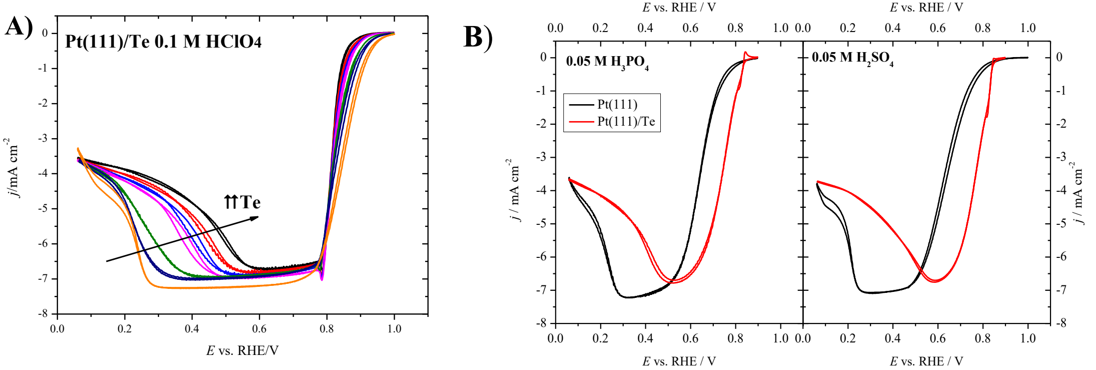

Figure 1: (A) Cyclic voltammetry profiles for the ORR in 0.05 M H_3PO_4 (top) and 0.05 M H_2SO_4 (bottom) on unmodified and Te-modified Pt(111) surface. (B) Cyclic voltammetry profiles for the ORR in 0.1 M $HClO_4$ on Pt(111) with increasing coverages of Te. Scan rate: 50 mV s^{-1}. Rotation rate: 2500 rpm.

Electrochemical Activation of Expanded Mesocarbon Microbeads Using Polyurethane-Crosslinked Polyacrylic Acid as a Binder for High-Voltage Symmetric Supercapacitors

The expanded mesocarbon microbead (EMCMB) is successfully made from MCMB through a combination of oxidation and thermos-expansion treatments, which shows excellent capacitive performance in the $TEABF_4$/PC solution after the electrochemical activation in the positive and negative potential regions. The purpose of the acidic oxidation process is to generate various oxygen-containing functional groups attached onto carbon atoms in the graphene layers. These groups were able to be removed in the gaseous form (i.e., CO and CO_2) during the thermal expansion process, which were expected to conquer the van der Waals force between graphene layers. Consequently, this effect leads to expanded/exfoliated graphene layers. MCMB, an artificial graphite, shows a very strong peak of facet (002), which refers to a d_{002} interlayer spacing of 0.335 nm, same as the typical interlayer spacing of graphite. By the Scherer's equation, the L_c and L_a values of MCMB are calculated to be 74.73 and 65.01 nm, respectively. After the oxidation and thermal expansion processes, the crystallinity of the expanded MCMB (EMCMB) decreases dramatically. The d spacing between graphene layer within EMCMB is distributed from 0.335 to 0.37 nm. In addition, the L_a value of EMCMB was estimated to be 8.77 nm, indicating that the crystal size of graphite has been cut down after the oxidation-expansion treatments.

To increase the energy of supercapacitors (SCs), the EMCMB is chosen to be electrochemically activated in 1 M tetraethylammonium tetrafluoroborate in propylene carbonate ($TEABF_4$/PC). The electrochemically activated EMCMB is able to be charged and discharged reversibly in a wide potential range between -2.6 and 1.4 V (vs. Ag/$AgNO_3$). Consequently, a 4 V and symmetric SC with good capacitive performances in 1 M $TEABF_4$/PC is constructed by such electrochemically activated EMCMBs, greatly enhancing the energy density to 77 Wh kg^{-1} on the basis of the total mass of EMCMB on both electrodes.

The electrochemical activation is a common technique enhancing the capacitive performances of carbons in high-voltage supercapacitors while volume expansion during the activation process often makes the active materials detachment, dropping the capacitance. In this work, the KOH-neutralized polyurethane-crosslinked-polyacrylic acid ($PUPAH_{10-x}K_x$) polymers are proposed to replace the polyvinylidene fluoride (PVDF) as a binder for expanded mesocarbon microbead (EMCMB) electrodes to buffer the volume expansion. The effects of binder rheology, morphology and neutralization degree on the capacitive performance of EMCMB are investigated. Introducing $PUPAH_6K_4$ with moderate viscoelasticity to EMCMB forms an expansion-buffering electrode and promotes the electrochemical activation process. In addition to a shorter activation time, EMCMB-$PUPAH_6K_4$ presents a maximal specific capacitance than others. The above results indicate that the specific capacitance of activated EMCMB electrodes is not directly proportional to the electrochemical activation time. Therefore, PUPAH neutralized with KOH changes the binder properties, affecting the charge storage characteristics of the resultant EMCMB coatings [1].

An adequate description of an electrochemical process requires to understand how the different parameters that are governing the reactivity of the electrodes affect a given electrochemical reaction. For this reason, numerous studies are devoted to investigating the effects on the electrochemical reactivity of the surface structure and composition of the electrode as well as the nature of the solution. However, other parameters such us surface charge, which also can play a significant role, are often overlooked. In this communication, the effect of surface charge and the solution pH on the hydrogen evolution and oxidation reactions (HER/HOR) on platinum will be investigated. Platinum is probably the most active pure metal for these reactions. This is especially true in acidic solutions. However, the activity of the HOR on platinum decreases two orders of magnitude in alkaline media. In order to understand these differences, the HER and the HOR were studied under near neutral pH conditions in the absence of anion specific adsorption. The selected buffered solutions allow establishing reliable trends in the activity from acidic to alkaline solutions from which conclusions can be obtained. Single crystal electrodes, namely, Pt(111), Pt(100) and Pt(110), have been used in the electrochemical measurements and DFT calculations. For the HER, it was found that the effect of pH is almost negligible in the studied pH range (figure 1, left panels). These results indicate that the ionic composition and pH of the solution has not a significant effect on the HER. Thus, the concentration of protons, which is the reactant for the HER, does not limit this reaction under near neutral pH conditions. By contrast, the HOR was found to be pH sensitive mainly on Pt(111) and Pt(100) (figure 1, right panels). The major difference in the experimental conditions at which these reactions take place are the electrode charge. As the solution pH increases, the potential region at which the HER/HOR reactions takes places shift to more negative potentials in the SHE. Thus, the electrode charge becomes increasingly more negative. With the aid of density functional theory calculations, the effect of the increasing negative surface charge on both reactions is untangled.

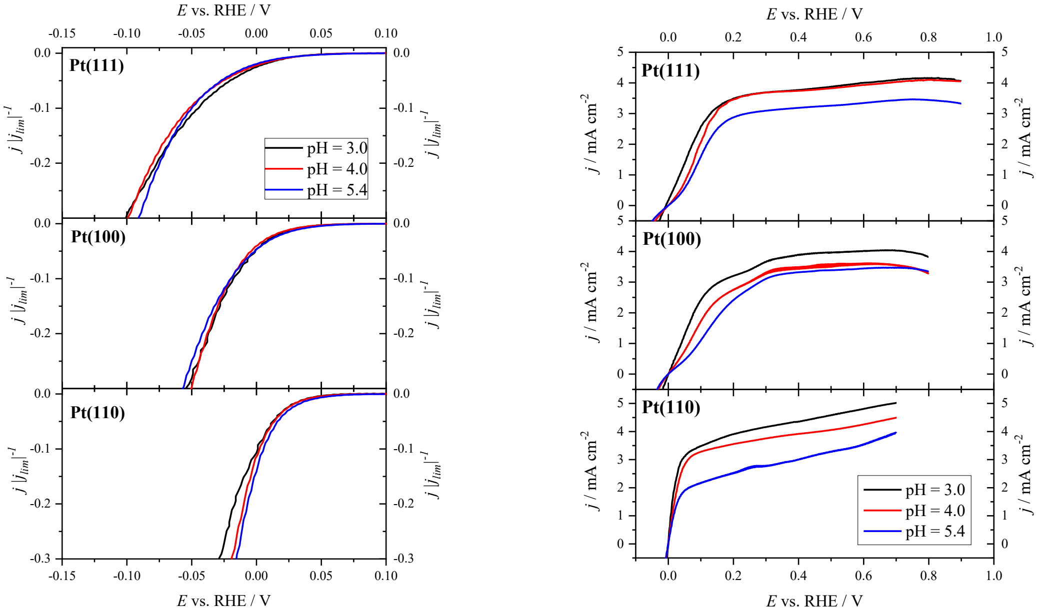

Figure 1. Effect of the solution pH in the activity of the HER (left panels) and HOR (right panels) for the different single crystal electrodes.

Surface charge and interfacial acid-base properties.

It is well documented that Pt(111) electrodes in contact with 0.1 M perchloric acid solutions saturated with CO_2 show spectroelectrochemical signals associated to adsorbed bicarbonate and carbonate anions 1]. The relative intensities of the absorption peaks at different pH and applied potential can be used to determine the interfacial pK_2 of carbonic acid, which results considerably smaller than in solution phase, irrespectively of the assumptions made in the analysis of data [1, 2]. The study on the Pt(111) electrode benefits from the fact that CO_2 is not reduced to adsorbed CO on this surface, thus enabling to determine the necessary coefficients related to the adsorbed carbonate and bicarbonate species through a simple interfacial mass balance which involves the consumption of dissolved CO_2.

On other Pt(hkl) structures, the reduction of CO_2 to CO will disturb this mass balance and complicate the band analysis and the subsequent calculation of the corresponding surface pKs. However, it is still possible to gain this information under appropriate experimental conditions, i.e. adjusting the lower potential limit to avoid the reduction to CO by adsorbed hydrogen. In addition, assuming that the absorption coefficients are those determined for Pt(111), the corresponding surface pKs can be estimated.

In this study the stepped surfaces vicinal to the Pt(111) pole have been examined. As shown in the figure below, for the Pt(110) limiting case, the surface pK_2 is lower than that of Pt(111), at the corresponding potentials of zero free charge. This means that the more open surface behaves as being more alkaline than the closest packed one and thus adsorbed bicarbonate dissociates more easily to adsorbed carbonate.

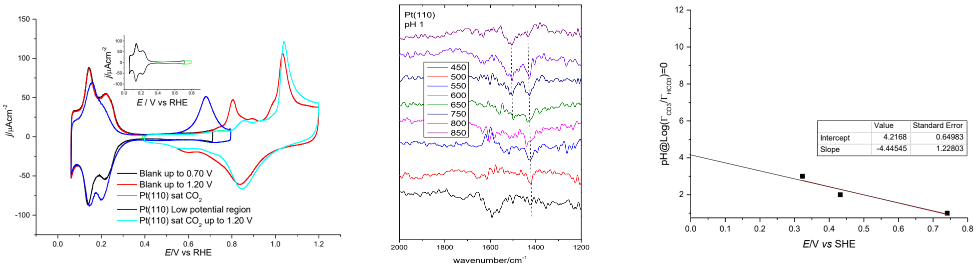

Figure. From left to right: voltammetry of Pt(110) in 0.1 M perchloric acid saturated with CO_2; spectra form this solution taken at different potentials: the bicarbonate band is observed (≈1400 cm^{-1}) and the carbonate band appears later (≈1500 cm^{-1}); plot of the surface pK_2 values at different potentials.

Zinc and zinc alloy coatings containing micro- and nano-Al_2O_3 particles offer a wide range of potential applications in various fields, due to promising economic benefits and their excellent properties such as wear and corrosion resistance [1]. Despite several reports that deal with plating of Zn-Ni composites containing Al_2O_3 particles, the electrodeposition of Zn-Mn-Al_2O_3 composite has not been reported yet. This type of coating could offer excellent corrosion protection, because the Zn-Mn alloy has been known to show the highest corrosion resistance among all Zn alloys, in chloride rich environment [2].

In this study, co-deposition of Zn, Mn, and Al_2O_3 particles via electrodeposition method was studied. Composite coatings were produced on steel substrate, using different deposition parameters such as current density and metal ion content of the bath solution. The electrodeposition bath was the simple chloride electrolyte commonly used for Zn-Mn electrodeposition, consisting of KCl, H_3BO_3, $ZnCl_2$ and $MnCl_2$, with added Al_2O_3 powder. Microstructural properties of the coatings were characterized by scanning electron microscopy, while the chemical composition was measured with electron dispersive spectroscopy. The corrosion behavior of the coatings in 3.5 mass.% NaCl aqueous solution was evaluated by using Tafel extrapolating method (determination of corrosion potential and corrosion current density) and electrochemical impedance spectroscopy.

It was found that co-deposition of alumina particles with Zn and Mn metals was successfully achieved via electrodeposition method, without agglomeration of ceramic particles. The electrodeposition conditions that enable the formation of non-porous coatings, where Al_2O_3 particles are distributed homogenously, were determined. The analysis of the chemical composition showed that the Mn content was low, i.e. up to 1.0 wt.%, while the Al content ranged between 0.10 and 7.0 wt.%. The increase in deposition current density from 10 to 40 mA cm^{-2}, results in decrease in alumina content of the coatings.

The measured corrosion current densities of Zn-Mn/Al_2O_3 coatings vary between 4.5 and 13.5 $\mu A\ cm^{-2}$, which is the typical corrosion rate of Zn alloy coatings in chloride environment. No correlation between Al_2O_3 content and the corrosion performance of the coatings was found. Therefore it is concluded that the alumina particles may be incorporated in Zn-Mn alloy coating, in order to enhance its mechanical properties, and without deteriorating its corrosion behaviour.

Lithium-ion batteries have become a key technology in our everyday lives, and great interest has grown during the past decade towards new materials and new configurations of the cells. Solid state lithium batteries (SSB) allow having higher energy density without compromising power and capacity, while assuring high safety at variable temperatures and good cycle stability. However, during the charge and discharge of these batteries, there are significant volume changes in the electrodes that produce stress and strain effects on the solid materials. These effects can make layers separate and cracks to form in the battery materials, which reduces the potentially improved performance of these batteries. Furthermore, these mechanical depredating effects are more several in cobalt-free materials (Ni-Mn-based oxide electrodes), which are an ethical alternative for materials in battery systems but present structural weakness that are subject of study.

Our main goal is to investigate structural stability of cobalt-free battery electrodes (LMO, LMNO) and to develop a tool that allows to determine under which operation conditions a solid-state battery can operate without suffering relevant mechanical stress. The approach used combines In-situ Spectroscopic Ellipsometry, AFM techniques and Finite Element Modelling. First results show evident degradation of the electrodes and thickness changes at different states of lithiation.

Electrodeless Photo-assisted Etching of Gallium Nitride with Potassium Peroxomonosulfate Oxidants

Kang Shi,* Sai Guo, Hui-Qing Hu

Siming South road 422, 361005, Xiamen, P.R China
kshi@xmu.edu.cn

While GaN has been widely used in fields of electronics and optoelectronics, its super stabile characteristic makes conventional chemical wet-etching methods inefficient. The photoelectrochemical etching is the only efficient approach because the photogenerated holes can activate GaN. For fabricating the GaN-based devices, the current mass manufacturing technology is the electrodeless photo-assisted etching that uses Ti/Pt nanofilm as electrochemical cathode and photo-mask to prepare the GaN pattern. However, this technology is still unable to prepare the flat and smooth GaN surfaces so far [1]. To improve this technology, we employed KSO_5 as oxidants. The electrochemical and photochemical responses of KSO_5 on Pt, Ru, and glassy carbon electrode were systematically investigated. Experimental results indicate that KSO_5 has a higher oxidation potential than $K_2S_2O_8$. The latter is the most frequently used oxidant in the currently electrodeless photo-assisted etching technology [2]. The use of KSO_5 enables the photoelectrochemical etching of GaN at a high potential. Thus, the roughening effect of electron-hole recombination, which preferentially occurs at dislocations in GaN film, can be avoided. However, it was found that a slight change in the pH of the GaN surface might cause a remarkable difference in the etching rate, which would lead to a rough GaN surface as well. To keep the pH of the whole GaN surface consistent during the etching process, a spin-etching method was developed. Results show that a flat and smooth GaN surface with a surface roughness Ra of 6 nm can be prepared at an etching rate of 18 nm/min.

Development of continuous processes for the Electrochemical Reduction of CO_2 to Formate: evolution with electrodes of different nature and configuration

Manuel Alvarez-Guerra, Guillermo Díaz-Sainz, Angel Irabien
University of Cantabria, Department of Chemical and Biomolecular Engineering
ETSIIT, Avda. Los Castros, s/n. 39005, Santander, Spain.
alvarezgm@unican.es

The historic Paris Agreement on Climate Change, which aims at holding global temperature rise to well below 2ºC, represents a call for further action and for investment towards a low carbon, resilient and sustainable future. In order to mitigate excess anthropogenic carbon dioxide (CO_2) emissions (approx. 4GtC yr^{-1}) and achieve the 2ºC target, a portfolio of strategies and technologies need to be implemented together, where Carbon Capture Utilisation and Storage (CCUS) can play an important role. The utilization of captured CO_2 as a useful raw material, and particularly, the electrochemical conversion of CO_2 into products with value added has gained renewed and increasing attention over the last years [1-2]. Formate, or formic acid depending on pH, is a product of great interest, because, apart from its industrial applications, it is currently considered as one of the most promising compounds for hydrogen storage and as a promising candidate fuel to be used in fuel cells.

This lecture will summarise some of the results obtained by the DePRO research group of the University of Cantabria on the development of continuous processes for CO_2 electroreduction to formate in a flow reactor, with a single pass of the reactants through the reactor, in which the performance has been progressively improved by using electrodes not just of different nature (Pb, Sn, Bi), but also of different configurations: e.g. plate electrodes, particulate electrodes made of nanoparticles deposited on porous supports, or “Gas Diffusion Electrodes” (GDEs). Special attention will also be paid to discuss the results obtained with the configuration of “Catalyst Coated Membrane Electrodes” (CCMEs), in which catalyst nanoparticles are directly sprayed over a Nafion membrane. The CCME configuration allows avoiding the use of a liquid catholyte, so that the input feed to the reactor is simply a mixture of CO_2 and vapour, making it possible to achieve higher formate concentration (of up to 26 $g \cdot L^{-1}$) with an energy consumption 50% lower than using the same catalysts in GDE configuration.

The results obtained so far are promising and they suggest a great future potential of these approaches. However, much more research is needed to overcome the current limitations of these processes so that they are able to combine, simultaneously, high Faradaic efficiency, high rates of formation of the product (measured by the current density at which the process can be operated), high concentration of the product obtained (to avoid the economic and environmental penalty of subsequent purification), and low overpotentials to allow an energy efficient process, necessary to explore their scale-up.

Corrosion of Zn-Ni coated reinforcing steel in simulated concrete pore solutions

Mihael Bučko[1], Jelena B. Bajat[2]

[1]University of Defense, Military Academy, 33 Pavla Jurišića Šturma St, 11000 Belgrade, Serbia

mbucko@tmf.bg.ac.rs

Zinc coating produced by the hot-dip galvanizing process is often used as a preventive corrosion measure in reinforced concrete structures exposed to carbonation or mild contamination with chlorides, because Zn forms a passive film of sufficient thickness [1]. However, during a prolonged exposure to the chloride-rich environment after the concrete carbonation, galvanized steel quickly corrodes once the threshold concentration of chloride ions is reached. Alloying with Ni is a common technique employed to increase Zn protective properties and hardness, and the market for corrosion resistant Zn–Ni coatings is large, primarily including coatings for automobile steel bodies and electronics industry. With this background knowledge, the present work is intended to study whether an electroplated Zn-Ni coating of a sufficient thickness may provide better long-term corrosion resistance to the reinforcing steel in concrete, in comparison to pure Zn coating. The Zn-Ni coatings were 40 μm thick and contained ~13 mass.% Ni.

There is no single electrolyte which may be used in a laboratory to simulate universal conditions in concrete, because in real concrete, many factors change with time, such as pH value and the concentration of corrosive species. Yet, based on previous studies [2], our work uses three different simulating electrolytes, to predict and compare Zn and Zn-Ni behavior in three environments: fresh concrete, concrete with CO_2 absorbed, and finally concrete with Cl^- ions. In order to compare their corrosion behavior, the pure Zn and Zn–Ni alloy coated steel samples were successively exposed to three different solutions. In corrosion testing, electrochemical impedance spectroscopy (EIS) and scanning electron microscopy (SEM) were used.

Impedance spectroscopy showed that both Zn and Zn-Ni were passivated in an alkaline solution (simulating fresh concrete) and carbonated solution, which simulated CO_2 ingress into concrete, but in the third, i.e. chloride rich solution, the deterioration of the passive layer on top of the coatings occurred, as expected. Nevertheless, the corrosion pattern is quite different for the two coatings: Zn–Ni surface was flat and black during the total immersion period in chloride solution, while Zn was covered with a white, chloride rich product that was constantly increasing in volume and peeling off the sample. The EIS measurements show significantly slower dissolution of Zn-Ni coating in the chloride environment, as compared to Zn. Therefore, it may be concluded that Zn-Ni could be a reasonable alternative to pure Zn for the protection of steel in concrete where a high chloride penetration is expected.

In the race of new technologies keen to obtain new sources of low-cost and sustainable energy, activation of abundant small fuel molecules (such as O_2, H_2O, CO_2 and H_2) is now widely studied to convert their chemical energy into an electric one[1]. However, the multi-electronic processes commanding these activations are not yet fully understood and controlled, but they have been observed to be efficiently catalyzed in nature through the action of metalloenzymes, in which a catalytic site is buried inside an organized molecular environment governing the reactivity.

Herein, we propose a strategy inspired from metalloenzymes to control the interfacial reactivity at the molecular level. This approach is based on the functionalization of metallic nanoparticles through the reductive grafting of calix[4]arene-tetradiazonium salts. The gold nanoparticles is then chemically modified with a well-organized monolayer of calix[4]arenes that are covalently bound to the surface.[2] These grafted nanocavities mimick an organized molecular environment that is likely to impact the orientation and approach of O_2 while ensuring strong stability of the electrocatalysts, thanks to multiple anchoring. The various functional groups at the calix[4]arenes small rim will modulate the interactions at the interface between the metal surface and the electrolyte/reactants due to their different hydrophilic and oxophilic natures. Herein, we will present the synthesis and electrochemical properties of these systems along with very promising results for obtaining stable and selective catalytic system for oxygen reduction reaction (ORR).

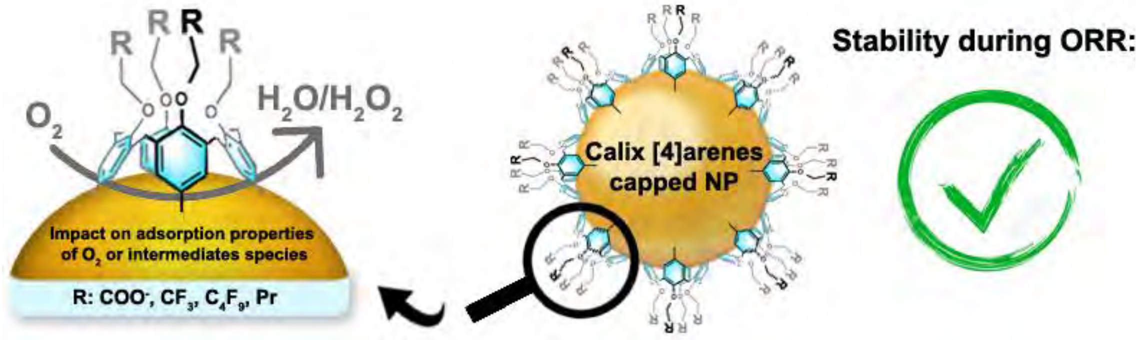

Figure 1. *Grafting of calix[4]arenes with various functional groups on gold NPs modifying O_2 adsorption phenomena and their influence on the ORR performances*

s-yoshino@mosk.tytlabs.co.jp

For improving the power density of polymer electrolyte fuel cells (PEFCs), the transport resistances of the reactants (oxygen and proton) and product (H_2O) in the cathode catalyst layer (CL) need to be reduced. For simultaneously reducing these resistances, a CL containing a non-woven mat of ionomer nanofibers formed by electrospinning has been found to be promising owing to the presence of continuous proton pathways and pores [1]. The robustness of the cell performance against the humidity and optimal structure of the CL are, however, yet to be clarified. In the present study, we fabricated CLs with ionomer nanofiber scaffoldings (iNFS-CL) where the ionomer loading and distribution between the mat and Pt/C region were systematically changed, and the cell performances were analyzed on the basis of the elemental characteristics, including the mass transport properties (proton, water, oxygen) under different humidity conditions.

A scanning electron microscope (SEM) image of an iNFS-CL fabricated by one cycle of the electrospinning and electrospraying is shown in Fig. 1a, and indicates that Nafion nanofibers are uniformly covered with the catalyst particles. The cell performances with the gas supplies of H_2/air (21 kPa O_2) were evaluated at the cell temperature of 80 ºC in the humidity range of 30%RH - 165%RH. Figure 1b shows the current densities at 0.5 V (IR-corrected with high frequency resistances) for the iNFS-CLs with different overall ionomer/carbon weight ratios (I/C) with the local I/C of 0.4 in the Pt/C region and for conventional CLs (Conv.). The three iNFS-CLs (overall I/C = 0.8, 1.0, and 3.0) show higher current densities than Conv.-1.0 (I/C = 1.0) over the humidity range of 30%RH - 165%RH. The Conv.-0.8 (I/C = 0.8) shows comparable performances above 50%RH but inferior performances below 50%RH to the iNFS-CLs. The results indicate that iNFS-CLs have higher robustness against humidity changes than for conventional CLs. In the meeting, the results on analyses of their elemental characteristics will be presented and the origins of the higher robustness for the iNFS-CLs will be discussed.

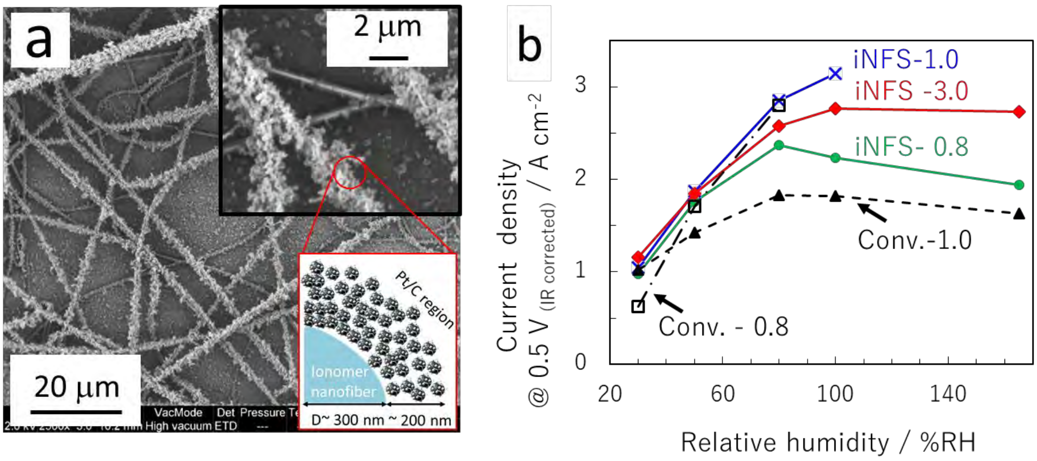

Figure 1 (a) SEM image of an iNFS-CL and schematic diagram of the cross-section of the ionomer nanofiber covered with the catalyst particles. (b) Humidity dependence of current density at 0.5 V (IR-corrected) of polarization curves in the anodic scan (10 mV s^{-1}).

yxjiang@xmu.edu.cn

High performance and durable bifunctional oxygen electrocatalysts are of great importance for the commercial application of environmentally friendly and sustainable energy through electrochemical devices such as rechargeable Zn–air batteries and fuel cells. Highly distributed catalysts with maximum atomic utilization are considered to be a promising alternative for current noble-metal-based catalysts. Herein, a high performance and durable bifunctional oxygen electrocatalyst for both ORR and OER is synthesized by a facile self-template and polypyrrole encapsulation method. The super performance AD-Fe/N-C-900 catalyst has a special open porous double shell hollow structure which is beneficial to exposure of more Fe-Nx active sites for ORR and OER, and improves mass transfer, resulting in a fabulous bifunctional ORR/OER electrocatalytic activity ($\triangle E$ =0.655 V), which is better than the commercial Pt/C ($\triangle E$ =1.035 V) and the commercial IrO_2 ($\triangle E$ =0.93 V), along with remark durability and long-term stability for the ORR in alkaline medium. Based on our results and analysis, the remarkable electrocatalytic activity of AD-Fe/N-C-900 might be attributed to the high content of mesopore, high density of Fe-Nx active sites, and robust double shell hollow structure. The novel design of the atomically dispersed Fe/N-codoped porous double shell hollow nanocarbon enable boosted oxygen catalyst by a facile method has certain enlightening effect on the design and development of other bifunctional electrocatalysts in the next generation reversible energy conversion systems. Our work provides a design idea for the synthesis of high activity and stability bifunctional atom-level distributed catalysts..

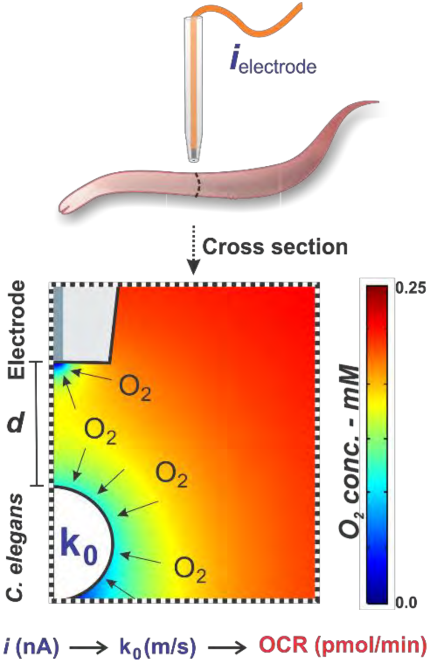

Scheme 1. Schematic representation of the experiment performed to determinate the local OCR in a single *C. elegans*.

Scanning electrochemical microscopy (SECM) was employed to investigate the respiration metabolism of the nematode *Caenorhabditis elegans*, an animal widely used as a model for aging and caloric restriction studies due to its metabolism, physiology, as well as easy handling and short-lifespan [1]. Drug effects and contribution of different diets on the animal's metabolism are commonly evaluated by accessing the respiration activity by measuring the oxygen concentration in a solution containing a large number of worms, as the oxidative phosphorylation is the last stage of the majority of metabolic processes. This is done by monitoring changes in the oxygen consumption rate (OCR), measured by commercial equipment (e.g.: Clark electrodes). The known advantages of SECM that allow gaining localized information by performing space-resolved electrochemical measurements were used here for investigating the local OCR at different parts of a single animal. A platinised platinum microelectrode working as an SECM tip in redox competition mode [2] (electrode/sensor and animal consumed the same species, oxygen) was employed as a tool for mapping the oxygen consumption at the vicinity of a single *C. elegans*. The local oxygen consumption rate (OCR) was determined by fitting a series of measurements performed in different regions of the animal to the calculated SECM tip response using Finite Element Method (FEM – COMSOL Multiphysics) (Scheme 1). The results indicated that the main contribution for the total oxygen consumption of the animal is the reproductive system (gonad) in the adult hermaphrodite *C. elegans*. For understanding the role of the reproductive system, we have compared the local OCRs in the wild (N2 Bristol) and mutant animals (glp-1), which has no development of the reproductive system. We also made use of fluorodeoxyuridine (FUdR) to interrupt egg development in the wild animal, allowing us to investigate the contribution of egg development in the reproductive system metabolism. This is the first time that such information is reported and may contribute to a better understanding of the animal's metabolism and help in the proper interpretation of bulk OCR measurements (large number of worms).

Carbon-free Cathodes for Li-O_2 Batteries based on Transition Metal Oxynitrides-Nitrides

Mario Aparicio, Jadra Mosa
Instituto de Cerámica y Vidrio (CSIC)
Kelsen 5, 28049 Madrid, Spain
maparicio@icv.csic.es

Oxynitrides-nitrides of several transition metals were synthesized by sol-gel using alkoxides and chlorates. Interconnected porosity was incorporated through phase separation of hydrophilic and hydrophobic blocks, and elimination of organic components with a thermal treatment. Partial substitution of oxygen by nitrogen was accomplished using thermal treatment in NH_3 atmosphere and incorporation of urea during the synthesis procedure. Powder characterization includes surface area (BET), scanning electron microscopy (SEM), X-ray diffraction (XRD) and cyclic voltammetry (CV). The results show surface areas higher than 150 m^2/g, and the catalytic activity depend on the combination of oxides, nitrides and oxynitrides.

Fabrication and Characterization of Electrospun PVAM/TEOS Based Gel Polymer Electrolyte

Gel polymer electrolyte (GPE) is a promising alternative for the toxic and flammable liquid electrolyte in lithium ion batteries because of leak proof, longer shelf life and safety concerns. GPE consists of a porous polymer host and liquid electrolyte saturated within and combines the advantages of both the liquid and solid components [1].

In this study, a novel three-dimensional network GPE based on poly(vinyl alcohol)/maleic anhydride/tetraethyl orthosilicate (PVA/MA/TEOS) with polymer fibers were developed. Crosslinked nanofibrous polymer membranes for GPE of various composition were fabricated by UV-electrospinning method. The dual crosslink polymer membranes were obtained after heat treatment of as-prepared polymer nanofibers, due to the condensation of hydrolyzed TEOS. The morphology of the electrospun membranes was studied using scanning electron microscopy as shown in Figure 1. The uniform and well cross-linked nanofibers were formed with addition of 5 and 10% of TEOS.

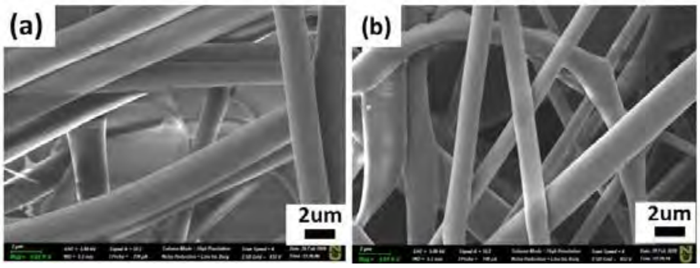

Figure 1. SEM image of PVA/MA/TEOS fibers with (a) 5% and (b) 10% TEOS

The excellent thermal properties of the membranes were proven using thermal gravimetric analysis. The membranes have an improved porosity and exhibit high uptake when activated with the liquid electrolyte of lithium salt in a mixture of organic solvents, and also show high liquid retention properties. Electrochemical impedance spectroscopy and linear sweep voltammetry testes showed a high conductivity and vide range (up to 5.5 V) electrochemical stability of prepared GPE. Electrochemical performance of the polymer gel electrolyte is evaluated in Li/polymer electrolyte/$LiFePO_4$ coin cell with various current density and showed promising results.

Capacity limiting effects for freestanding, monolithic TiO_2 nanotube electrodes with high mass loadings

Charlotte Ihrfors, Wei Wei, Fredrik Björefors and Leif Nyholm
The Ångström Advanced Battery Center, Department of Chemistry-Ångström, Uppsala University
Box 538, SE – 751 21 Uppsala, Sweden
charlotte.ihrfors@kemi.uu.se

TiO_2 nanostructures have been extensively studied as alternative electrode material for lithium-ion batteries specifically for applications where high power is needed [1]. The high operation potential, 1.8 V, makes TiO_2 a safer alternative compared to graphite but also increases the demand for positive electrode materials with high potentials to yield a battery with a descent cell voltage [1]. The theoretical capacity of TiO_2 is 335 mAh/g but in practice lithiation degrees corresponding to around $Li_{0.5}TiO_2$ are reported [2,3]. The electrical conductivity of TiO_2 is comparably low and this has been reported as a problem for bulk electrode materials, although nanostructuring of the electrode materials can be used to decrease this problem significantly. TiO_2 nanotubes can be synthesized in a two-step anodization process with a fluoride containing electrolyte resulting in freestanding TiO_2 nanotubes on a titanium substrate [4].

In the present work, the capacity limiting factors are studied for TiO_2 nanotubes with mass loadings up to 10.5 mg/cm^2, corresponding to tube lengths from 4.5 µm to 40.5 µm. The results show that higher capacities are obtained for cyclic voltammetry compared to galvanostatic cycling. A diffusion controlled decrease in capacity is seen for the nanotube electrodes as the cycling rate is increased and a maximum average lithiation degree corresponding $Li_{0.55}TiO_2$ is obtained. This effect stems from the decrease in the diffusion rate as the concentration of Li_xTiO_2 increases in the electrode. The results also indicate the presence of a lithium-ion trapping in the electrode during cycling with a similar behavior as that previously seen [5] for lithium-alloy forming electrode materials.

Activity Enhancement of thin-film Pd catalysts by Bi adatoms towards alcohol electrooxidation in alkaline media

Jelena Lović, Sanja Stevanović
ICTM Department of Electrochemistry, University of Belgrade
Njegoševa 12, 11001 Belgrade, Serbia
jelena.lovic@ihtm.bg.ac.rs

Thin-film Pd catalysts with low metal loadings (55 and 110 µg cm^{-2}) were obtained by electrodeposition on CG electrode from a surfactant-free green electrolyte. Surface of Pd electrode was modified by irreversibly adsorbed Bi as fast and easy to do method. The catalysts were characterized by AFM technique and demonstrated that the nanoparticle clusters was formed from the agglomeration of single crystal particles. The catalytic activity and durability of Bi-modified Pd electrodes on methanol and ethanol electro-oxidation in alkaline media was investigated. The participating roles of Pd and Bi was examined from the aspect of different Pd metal loadings and Bi surface coverages. The presented electrochemical tests shown that the modification with the appropriate amount of Bi on thin-film Pd catalysts enhance activity toward MOR and EOR up to about 2-3 times compared to unmodified catalysts. Besides surface Bi coverage (Θ_{Bi}) of 0.6 increase durability and provides more poisoning tolerant Pd/GC electrode in both studied reactions as it is presented in Fig. 1.

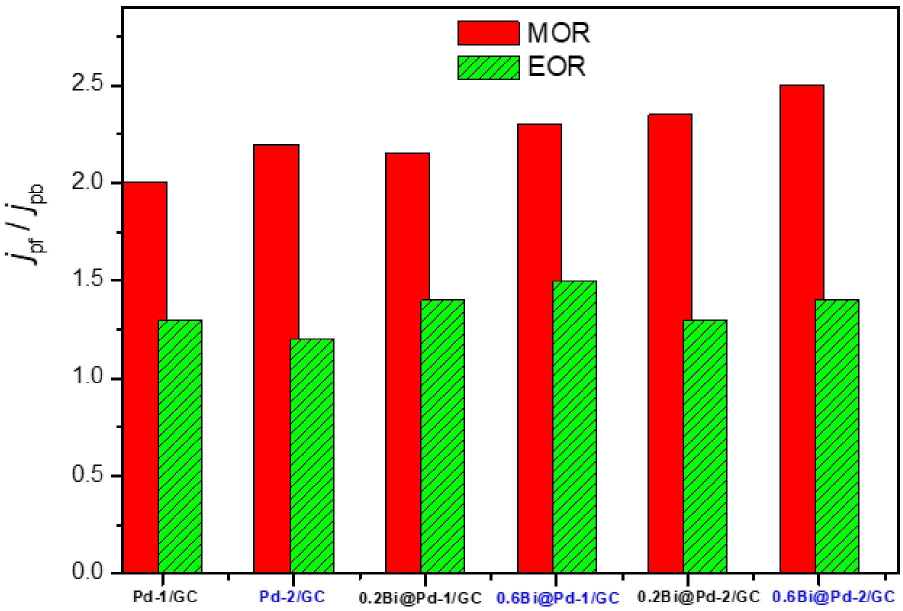

Fig. 1 The ratio of the forward peak current density (j_{pf}) and the backward peak current density (j_{pb}), as the parameter of the poisoning tolerance to the carbonaceous species for Pd catalysts in methanol and ethanol oxidation reaction in alkaline media.

It was concluded that the combination of third body and bifunctional effect is responsible for the electrocatalytic improvement of thin-film Pd catalysts modified with Bi in examined reactions of alcohol oxidation in alkaline media. Electrochemical investigations of such modified electrodes signify how to direct research in order to develop an efficient catalyst.

Understanding and controlling charge transport across multiple parallel molecules is fundamental to the creation of innovative functional electronic components,[1] as future molecular devices will likely be multi-molecular.[2] The smallest possible molecular ensemble to address this challenge is a dual-molecule junction device, which has potential to unravel the effects of intermolecular crosstalk on electronic transport at the molecular level that cannot be elucidated using either conventional single-molecule or self-assembled monolayer (SAM) techniques. Herein, we demonstrate the successful fabrication of an STM dual-molecule junction device, which utilizes noncovalent interactions and allows for direct comparison to the conventional STM single-molecule device. STM-BJ measurements reveal a decrease in conductance of 10% per molecule from the dual-molecule to the single-molecule junction device. Quantum transport simulations confirm this decrease is attributable to direct intermolecular crosstalk (i.e. intermolecular π-π interactions), with contributions from substrate-mediated coupling (i.e. molecule-electrode). This study provides the first experimental evidence to interpret intermolecular crosstalk in electronic transport at the STM-BJ level, and translates the experimental observations into meaningful molecular information to enhance our fundamental knowledge of this subject matter. This approach is pertinent to the design and development of future multi-molecular electronic components, and also to other dual-molecular systems where such crosstalk is mediated by various noncovalent intermolecular interactions (e.g. electrostatic and hydrogen bonding).

rudolf.holze@chemie.tu-chemnitz.de

Electrode materials employed in supercapacitor electrodes are always highly porous with large specific surface area residing inside pores of the material. This applies in particular to carbon-based materials used in currently commercially available electrochemical double layer capacitors (EDLC), it is also true for redox active materials (e.g. metal oxides [1], mixed metal oxides [2], intrinsically conducting polymers or composites of these materials [3]). With increasing porosity yielding the requested large surface area needed for charge storage in particular with EDLC the challenge of complete utilization of the surface area as measured e.g. with porosimetry or BET-method as contact area between the electronically conducting electrode material and the ionically conducting electrolyte solution grows. In addition some of the surface of these materials might not be as hydrophilic as would be preferable for complete wetting.
Addition of surfactants (non-ionic, cationic as well as anionic [4]) has been suggested and examined mostly with carbon-based materials [5]. We have examined this concept with a representative metal hydroxide $Ni(OH)_2$ and a mixed metal oxide $MgCo_2O_4$ electrode material.

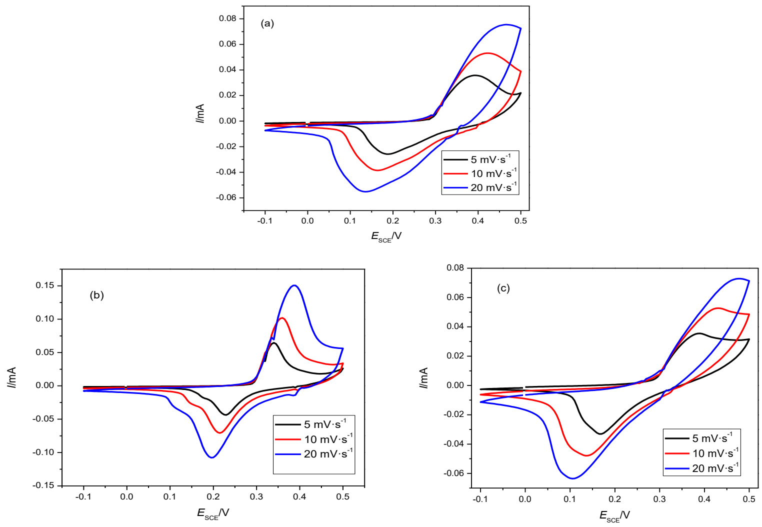

Fig. 1: CVs of (a) the as-prepared "α-$Ni(OH)_2$"-coated electrode in an aqueous solution of 1.0 **M** KOH; (b) with added 10 **µM** Triton X-100; (c) with added 10 **µM** SDS.

Addition of the non-ionic surfactant Triton X-100 resulted in a significant increase of peak current density, peak separation decreased in addition indicating enhanced electrode kinetics. With anionic SDS the effects were less pronounced. Galvanostatic charge-discharge measurements confirmed these observations, they also showed higher capacitance retention with increasing current density. Within the limited timespan of our preliminary experiments, stability of the performance was improved by surfactant addition. Coulombic efficiency closely related to self-discharge was improved with SDS addition, with Triton X-100 efficiency was poorer at low current densities. The mixed metal oxide did not show any improvement, possibly related to surface reactions of this material elsewhere used in heterogeneous catalysis with the added surfactants.

Organic Polymers as Electrodes for Structural Energy Storage

Adriana M. Navarro-Suárez[a], Milo S.P. Shaffer[a,b]
[a] *Department of Chemistry, Imperial College London*
[b] *Department of Materials, Imperial College London*
London, SW7 2AZ, United Kingdom
a.navarro-suarez@imperial.ac.uk

Volume and/or weight savings in mobile devices, electric/hybrid ground transport and aircraft are critical design drivers. One approach to improve the system level specific energy is by adding electrical energy storing capability to structural components, making multifunctional materials.[1,2] However, commercialized batteries and supercapacitors, traditional energy storage devices, are typically rigid and heavy due to the currently used fabrication techniques based on the slurry-casting method and traditional configuration.[3]

The application of organic redox-active polymers as electrode materials has attracted remarkable attention owing to their flexibility, low cost, recyclability, fast response ($<10^{1-3}$ s), capacity ($>10^2$ mAh g^{-1}), and capability for tuning the redox potential.[4] In this study, we hybridize two aromatic carbonyl derivative polymers with carbon-based materials to improve the efficiency of energy storage devices by compensating for the low polymer conductivity, contributing electrical double-layer capacitance, and improving the mechanical properties of the electrodes. These materials are discussed in terms of their physico-chemical, mechanical and electrochemical properties (Figure 1), before being used as electrodes in aqueous batteries. The aqueous electrolyte provides greater safety, much lower cost, higher power density, and much faster recharge rate due to more efficient ion transport. The hybrid cathode provides 4 times higher gravimetric capacity than the unmodified carbon-based material.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 838892.

The impacts of climate change and global warming have become a topical subject in both the political and scientific landscapes in recent times. The significant increase of anthropogenic carbon dioxide (CO_2) in the atmosphere through the widespread use of fossil fuels to produce energy to meet the ever-increasing global demand and consumption of energy is of great concern. The capture and recycling of atmospheric CO_2 is a promising pathway to address this global challenge. In particular, the electrochemical conversion of CO_2 to useful, value-added chemicals is the subject of significant research effort because this avenue affords an opportunity to take advantage of electrical energy generated by renewable sources such as wind, water and solar.

The specific chemical and physical properties of the CO_2 reduction reaction (CO_2RR) catalyst plays a significant role in the catalytic process. Elemental composition, surface geometry, oxidation state, particle size and morphology impact the selectivity and efficiency of CO_2RR.[1,2,3] Copper and copper oxide-derived surfaces are the only catalysts that can electrochemically convert CO_2 to high value and energy-dense C2 and C3 products.[2,4]

Herein, we present time-resolved *in-situ* XAS monitoring of the Cu oxidation state during CO_2RR in a neutral aqueous media for a series of Cu-titanate nanoparticles. Electrochemical characterization combined with On-line Electrochemical Mass Spectrometry (OLEMS) provides insight into the impact of Cu oxidation state on product selectivity.

p- and e- type Silver functionalized Dense Titanium Dioxide Semiconductor Layer for Efficient Perovskite photovoltaics (SOLAR)

Natasha Ross[a], **Kevin Tambwe**[a], **Priscilla Baker**[a]
[a]*University of the Western Cape, Bellville, South-Africa.*

e-mail: nross@uwc.ac.za

Perovskite solar cells (PSC) have an advantage over conventional silicon solar cells in its simplicity of processing and notable power conversion efficiency (PCE) of ~ 22%. However, their performance is limited by the recombination of charge carriers occurring at the TiO_2/PSC interface[1]. This work controls recombination at the Electron transport layer (ETL) (c-TiO_2+mp-TiO_2)/Perovskite interface through elimination of pinhole defects followed by Silver- functionalization (dense-TiO_2/mesoporous-Ag-TiO_2) to enhance the electrochemical surface and photo-absorptivity. An innovative method was used to construct a compact Ag functionalized a-TiO_2 film consisting of a mixture of ethanol, titanium(IV) isopropoxide, and silver nitrate spin coated on a fluorine-doped tin-oxide substrate in the absence of ZnO as supportive photoanode[2]. The performance of PSC/Ag–TiO_2 and TiO_2 films were probed using scanning electron microscopy (HRSEM), x-ray diffraction (XRD), UV-visible spectroscopy, cyclic voltammetry (CV), and electrochemical impedance spectroscopy (EIS). The uniformly distributed Ag-nanoparticles attached to the mesoporous TiO_2 matrix fashioned a TiO_2 compact layer with excellent blocking capability and improved electron mobility as observed in Fig.1. Particular Ag doping percentage of ~ 0.9% altered the electrical conductivity of the TiO_2 film, reducing the recombination process occurring at the ETL/PSC interface [3]. From IV-measurements, the PSC developed via two steps, yielded satisfactory effiencies. The dense-TiO_2/mesoporous-Ag-TiO_2 UV-Vis results revealed an induced red shift and band gap of 3.29 eV; indicative of enhanced luminescent properties. Hence, the synergy of dense TiO_2 and the surface plasmon resonance effect of metallic Ag nanoparticles successfully enhanced the optical absorption in the visible light region as well the power conversion efficiency compared to the pristine TiO_2 perovskite solar cell.

Nickel Hydroxide Anodes for Decoupled Water Splitting in an Electrochemical – Chemical Cycle

Avigail Landman, Hen Dotan, Avner Rothschild, Gideon Grader
Technion – Israel Institute of Technology
Haifa, 3200003
slandman@technion.ac.il

As the human population grows, a transition towards clean and renewable energy sources becomes critical in curbing the negative effects of fossil fuel combustion. To facilitate this transition, renewable sources must be combined with energy storage and transportation infrastructures.

Hydrogen production by water splitting has long been considered a promising solution to mitigating the intermittency issues of renewable energy, while also providing a high energy fuel for transportation. However, water splitting technologies still face challenges to improve their performance, efficiency, and cost, especially when combined with renewable power sources [1]. In conventional electrolyzer technologies, hydrogen and oxygen are evolved simultaneously in the same cell, and a membrane or diaphragm is essential for product separation (Figure 1a). Nevertheless, dangerous H_2/O_2 mixtures may still form under partial load conditions, which are inherent to renewable power source. Such H_2/O_2 mixtures lead to accelerated membrane degradation, in addition to posing a safety hazard. Furthermore, the four-electron oxygen evolution reaction (OER) that takes place at the anode requires large overpotentials of over 400 mV, resulting in significant energy efficiency losses.

In this work, we present a strategy for high-efficiency decoupled water splitting, wherein hydrogen and oxygen are produced in two separate steps in an electrochemical – thermally-activated chemical (E-TAC) cycle [2]. The conventional OER catalyst anode is replaced by a cobalt-doped nickel hydroxide [$Ni(OH)_2$] anode; in the first step, hydrogen is produced at the cathode while the anode is oxidized to nickel oxyhydroxide [NiOOH] in an efficient one-electron reaction, having a significantly lower overpotential compared to the OER (Figure 1b, left). In the second step, the oxidized NiOOH anode is disconnected from the electrical circuit and heated, inducing its spontaneous chemical reduction reaction, which restores its initial composition while oxidizing water and releasing oxygen (Figure 1b, right). This E-TAC process enables hydrogen production at low voltages in a simple, cyclic process with high efficiency, robustness, safety, and scale-up potential.

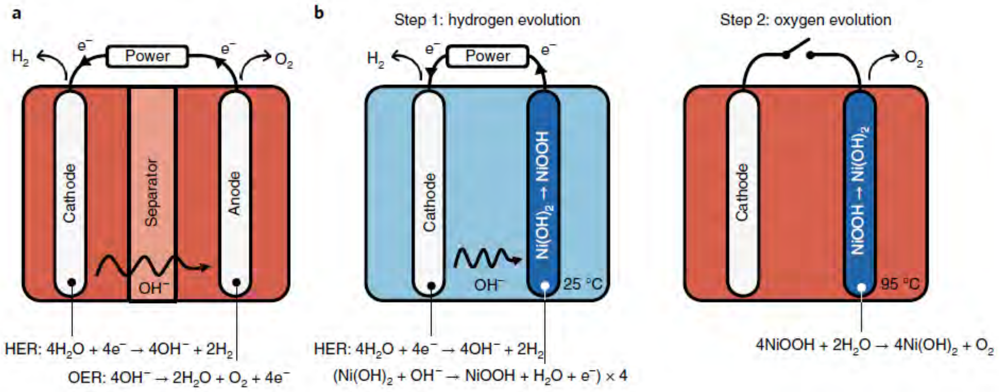

Figure 1: Schematic of alkaline water electrolysis (a) and the E-TAC water splitting process (b).

e-mail: rgdu@xmu.edu.cn

TiO_2 semiconductors can provide photoelectrochemical cathodic protection for metals due to their special photoelectrochemical properties. However, pure TiO_2 semiconductors cannot sustain photoelectrochemical cathodic protection in the dark, which may limit their practical applications. Therefore, in this work we fabricated a $ZnSe/MoO_3$ co-modified TiO_2 nanotube composite film with charge storage ability and investigated its photoelectrochemical cathodic protection effect on 403 stainless steel.

A TiO_2 nanotube array film was prepared on a Ti foil in a two-electrode cell by anodic oxidation, then MoO_3 and ZnSe particles were deposited onto the film by cyclic voltammetry and pulse electrodeposition, respectively. Finally, a $ZnSe/MoO_3/TiO_2$ nanotube composite film with a cascade band structure was fabricated. The prepared films were characterized by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), UV-Vis spectroscopy, and photoluminescence measurements. The photoelectrochemical cathodic protection effects of the prepared films were investigated by photoelectrochemical measurements.

The results showed that the TiO_2 film consisted of ordered nanotubes with an average inner diameter of about 100 nm and wall thickness of about 15 nm. This nanotube structure remained intact after MoO_3 and ZnSe particle deposition on the film. EDS, XRD, and XPS analyses indicated that the prepared nanotube composite film was composed of ZnSe, MoO_3 and TiO_2. The photoresponse of the $ZnSe/MoO_3/TiO_2$ composite film was extended to the visible light region, and the photo-induced electron-hole pair recombination was reduced. The photocurrent intensity of the composite film in a 0.5 M KOH solution was two-fold higher than that of the pure TiO_2 film. Under white light illumination, the $ZnSe/MoO_3/TiO_2$ composite film as a photoanode decreased the potential of the coupled 403 stainless steel in a 0.5 M NaCl solution by 470 mV relative to its corrosion potential, showing an effective photoelectrochemical cathodic protection effect. After the illumination was stopped, the composite film could continuously provide cathodic protection for 22.5 h resulting from its charge storage capability. The electrochemical impedance spectroscopy results also indicated that the composite film had the photoelectrochemical cathodic protection effect on 403 stainless steel.

Electrochemical Deposition of Tin from Deep Eutectic Solvents

A.E. Bolzán[a], L.A. Azpeitia[a], C. A. Gervasi[a,b]
[a]Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas (INIFTA), Sucursal 4., Casilla de Correo 16, (1900) La Plata; [b]-Facultad de Ingeniería, UNLP, 1 y 47, (1900) La Plata, Argentina.
aebolzan@inifta.unlp.edu.ar

The electrodeposition of Sn from deep eutectic solvents (DES) on copper substrates was studied in the temperature range 303 -- 353 K using the mixtures of choline chloride with either ethylene glycol (ethaline) or urea (reline) in the ratio 1:2. For the characterisation of the electrochemical process, voltammograms were run between -0.25 and -1.0 V (vs. Ag wire quasireversible reference electrode). For both DES, the negative-going potential scans show first an underpotential deposition process, which is immediately followed by an overpotential electrodeposition process. The former is, however, considerably less distinguishable in DES compared with that obtained in aqueous acid solutions. Some significant differences were observed between the voltammetric profiles recorded in ethaline and reline. First, the current densities are much lower in reline, at all temperatures, probably related to the much higher viscosity and much lower conductivity of reline. Secondly, in ethaline the voltammogram presents a main single cathodic current peak while in reline, depending on the temperature, two or three electroreduction current peaks can be recorded. By means of a rotating disc electrode, Levich plots were obtained from which the diffusion coefficient of Sn(II) ions was determined at different temperatures within the studied range. Moreover, while a limiting current plateau is recorded bellow -0.4 V during the electrodeposition of tin from etaline, in reline the limiting current is preceded by a series of three small cathodic peaks. From the corresponding Arrhenius plots, the activation energy for the diffusion process was determined and compared to data from acid aqueous solutions. Both, voltammetric and chronoamperometric measurements provided evidence of a nucleation and growth process. Non-dimensional plots derived from chronoamperometric experiments at different electroreduction potentials were consistent with the occurence of a 3D instantaneous nucleation and growth process under diffusion control during the overpotential deposition. Impedance data recorded between 60kHz and 10 mHz showed the presence of two capacitive time constants in the potential range related to the underpotential deposition process and a single capacitive time constant at potentials related to the overpotential electrodeposition of Sn ions. SEM images obtained for the deposits formed in both DES show the presence of different morphologies according to both, the nature of the electrolyte and the electrodeposition routine employed.

francisco.montilla@ua.es

The operation of most organic optoelectronic devices based on conjugated polymers, namely organic light-emitting diodes, organic photovoltaic cells or luminescent electrochemical cells is determined by the interaction of photoexcited states (i.e. excitons) and charged species (i.e. polarons) of polymer films.

The measurement of exciton diffusion is a key aspect to design efficient devices. This is usually performed by means of spectroscopic techniques, which measure the efficiency of radiated photons in the presence of quenchers. The photoluminescence (PL) of thin films is usually measured in the absence and in the presence of a quenching site and the exciton diffusion length is derived from the PL quotient. In these studies, a statistically significant number of experiments are required to obtain consistent results and therefore many samples must be prepared. Electrochemical methods allow a reversible and controlled charge injection in conjugated polymers, leading to the formation of charged states, such as polarons which serve as quenching sites for excitons. The use of electrochemical instrumentation allows fine and precise control of the quencher concentration, thus permitting a simultaneous analysis of exciton dynamics within a single sample of conjugated polymer. The electrochemical *in situ* fluorescence spectroscopy (also known as electrofluorochromism) is a relatively novel tool that has been applied to the characterization of luminescent molecular systems and to the development of novel optoelectronic devices[1,2]. In the present work, a combination of electrochemical *in situ* steady-state fluorescence spectroscopy and UV-vis spectroscopy has been employed for the first time to determine the diffusion coefficient of excitons. The material selected for this study is MEH-PPV, poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene], an orange-red emitter widely employed in OLEDs and bulk heterojunction photovoltaic cells. In these systems, an annihilation process can occur when a photogenerated singlet exciton (S_1) finds a quencher (p):

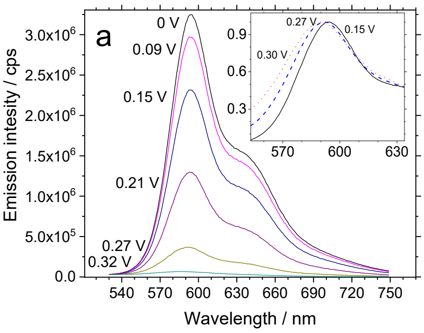

Figure 1: Evolution of the PL emission spectrum during the p-doping of a MEH-PPV film (λ_{exc}= 500 nm)

$$S_1 + p \overset{k_q}{\rightarrow} S_0 + p + phonons$$

being k_q the annihilation polaron-exciton rate constant. This bimolecular process competes with the monomolecular intrinsic de-excitation of excitons. The quenching process observed upon electrochemical doping (figure 1) follows a Stern-Volmer mechanism at low doping levels, with a time-independent rate constant typical of diffusion-controlled annihilation processes [3]. From both the Stern-Volmer rate constant and the exciton-polaron critical distance, an exciton diffusion coefficient can be derived [4]. These results support the suitability of spectroelectrochemical techniques as fast and powerful alternative tools for the reliable determination of exciton diffusion coefficients in conjugated polymers.

On the Electrochemical Exfoliation of Graphite to Graphene

Duhong Chen, Dongping Zhan*

e-mail address: dpzhan@xmu.edu.cn

Shortly after the birth of graphene, electrochemical exfoliation has been adopted to prepare graphene from various raw materials of graphite. In general, there are mainly three processes, ion intercalation/deintercalation, surface tailoring and bubbling dispersion, during the electrochemical exfoliation of grahite. We propose programed potential modulation strategies to balance these processes and obtained high-quality graphene with high crystallinity, low oxidation degree, uniform size distribution and few layers.

Another important issue is to functionalize the graphene simultaneously in the electrochemical exfoliation of graphite. GO plays important roles in the sustainable development of energy and the environment, taking the advantages of oxygen-containing functional groups for good dispersibility and assembly. Compared with Hummers' method, electrochemical exfoliation of graphite is considered facile and green, although the oxidation is pretty low. To synthesize GO with better crystallinity and higher oxidation degree, we present a photo-synergetic electrochemical method. By using oxalate anions as the intercalation ions and coreactant, the interfacial concentration of hydroxyl radicals generated during electrochemical exfoliation was promoted, and the oxidation degree was comparable with that of GO prepared by Hummers' method. In addition, the crystallinity was improved with fewer layers and larger size. Moreover, the aniline co-assembled GO membrane was selectively permeable to water molecules by the hydrogen-bond interaction, but it was impermeable to Na^+, K^+ and Mg^{2+}, due to the electrostatic interactions. Thus, it has a prospective application to water desalination and purification. This work opens a novel approach to the direct functionalization of graphene during the electro-exfoliation processes and to the subsequent assembly of the functionalized graphene.

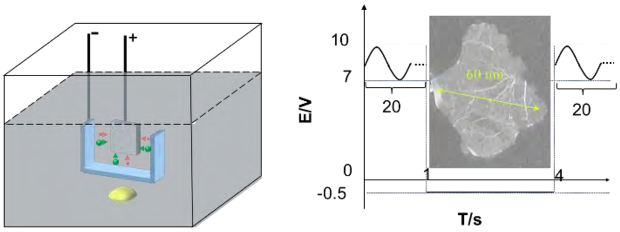

Fig. 1 the high-quality graphene produced by programmed potential modulations by balancing the ion intercalation/deintercalation, surface tailoring and bubbling dispersion processes in the electrochemical exfoliation of graphite.

Bipolar electrochemistry for site-selective multifunctional modification of conducting objects

Paul Chassagne, Alexander Kuhn

16 av. Pey Berland, 33600 Pessac, France.
paul.chassagne@enscbp.fr

Bipolar electrochemistry is a powerful technique for the asymmetric modification of conducting particles in the bulk. When placing a conducting object in an electric field produced by a pair of feeder electrodes, the potential distribution along the object polarizes it. If the potential difference between the extremities of the object is large enough, cathodic and anodic poles are created on which electrochemical reactions can occur and break the symmetry of the system. This "wireless" technique has been used for the bulk synthesis of Janus particles [1]. This method has also been used for the synthesis of ringed particles [2] and for the bifunctional modification of particles [3].

In this contribution, we present a method for the multifunctional modification of conducting particles using bipolar electrochemistry. Using AC potentials, it is possible to iteratively electrodeposit several metallic patches of different compositions on a conductive particle in a site-selective manner (Fig. 1). This method allows for the bulk synthesis of sophisticated asymmetric particles. The final objective of the work is the use of this symmetry-breaking concept to deposit four different patches in a tetrahedral geometry, which is impossible with any other deposition approach. This results in particles with a chiral character, analogous to an asymmetric carbon atom with four different substituents. Such objects could have numerous applications ranging from catalysis to chiroptics.

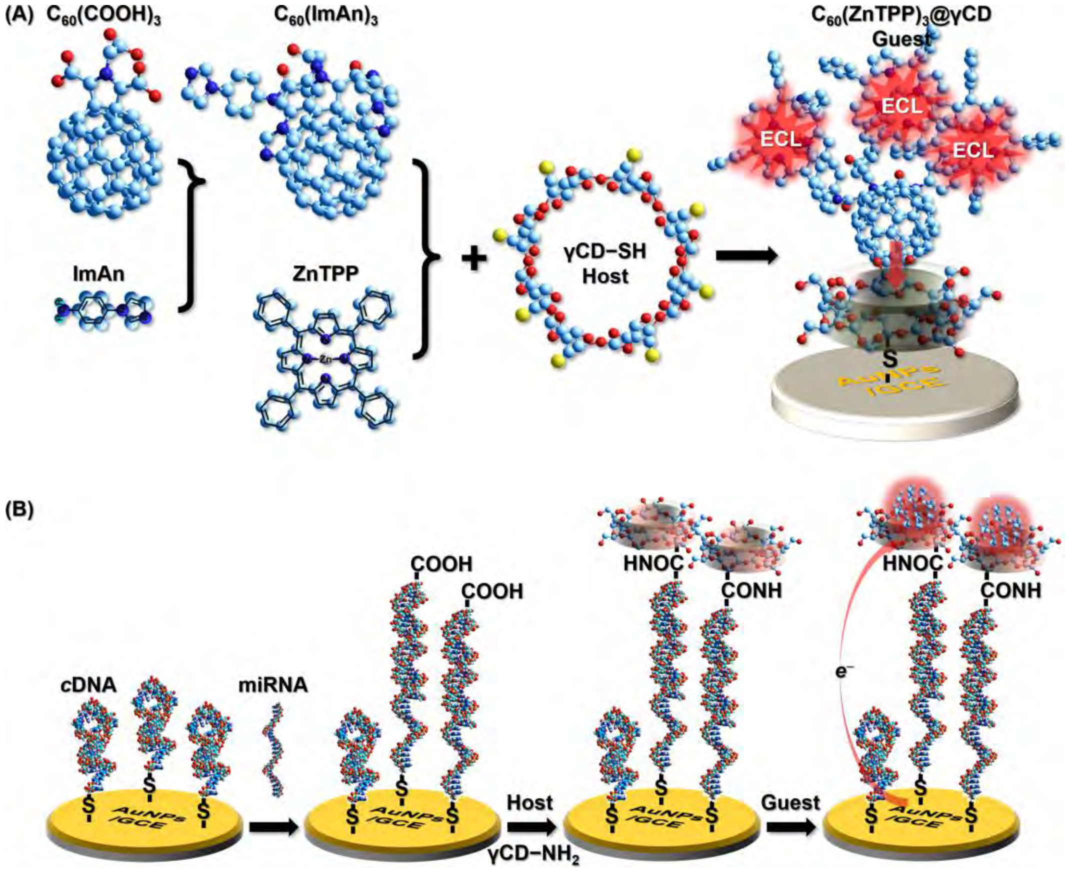
Herein, pyrrolidyl C_{60} derivative was recruited as an unadulterated and congruent nano-hub to converge three zinc porphyrins on its monopole. Such peculiar assembly was convinced via micro-imaging and spectrophotometry. Making the best of fullerenyl proficiency in catalytic singlet O_2 generation and excited-state preservation, a multiplied electrochemiluminescence (ECL) emission bursted out from the porphyrin trinity in a synergistic manner. Without any prebio-conjugation, this orderly ECL-active individual turned to anchor in the toroid of a peripherally modified gamma-cyclodextrin in a good shape match. From the facile direct mounting of the latter derives a universal bio-probing technique based upon such host-guest inclusion. Its binding pattern and the concomitant effects on interfacial properties were revealed by systematic process characterizations. Taking advantages of this uniform ensemble in both size and stoichiometry, an *in situ* terminal labelling strategy during the recognition-induced allosteric event came into being, which managed a neat signal enhancement for the detection of model miRNA marker. Even in real samples, the developed sensing approach could achieve high precision, comparable sensitivity and satisfactory selectivity. The adaptation of macrocyclic chemistry for refined biotransducers and efficient ECL amplifiers would offer a generic and potent alternative to the analyte-specified ECL indicator-receptor build in bioassays.



Scheme 1. (A) Synthetic route of $C_{60}(ZnTPP)_3$ the guest with precursor and intermediate models, and its inclusion in γCD−SH the host self-assembled on GCE/AuNPs. **(B)** Simplified miRNA assay workflow ended in *in situ* labelling with the signal indicator $C_{60}(ZnTPP)_3$@γCD.

Tracking CO_2 reduction products in real time

Forschungszentrum Jülich GmbH, Helmholtz-Institut Erlangen-Nürnberg (HI ERN)
Egerlandstr. 3, 91058 Erlangen, Germany
i.katsounaros@fz-juelich.de

Time-resolved characterization methods provide fundamental insights into electrode processes by capturing events that occur at short time scales. We recently developed the *electrochemical real-time mass spectrometry* (EC-RTMS) to determine gaseous and liquid products of electrochemical reactions shortly after their formation, with resolution in the order of few seconds [1]. After describing its basic components, I will present some representative examples of using EC-RTMS to monitor the products of CO_2 reduction under dynamic conditions, on various copper electrodes.

Development of a noble metal free, efficient and durable electrocatalysts for oxygen reduction reaction (ORR) is a key requirement for a broader outreach of clean energy technologies like fuel cells, which also get utmost relevance in the present scenario of global warming. In this direction, nanocomposites of M-N-C molecular macrocycles and carbon nanomaterials has attracted tremendous attention because of simple and low cost synthesis methods and competitive ORR characteristics as compared to conventional platinum based catalysts [1]. In our ongoing studies, a nanocomposite based on cobalt phthalocyanine (CoPc) supported on reduced graphene oxide (rGO) has been synthesized by non-covalent functionalization followed by electrochemical reduction and its electrocatalytic properties towards ORR has been investigated. Through an extensive structural , topographic and morphological characterizations of the resultant CoPc/rGO composite, it was confirmed that electrochemical processing step was the key factor in synergically enhancing the ORR properties by simultaneously breaking the bigger aggregates of CoPc and reducing the oxygenated groups in GO, thereby improving the dispersion of CoPc nanoclusters on planar graphene support (Fig. 1a) [2]. Therefore, electrochemical reduction facilitates the improved exposure of ORR sites (metal center in CoPc), strengthens the π-π stacking in the composite and enhanced the conductivity of the catalytic materials. The ORR activity of the catalytic materials coated on a glassy carbon electrode were evaluated by voltammetric studies performed in a rotating ring disk electrode (RRDE) set up, which revealed a synergic ORR catalysis at the nanocomposite surface highlighted by larger current densities, 300 mV positive shift of the onset potential, and negligible generation of H_2O_2 as compared to CoPc and GO (Fig. 1b). Moreover, CoPc/rGO material has shown longer ORR catalytic lifetime than Pt based catalysts and resistance to methanol poisoning, making it an appropriate alternative of conventional ORR catalysts in methanol fuel cell.

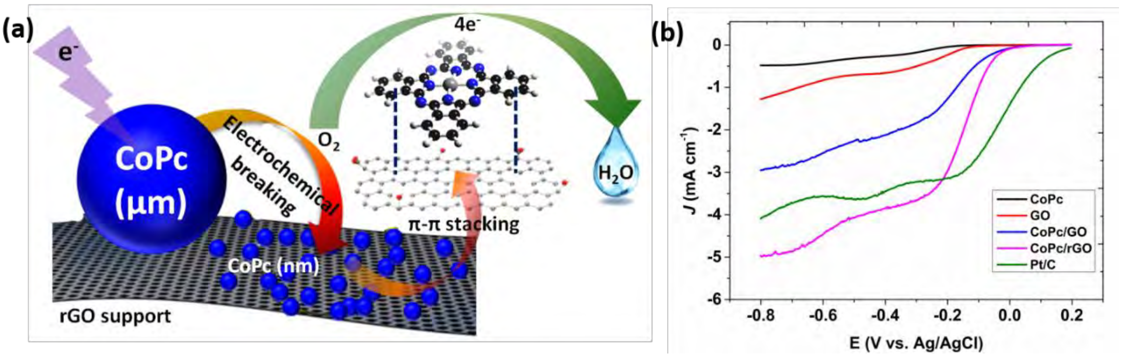

Fig. 1: *Schematic of electrochemically assisted dispersion of CoPc on graphene support and its ORR activity (a). Comparison of voltammograms of different catalytic materials in oxygen saturated 0.1 M KNO3 solution (b).*

Surface functionalization by electrografting of aryls to tune the electrical characteristics of organic electronics devices

Abhishek KUMAR*, **Mickael MATEOS**, **Rita MEUNIER-PREST**, **Marcel BOUVET**

Institut de Chimie Moléculaire de l'Université de Bourgogne, UMR CNRS 6302,
Université Bourgogne Franche-Comté, Dijon, France
**Abhishek.Kumar@u-bourgogne.fr*

Electrochemical grafting of aryl molecules on the electrode surfaces is a facile, well-controlled and extremely useful surface functionalization strategy to modulate the electrical characteristics of organic electronics devices. One of the preferred approach to realize such electrografting is via *in situ* diazonium formation from substituted aniline [1] to attach substituted benzenes on the conducting surfaces. Our endeavor in this direction is to functionalize Indium Tin Oxide (ITO) surfaces with benzene molecules bearing electron donating or accepting ligands to tune the electrical characteristics of the devices fabricated thereafter using such electrochemically processed ITO electrodes. Accordingly, Fig. 1 exhibits the cyclic voltammograms (CV) associated with electrografting of trifluoroethoxybenzene (TFEB) from the electroreduction of trifluoroethoxybenzenediazonium generated *in situ* from trifluoroethoxyaniline (TFEA) in an acidic medium. The progress of the electrodeposition is highlighted by the decrease in the reduction current with increasing CV cycles as a consequence of electrode conducting surface blockage by the relatively less conducting TFEB films. A simple schematic depicting grafting of TFEB molecules from TFEA precursor on the ITO surface during electrochemical processing has been shown in the inset of Fig. 1a. An optimization of this electrochemical step can result in the coating of a monolayer or a multilayer of such molecules on the electrode surface. The implications of such electrochemical grafting on the electrical properties of organic electronics devices like a Lutetium bis-phthalocyanine ($LuPc_2$) resistor can be profound. As a result of electrografting of TFEB film, the current-voltage (I-V) characteristics of the $LuPc_2$ resistor changed from an Ohmic to Schottky behavior (Fig. 1b), which can be attributed to the formation of an organic heterojunction interface because of electrografting [2]. Nature of these organic heterojunction interfaces and the built-in interfacial potential barrier so developed can be effectively tuned by the appropriate selection of substituents in the aryl molecules to be electrogrtaed at the electrode surface. Modulation of the interfacial potential barrier by electrografting in such organic heterojunction based devices and their applications in the development of conductometric gas sensors microsystem is the main scope of our ongoing work.

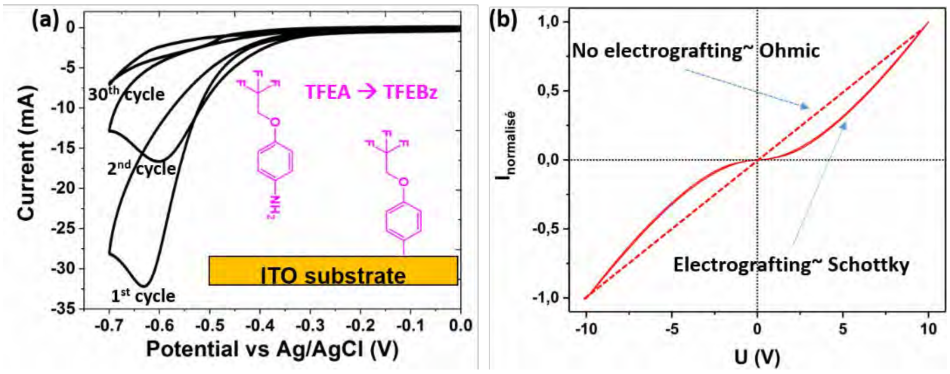

Fig. 1: *Cyclic voltammograms of ITO electrode in 2 mM* trifluoroethoxybenzenediazonium *in 1 M $HClO_4$ at a scan rate of 40 mVs-1 and schematic of electrografting of TFEB from TFEA on the ITO substrate in the inset (a). I-V characteristics of $LuPc_2$ resistor without and with electrografting of TFEB (c).*

The production of hydrogen through water splitting appears as an attractive way to face the intermittency of renewable energy power sources. In acidic media, the hydrogen evolution reaction exhibits very good kinetics on platinum electrocatalysts. However, in alkaline media, the HER exhibits relatively poor kinetics. After years of research efforts, a consensus has emerged at recognizing that the sole change in the energy of the surface intermediates cannot explain these different behaviors. Indeed, the structure of the interfacial water has been highlighted as a major parameter that controls the interfacial charge transfer, and thus the HER kinetics.[1-6]

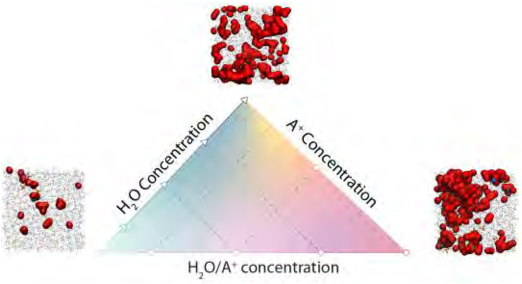

Figure 1. Snapshots of molecular dynamics simulations of water in acetonitrile for different water/salt ratios that illustrate the formation of *aqueous nanoreactors*.

To gain a deeper understanding on how these weak interactions affect the water reactivity, we have successfully explored a strategy consisting in confining water in an organic inert and liquid matrix (acetonitrile). Doing so, *aqueous nanoreactors* with controlled size and chemical compositions can be prepared. Hence, by playing on the water concentration, and/or on the supporting salt nature and/or concentration, the short and long-range environment of water molecules can be tuned, as we demonstrated by the combine use of classical molecular dynamics simulations, small-angle X-Ray scattering and NMR spectroscopy. Indeed, we show that water molecules can be isolated to independently study the influence of the water-cation interaction. Furthermore, by varying the size of the aqueous nanodomains, the amount of H-bonds formed between water molecules can be controlled, as illustrated in the **Figure 1**. Comparing this structural information with the measured activity for the water reduction on a platinum electrode, we can draw a picture of how the cation-water and water-water interactions compete, and how they govern the water reactivity at negatively charged electrodes. Overall, our results confirm the critical role of the transport of hydronium/hydroxides ions through the electrical double-layer on the water electrochemical reactivity. We believe that this simple chemical approach provides valuable information at the atomic level on the effect of water structure; these information were hardly attainable so far since it requires the use of complex experimental (temperature-jump, XAS, etc.) or computational techniques. Furthermore, developing such strategy to control the short- and long-range interactions in aqueous electrolytes will certainly prove very useful for studying other electrocatalytic reactions (OER, CO2RR, etc.).

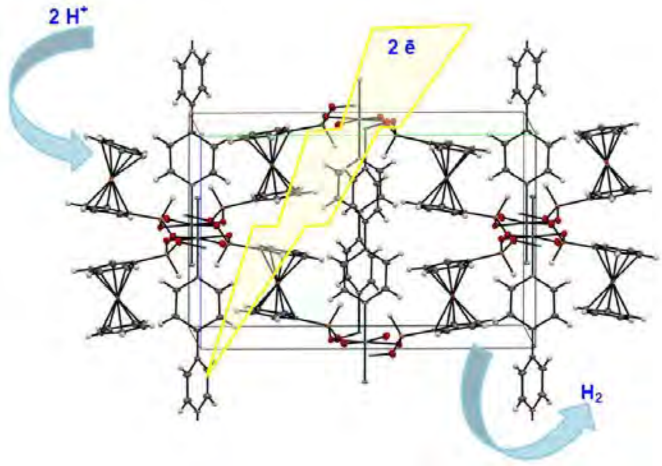
yulia@iopc.ru

Replacing platinum in hydrogen fuel cells with earth abundant metals will be a crucial step toward the viable use of H_2 as a solar fuel. Understanding the factors that control the binding and heterolysis of H_2 to these metals can play a key role in improving H_2 activation/production. The [FeFe]- and [NiFe]-hydrogenases easily catalyze reversible interconversion between dihydrogen gas and protons and electrons at mild conditions. The structures of hydrogenase active sites have provided attractive targets for synthetic chemists to advance our understanding of the electronic structure and reactivity of these unique enzyme active sites. These efforts contribute to the synthesis of new Fe, Co and Ni catalysts for hydrogen oxidation or production that could have significant impacts on alternative and renewable energy solutions. In recent times, highly active widespread numerous electrocatalysts, both homogeneous or heterogeneous (immobilized on the electrode), such as transition metal complexes, heteroatom- or metal-doped nanocarbons, metal-organic frameworks, and other metal derivatives (calix[4]resorcinols, pectates, etc.), which are, to one extent or another, structural or functional analogs of hydrogenases, have been extensively studied as alternatives for Pt-based catalysts, demonstrating prospects for the development of a "hydrogen economy". The development of new biomimetic catalytic systems mimicking the action of metalloenzymes and biological nanoreactors is based on cage structures, which contain P, N and S donor atoms coordinated to metal atoms and form cavities composed of macrocycles. The maximum TOFs of hydrogen evolution from the best Ni catalysts reach 15200 s^{-1}, which exceeds the values for most synthetic electrocatalysts known in the literature and is comparable with the activity of natural hydrogenases. In recent years new materials have been created for fuel cells based on organometallic hydrogenase models, which have shown their effectiveness. So, the diaza-diphosphacyclooctane nickel(II) complex $[Ni(P^{Py}{}_2N^{p\text{-}Tol}{}_2)_2]^{2+}{}_2$ on Vulcan XC-72(C) functions as both the cathode and anode catalysts in polymer electrolyte membrane fuel cell with the cathode the power density of 14.66 $mWcm^{-2}$, which is the highest power density of the none-noble organometallic analogs. Membrane-electrode assemblies with a cathode catalyst made of a nickel sodium pectate complex PG-NaNi with maximum current density of 59 $mAcm^{-2}$ and power density of 5.9 $mWcm^{-2}$ have been successfully created. These results permit the development of environmentally friendly and stable catalysts for PEMFCs made of a available biological raw material. The main advances in the development of synthetic analogues of natural metal-containing hydrogenases and materials based on them are analyzed and summarized.



MbpyfcdHp (M=Ni, Co)

HER performances up to:

η 350 mV at the current density of 10 $mA \cdot cm^{-2}$;

TS of 60 $mV \cdot dec^{-1}$;

superior long-term durability (up to 10,000 cycles)

The transition-metal-catalyzed reactions are among the most valuable transformations in organic synthesis and are generally rests on catalytic cycle involving transition metal complexes at various oxidation states. In this context, electrochemistry provides advantageous methods both for synthetic purposes and for mechanistic investigation. Electrosynthesis is useful in transition metal catalysis to generate the active catalyst form without specially added reducing or oxidizing agents. Performed in mild conditions it offers more environmentally non-polluting alternatives to traditional organic synthesis. Electrochemical methods should be used in combination with spectroscopy techniques to provide detailed characterization of the intermediate species. The merger of metal catalysis and electrosynthesis, metalla-electrocatalysis, has been identified as a powerful strategy towards sustainable synthesis, which was substantiated by electrochemical metal-catalyzed C-H functionalizations in recent years. We propose a "green" one-step catalytic method for introduction of fluorine-, phosphorus- or nitrogen-containing functional groups to different compounds with C(sp^2)-H bonds assisted by electrochemical reduction or oxidation of metal complexes under mild conditions. The catalytically active form of metal complexes in high oxidation state (Ni^{III} or Pd^{III}, Fe^{II}, Ag^{I} etc.) is generated and regenerated on the electrode without specially added oxidants. Key organometallic intermediates are isolated and characterized. The patterns of these reactions have been established. High-valent cobalt^{IV}-bpy and other complexes stabilized in silica matrix were detected as catalytically active form and intermediate in cobalt-mediated oxidative C-H/NH cross-coupling reaction. Radical reaction pathways were found in some cases. Advantages of directed metal-induced aromatic C-H-fluoroalkylation, phosphorylation or amination are demonstrated.

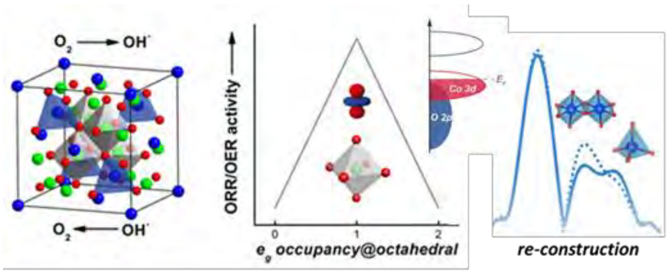
Exploring efficient and low-cost oxygen electrocatalysts for ORR and OER is critical for developing renewable energy technologies like fuel cells, metal-air batteries, and water electrolyzers. This presentation will present a systematic study on oxygen electrocatalysis (ORR and OER) of transition metal spinel oxides. Starting with a model system of Mn-Co spinel, the presentation will introduce the correlation of oxygen catalytic activities of these oxides and their intrinsic chemical properties. The catalytic activity was measured by rotating disk technique and the intrinsic chemical properties were probed by synchrotron X-ray absorption techniques. It was found that molecular orbital theory is able to well-explain their activities. The attention was further extended from cubic Mn-Co spinels to tetragonal Mn-Co spinels and it was found that the molecular theory is again dominant in determining the catalytic activities. This mechanistic principle is further applied to explain the ORR/OER activities of other spinels containing other transition metals (Fe, Ni, Zn, Li, etc.). The talk further gives insight on surface reconstruction on spinel oxides and how the bulk properties affect such reconstruction during OER. In addition, the talk will also discuss the possibility of the spin-selected charge transfer during oxygen electrocatalysis through transition metal oxides.



Dual-cathode Pulsed Current Electro-Fenton System: Enhancement for H_2O_2 Generation and Fe^{3+} Reduction

Fengxia DENG [a], Shan QIU [a]
[a] *State Key Laboratory of Urban Water Resources Centre, School of Environment, Harbin Institute of Technology, Harbin, 150090, P.R. China*
dengfx@hit.edu.cn

Abstract: In conventional electro-Fenton (EF), high H_2O_2 generation and fast Fe^{3+} reduction rate are hard to simultaneously achieve on single cathode(**Liang et al., 2018**; **Deng et al., 2019**; **Xia et al., 2020**). Then a dual-cathode pulsed current EF is offered, where constant current imposes on gas diffusion cathode (GDE) and carbon felt alternately. In this system, GDE is mainly for H_2O_2 accumulation, while carbon felt is primarily for Fe^{3+} reduction. Optimal current density for H_2O_2 formation on GDE is 10 mA cm^{-2}, while it is 2.5 mA cm^{-2} for Fe^{3+} reduction on carbon felt. Switching time of 20 s is alternatively applied on each cathode (**Fig.1**). Under optimal conditions, H_2O_2 reaches 1400 μM, which is higher than the sum of H_2O_2 generation (1289.86 μM) on GDE and carbon felt in the conventional one. In addition, its energy consumption experiences the lowest level as 31.16 W h/mol H_2O_2. Moreover, a higher Fe^{3+} reduction rate (93.8%) is observed than the conventional single carbon felt system (71%). And total iron keeps stable since iron precipitation near-cathode vicinity is alleviated. A 98.5% sulfamerazine decay coupled with 85.6% mineralization confirms the superiority of the system, where a higher concentration •OH is detected compared to the conventional one. In conclusion, the proposed system coordinates H_2O_2 formation and Fe^{3+} reduction.

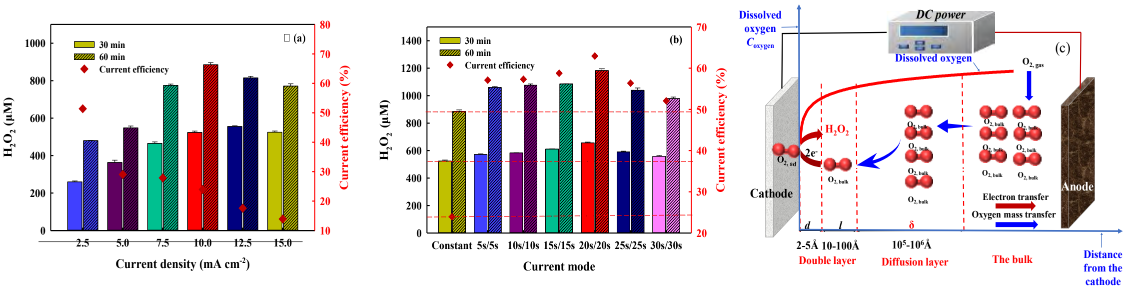


Fig. 1. (a) Effect of current density on H_2O_2 accumulation and related current efficiency (CE) at GED cathode, (b) influence of current mode on H_2O_2 accumulation and current efficiency (CE), (c) the whole process for two-electron ORR. Conditions: pH=3, $[Na_2SO_4]$ =50 mM, [oxygen flow rate] =300 mL min^{-1}, BDD sheet anode and GDE cathode (1 cm×2 cm).

Biomarkers real time monitoring of biological fluids plays an important in preventive medicine [1]. Generally, bodily fluids serve as carriers for biologically active compounds and as medium in which biochemical reactions take place, therefore, a large range of information can be obtained by monitoring alterations to their composition in real time, or as response to external stimulus [2]. The most common example is the determination of glucose in blood. Particularly, sweat contains a large amount of small molecules and ions with biochemical interest, being an accessible biological fluid, continuous monitoring biomarker concentration in sweat represents an alternative to traditional methods avoiding discomfort to patients. To achieve this, wearable devices are designed for direct contact with the epidermis. The goal of of this work was to obtain flexible electrodes that allow direct contact with the skin by producing microscopic fibers of poly-methyl methacrylate (PMMA) by electrospinning [3]. Consequently, the microscopic fiber networks were metalized by thermal evaporation and magnetron sputtering with metals such as Au, Ag and Pd, [4], conductive and highly porous networks were obtained, which were then transferred onto polyethylene terephthalate flexible supports (PET).

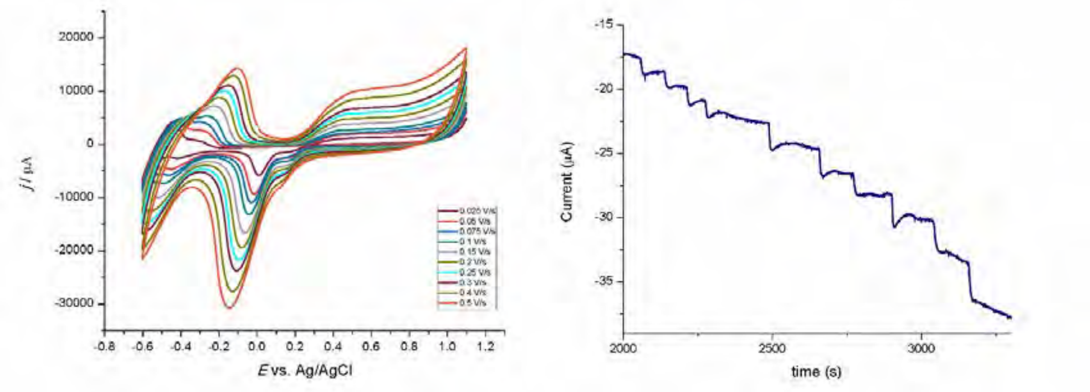

Fig. 1. A) Cyclic voltamograms of Pd/PMMA/PET electrode at different scan rates and **B)** amperometric response at -0.20 V after consecutive injections of 1 mM H_2O_2 in 0.1 M phosphate buffer pH 7.0, at Au/PMMA/PET electrode

Metalized flexible electrodes were applied for the detection of enzymatic products/coproducts like hydrogen peroxide by fixed potential amperometry. Optimum operational conditions were assed and analytical parameters were calculated for H_2O_2. PMMA metalized fibers were modified with different ionophores [5], in order to obtained sensors for target analytes such as Ca^{2+}, H^+, NH^{4+} and Cl^-. Ionophores immobilization procedure was optimized in order to improve sensitivity to analyte presence. The obtained interface was characterized by scanning electron microscopy with energy-dispersive X-ray spectroscopy, cyclic voltammetry and electrochemical impedance spectroscopy.

The impact of nanowire geometry over the electric properties of ZnO nanowires based devices

Melania Loredana ONEA[1,2], Elena MATEI[1], Monica ENCULESCU[1], Ionut ENCULESCU[1]
1. *National Institute of Materials Physics, Atomistilor 405A, 077125, Magurele Romania*

melania.onea@infim.ro

Fabrication of nanostructures with controlled morphology is extremely practical when it comes to applications like sensing devices. One of the most versatile nanostructures are semiconductor nanowires because they allow a control of key parameters such as chemical composition, diameter, length, dopping, electronic properties. Having been used in energy production, photocathalysis, light emitting devices, sensors or logic circuits, zinc oxide is one of the best candidates to build field effect transistors. This material is interesting due to its intrinsic physical properties, to its high occurrence/low cost and nontoxicity. [1, 2, 3, 4] Using a material which properties have been intensely studied makes it easier when one wants to observe the geometrical effect of ZnO nanowires over the electric response of a field effect transistor.

With the use of two types of polycarbonate membranes which have cylindrical pores (with the diameter of 200nm and 100nm), ZnO has been electrodeposited at two different deposition potentials. This resulted in four types of ZnO nanowires having different diameters (leading to a change of the surface/volume ratio) and having different concentration of Zn (leading to a change of the majority charge carriers).

Electron beam lithography (EBL) followed by sputtering techniques were employed in order to contact the nanowires to the electrodes. To understand how the size of the channels influences the properties of the final device, for each of the four types of nanowires used, two different channel lengths were made using EBL.

Scanning electron microscopy, energy-dispersive X-ray spectroscopy, reflection and X-ray diffraction were used to characterize the nanowires and the field effect transistors obtained. Thus we were able to analyze the morphology, the composition, the structure and the value of the bang gap in order to have a better understanding over the electrical measurements that have been made at different temperatures. The goal of this study is to functionalize the field effect transistor with electrodeposited ZnO nanowire channel in order to obtain a device which is sensitive to organic compounds such as biotin.

Influence of superimposed magnetic field on Co-Fe alloy 1D nanocone array electrodeposited in AAO template.

K. Skibinska, K. Kolczyk-Siedlecka, D. Kutyla, A. Kwiecinska, R. Kowalik, P. Zabinski
University of Science and Technology, Faculty of Non-Ferrous Metals, Mickiewicza 30, 30-059, Krakow, Poland
kskib@agh.edu.pl

One-dimensional (1D) nanostructures such as nanotubes, nanopores, nanodots and nanocones are fabricated using porous anodic alumina oxide (AAO) template produced in two-step anodization. Due to their large active surface area and small geometrical size these materials are characterised by better catalytic properties than bulk material [1]. Alternating cycles of the anodization in oxalic acid and pore widening process in phosphoric acid led to obtain conical nanopores templates. To obtain free standing nanocones the Al_2O_3 template has to be chemically etched.

Co-Fe alloy nanocones were electrodeposited in AAO templates. The magnetic field with different intensity has been superimposed during electrodeposition. The hydrodynamic conditions during electrochemical process are changed by the magnetic field. This cause the modification of composition and morphology of Co-Fe nanocones. The active surface area of samples were calculated from SEM photos. The electrocatalytic properties of fabricated nanostructures were measured in 1M NaOH and compared with bulk materials.

Determination of bisphenol S, simultaneously to bisphenol A in different water matrices or solely in electrolyzed solutions, using a cathodically pretreated boron-doped diamond electrode

Jhonys Machado Freitas, Naihara Wachter, Romeu C. Rocha-Filho
Departamento de Química, Universidade Federal de São Carlos
C.P. 676,13560-970 São Carlos, SP, Brazil
jhonysmf@gmail.com

As the hazardous effects of bisphenol A (BPA) are being revealed, alternative "BPA-free" products are coming out. Bisphenol S (BPS) is one of the most widely used substitutes for BPA. However, it has been shown by recent studies that BPS could be unsafe similarly to its analog BPA[1]. The widespread use of BPS and BPA and their persistence in the environment make them arise as worrisome pollutants. In this context, analytical methods capable of simultaneously determining BPS and BPA in different environments liable to contamination, like waterbodies, are required. In this work, a simple, accurate and environmentally friendly method for the simultaneous determination of BPS and BPA was developed and validated. The determination was performed by square-wave voltammetry (SWV) using a cathodically pretreated boron-doped diamond (BDD) as the working electrode, with 0.1 mol L^{-1} H_2SO_4 as the supporting electrolyte. Under optimized conditions, a wide linear working range ($R^2 = 0.999$) from 0.20 to 80.0 mg L^{-1} (8.0×10^{-7} to 3.20×10^{-4} mol L^{-1}) with a limit of detection ($S/N = 3$) of 0.060 mg L^{-1} (2.4×10^{-7} mol L^{-1}) was attained for BPS. For BPA, a linear correlation ($R^2 = 0.992$) from 0.10 to 50.0 mg L^{-1} (4.4×10^{-7} to 2.19×10^{-4} mol L^{-1}) was attained, with a limit of detection of 0.030 mg L^{-1} (1.3×10^{-7} mol L^{-1}). Figure 1 presents the baseline-corrected square-wave voltammograms for both concentrations being varied simultaneously (Fig. 1A), and the I_p vs. [BPS] or [BPA] plots (Fig. 1B) for the lower concentrations of the linear working ranges.

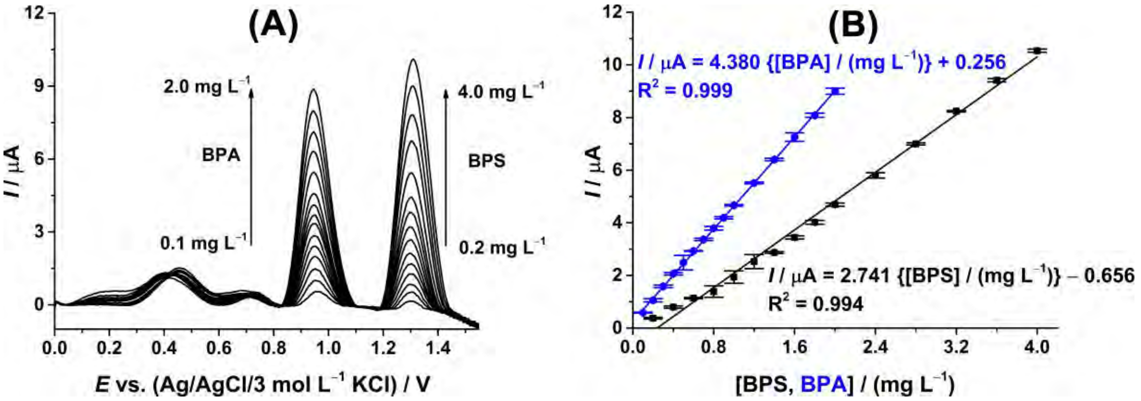

Fig. 1. (A) Baseline-corrected square-wave voltammograms at the cathodically pretreated boron-doped diamond electrode for the simultaneous addition of increasing concentrations of BPS and BPA in 0.1 mol L^{-1} H_2SO_4. **(B)** Respective calibration curves for BPS (black) and BPA (blue) obtained from the simultaneous addition data. SWV parameters: amplitude: 50 mV, frequency: 60 Hz, step potential: 6 mV

As can be seen in Figure 1, independent increases of the oxidation current peaks were observed with a linear behavior ($R^2 \geq 0.994$). Thus, it can be concluded that the simultaneous determination of BPS and BPA is feasible in the given conditions. The method was applied to the simultaneous determination of BPS and BPA in real water samples, with minimum sample preparation processes (only dilution and acidification). Excellent recovery values were achieved, ranging from 94.9 to 98.8%. Additionally, the method was applied to the monitoring of the electrochemical degradation (anodic oxidation) of BPS using a recirculating flow system fitted with a BDD anode. The decay of [BPS] with time was also checked by an HPLC method, with results statistically similar to those obtained by the proposed electroanalytical method. Hence, the proposed method is a reliable, greener and low-cost alternative to monitor simultaneously BPS and BPA in aquatic matrices or only BPS in wastewater treatment processes.

Recent years have witnessed significant increase in the interest towards H_2-O_2 (air) anion exchange membrane fuel cells (AEMFCs), largely stimulated by the development of AEMs and platinum group metal (PGM) free catalysts for the hydrogen oxidation reaction (HOR) [1-7]. The latter are typically based on nickel, benefiting from its low cost and high corrosion stability in alkaline media. Since pure metallic Ni demonstrates rather poor performance in the HOR, various means have been suggested for its ‘activation’. Alloying of Ni with a second metal is one of the most popular approaches [1-3]. The activity enhancement is usually attributed to an electronic effect of the second metal, while the exact physical origin of this ‘electronic’ effect has not been fully understood yet. Meanwhile, such an understanding is of paramount importance for the development of efficient anode catalysts for AEMFCs.

In this work, we prepare a series of monometallic Ni/C and bimetallic NiMo/C and NiCu/C catalysts using an incipient wetness impregnation. Their HOR activities are compatible with the best reported PGM-free catalysts [3-6]. By complementing electrochemical studies with a thorough physicochemical analysis (HR-(S)TEM, EDS, XRD, XPS) of the prepared catalysts before and after their reductive treatment, by performing Monte Carlo simulations of bimetallic nanoparticles we demonstrate several important findings. First, we show that the surface state of monometallic Ni/C catalysts is a determinant factor for their specific activity in the HOR independent of the synthetic procedure (electrodeposition or chemical deposition). Second, more importantly, by comparing HOR activity of mono- and bimetallic (NiMo/C and NiCu/C) catalysts either taken from air or subjected to thermal reduction by H_2 right before the electrocatalytic measurements we discover that the state of the Ni surface (metallic *vs* partially oxidized) has stronger influence on the HOR than the presence of the second component (Fig. 1). At the same time, the second metal might help to maintain (up to some extent) the desired state of Ni surface in the resulting catalyst thus affecting its stability in the HOR.

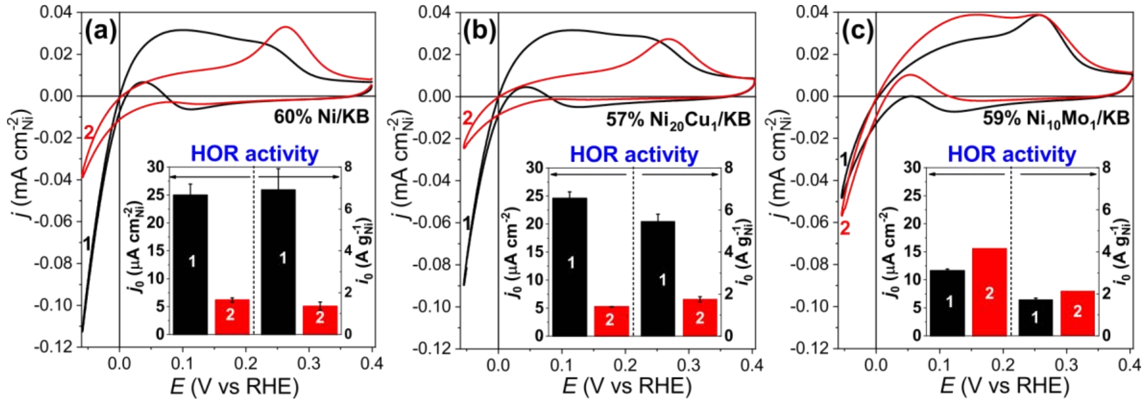

Figure 1. HOR polarization curves (0.1 M NaOH, 25 °C, 5 mV/s, 1600 rpm) and the corresponding surface- and mass-normalized HOR exchange current densities (insets) for Ni/KB (a), $Ni_{20}Cu_1$/KB (b), $Ni_{10}Mo_1$/KB (c) catalysts either taken from air (1) or subjected to thermal reduction by H_2 (2).

Formation and Reactivity of Phosphorous Acid on Platinum at Conditions Relevant to HT PEM Fuel Cell

M. Prokop, T. Bystron, M. Paidar, K. Bouzek
University of Chemistry and Technology, Prague
Technicka 5, Prague 6 166 28, Czech Republic
prokopm@vscht.cz

Proton-conductive membranes, based on doping of polymers with H_3PO_4, are often utilised in fuel cells operating above the temperature of 120 °C. The main advantage of operating at elevated temperatures is feasible heat recuperation and absence of demanding water regime. Particularly, high temperature fuel cell with proton-conductive membrane (HT PEM FC), operating in temperature range of 120 to 180 °C, is one of promising types. It utilizes Pt nanoparticles as a catalyst on both electrodes, hydrogen as a fuel and oxygen as an oxidant. In membrane, H_3PO_4 is used as a dopant with high proton-conductivity and, supposedly, high stability. However, the stability has been questioned in recent years, as electrochemical reduction of H_3PO_4 on a Pt surface can lead to formation of H_3PO_3 and other phosphorus compounds like Pt-P.

One of the profound problems related to HT PEM FC is degradation of Pt catalyst on the cathode and, consequently, diminishing of Pt surface area during the operation. The degradation of Pt nanoparticles proceeds via Ostwald ripening mechanism, with Pt dissolution as rate-determining step [1]. To avoid deterioration of cathodic Pt surface area, general recommendation is to avoid voltage cycling [2], induced by the start-up and shut-down procedure. At this point, it is important to stress that at such conditions, reduction of H_3PO_4 following by the oxidation of reduction products, takes place on the cathode [3]. The effect of this process on the catalyst is still undescribed, also due to lack of data on electrochemical behaviour of H_3PO_3 and Pt-P on a Pt surface. What is confirmed, however, is chemical behaviour of H_3PO_3 in terms of its reducing and adsorbing properties [4]. Therefore, the impact of H_3PO_3 on a degradation of Pt nanoparticle catalyst is potentially significant.

The goal of this study was the description of H_3PO_3 formation and electrochemical behaviour on bulk Pt electrode in concentrated H_3PO_4 electrolyte at temperatures above 120 °C. Experiments were performed in three-electrode arrangement, using voltammetric methods. Important features of H_3PO_3 behaviour were evaluated, including its oxidation kinetics and adsorption isotherms on a Pt electrode surface and interaction with oxidised Pt surface. Results proved that H_3PO_3 presence in Pt/H_3PO_4 system at elevated temperatures has, indeed, high impact on Pt surface reactions dynamics. In the next step, experimental data will be verified using gas-diffusion electrode in half-cell arrangement.

This study was supported by the Grant Agency of the Czech Republic under project No. 19-02964J.

DNA-based biosensors attract an enormous interest due to their potential applications, such as detection of DNA base damage in clinical diagnosis or evaluation of DNA-drug interaction mechanisms.[1] Understanding the adsorption of individual DNA bases on solid substrates is of fundamental interest since different structural conformations adopted by DNA can lead to different interactions, changes the accessibility of drugs to the DNA grooves, or promote different rates of hybridization.[1] These conformational changes in DNA can be induced by changes in the acid-base or tautomeric equilibria of the bases, originated either by the interaction with the substrate or by the application of an external electric field. Guanine is one of the DNA bases that undergoes two acid/base equilibria, pKa values 4.2 and 9.5, (Figure 1) and may present several tautomeric forms in aqueous solutions.[2]

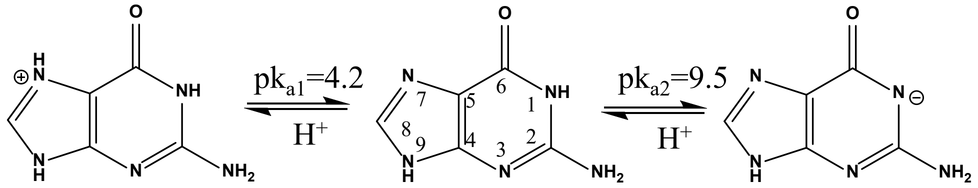

Figure 1. Acid-base equilibria of guanine

In the present work, we report a spectroelectrochemical study by in situ Surface-Enhanced Infrared Absorption Spectroscopy in the Attenuated Total Reflection mode (ATR-SEIRAS) to understand and characterize the guanine adsorption on gold thin-film electrodes from solutions at two pH values under the first pK_a using H_2O and D_2O as solvents. The spectra are interpreted on the basis of DFT calculations over different acid-base and tautomeric forms of the molecule.

Ammonia is one of the most important industrial chemicals, with *ca* 1 % of the world's energy being used for its production. It is mainly used to produce artificial fertilisers, which are essential for the sustenance of the growing global population. Even though molecular nitrogen is readily available, the N_2 molecule is notoriously inert and its reduction to NH_3 is challenging. NH_3 is currently produced in the energy intensive Haber-Bosch process, which requires high temperature and pressure in order to activate N_2. This necessitates production in large, centralised plants. Considering this, there is a certain interest in the development of alternatives which could be implemented in a more decentralised manner. The electrochemical reduction of ammonia would be an attractive option, as electrochemical potential could be used to drive the reaction, enabling on-site production using electricity from renewable energy sources. This prompted widespread scientific interest for the investigation of this reaction. The field of electrochemical nitrogen reduction (N_2RR) was, and to a large degree still is, struggling with numerous issues regarding reliable NH_3 detection, signal-to-noise ratio, contamination and reproducibility. Nonetheless, Li-mediated N_2RR in non-aqueous electrolytes has been shown to be a viable method to reduce molecular nitrogen to ammonia[1], at least on the laboratory scale. It is generally assumed that in the process the electrodeposited Li reacts with dissolved nitrogen forming Li_3N, which subsequently receives protons from a proton carrier, such as an alcohol, forming NH_3 and an alkoxide, Figure 1A. The implementation of an electrochemical quartz crystal microbalance (EQCM) allows the direct measurement of the deposition on the electrode, which coupled with isotope labelling experiments, can shed light on these processes. The monitoring of mass deposition on the electrode surface during the potential scan using an EQCM, Figure 1B, can give indications about the SEI formation, possible side reactions, and information about the Li deposition process and subsequent reactions[2]. While nitrogen reduction in ambient conditions is an interesting prospect, this electrochemical system does have certain limitations: only modest Faradaic efficiencies were achieved, it requires oxygen- and water-free conditions, non-green solvents are usually used, and the proton carriers are irreversibly lost in the reaction. The prospects of overcoming these and other issues will be discussed, and possible directions for future research will be laid out.

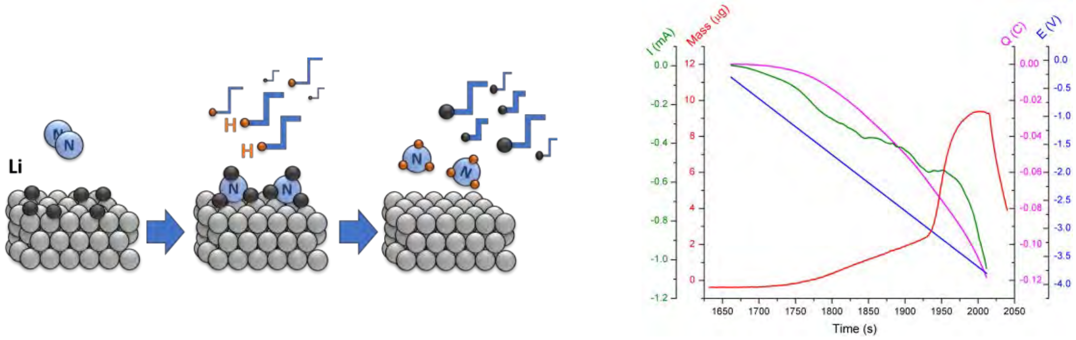

Figure 1: (A) The proposed reaction scheme (B) Mass deposition, current and charge passed during potential scan as detected by EQCM

CO_2 Reduction Reaction on Cu_2O Electrodes: High Alcohol Selectivity at Low Overpotential Accompanied by Current Oscillations

André H. B. Dourado, Katharina Krischer
Nonequilibrium Chemical Physics - Technical University of Munich
James-Franck-Str. 1, 85748 Garching, Germany
e-mail: andre.dourado@tum.de

The electrochemical reduction of CO_2 (CO2RR) provides an attractive means to synthesize fuels and feedstock chemicals in a sustainable way. However, a large-scale utilization is still hampered by the low selectivity of most catalysts for many of the potential products as well as high overpotentials. So-called Cu oxide-derived Cu (Cu-OD) has been identified as promising electrode material, overcoming in part these limitations. The catalytically active Cu-OD electrode is obtained operando from Cu_2O primary material at CO2RR electrode potentials and exhibits a high selectivity for C_2 products, in particular for ethylene. On the other side, it has been believed to be inactive towards alcohol formation [1]. In this paper we present a modified protocol for the generation of Cu-OD electrodes that is highly selective for alcohol formation and yields current densities as high as 300 mA/cm^2 geometrical area at overpotentials as low as -0.7 V_{RHE}.

The Cu-OD catalyst was electrochemically synthesized by sequential depositions, leading to a high surface area Cu_2O (with a roughness factor r = 35.2 for the electrochemical surface area). Characterization of the material and the Cu-OD surface by XPS, showed that the catalytically active surface has an unusual large number of oxygen vacancies.

The CO_2RR was measured in a CO_2-saturated, 0.5 M K_2CO_3 electrolyte. CO_2RR current densities obtained were in the order of 10 mA cm^{-2}_{ECSA}, i.e. 350 mA $cm^{-2}_{geometrical}$, at -0.70 V_{RHE}, one of the highest activities ever reported at this overpotential [1,2]. This high current value is observed together with another feature, so far not observed during CO_2RR, namely current oscillations , manifesting that for this set of conditions CO_2RR presents non-linear behavior. Liquid products analysis was performed by nuclear magnetic resonance (NMR) after keeping the electrode for 1h under oscillatory conditions. Ethanol (EtOH) and methanol (MeOH) were the main products, with faradaic efficiencies of 33.1 (EtOH) and 31.7 (MeOH) %. This amounts to activities of -3.35 (EtOH) and -3.20 (MeOH) mA cm^{-2}_{ECSA} or -119.26 (EtOH) and -114.18 (MeOH) mA cm^{-2}_{geom} (see table I). Only when the reaction rate exhibited oscillations were these high activities observed. XPS data suggested that under these highly active and oscillatory conditions the density of oxygen vacancies had increased compared to less negative potentials, pointing to a close relation between oscillatory conditions, alcohol selectivity and degree of oxygen evacuation.

Table 1. Faradic efficiencies (FE) and activities (as function of geometrical area and ECSA) for alcohols obtained during CO_2RR at 0.70 V_{RHE}.

Product	FE / %	Activity / mA cm^{-2} $_{geom}$	Activity / mA cm^{-2} $_{ECSA}$
MeOH	31.7	-114.18	-3.20
EtOH	33.1	-119.26	-3.35

Pore Network Modelling of Invasion Processes in Electrochemistry

H. Altaf[1], N. Vorhauer[1], T. Vidakovic-Koch[2], E. Tsotsas[1]
[1]Otto von Guericke University, Institute of Process Engineering, 39106 Magdeburg, Germany
[2]Max Planck Institute (Dynamics of Complex Technical Systems), 39106 Magdeburg, Germany
**haashir.altaf@ovgu.de*

Flow in porous media has widespread importance in various fields of science. For the understanding of transport phenomena within a porous medium, at a meso- or microscale, Pore Network Modelling (PNM) has been of great use. PNM has been prevalent in geo-material and drying applications for a long time. In the recent time, PNM has found its way into electrochemistry; precisely in analyzing the two-phase transport within the porous components of fuel cells, electrolyzers or batteries. The efficiency of these systems depends significantly on the transport kinetics and the evolving dynamic distributions of gas and liquid e.g. inside the catalyst layer, where the electrochemical reactions occur. For example, in the case of electrolysers, the oxygen gas produced at the anode must be removed so that the water supply adequately persists. The oxygen coverage of the catalyst layer obstructs the water supply towards the reaction zone[1]. This can lead to a decrease in the rate of reaction. On the contrary, in fuel cells, water produced as the result of the electrochemical reaction must be removed efficiently[2]. For these systems, to be more marketable and serve as a viable option for future energy problems, they must be optimized in terms of performance. The mass transfer through these diffusion and transport layers thus becomes an important issue to be investigated for a better understanding of the transport limitations, as they play a major role in defining the performance of these systems. This requires a deep understanding of the pore scale distribution of gas and liquid phase at different operating conditions.

PNMs conceptually represent the porous media. Micro computed tomography is used to extract the required information about e.g. pore size distribution, pore connectivity, pore shape etc. The model uses this information to generate an interconnected network of pores. This network of pores portrays the voids of the porous medium through which the phase transport occurs. Relevant two-phase flow physics are used to study the transport limitations at microscale. Compared to existing macroscopic models; PNM is suitable for low capillary numbers, takes wetting characteristics into account and resolves the invasion process on the pore scale. It can be shown by PNM that the tortuosity of the gas/liquid paths and permeabilities essentially depend on the pore structure, local temperature and wettability of the porous medium as well as local pressure differences. Use of PNM for imbibition and drainage phenomena allows the study of the correlation between material properties and operation conditions and the relevant effective transport parameters, and it can also be used to parameterize the macroscopic continuum models. Thus, PNM can also facilitate optimization of the structural parameters of these materials that are required for an efficient operation.

Nanoporous gold (NP-Au) is a promising versatile material that can be used in many fields, a result of its high conductivity, large surface area, and excellent stability. NP-Au is commonly functionalized in combination with other materials; however, difficult syntheses are obstacles to catalyst development. In this presentation, a simple method for the fabrication of binary nanoporous gold-palladium (NP-AuPd) with a tunable Au/Pd ratio is developed [1]. Ternary alloy films of Au-Pd-Mg are prepared by sputter deposition and Mg is dissolved from the alloy to make nanoporous structures. The Au and Pd in NP-AuPd are evenly distributed over the entire structure. The electro-catalytic activity of the developed NP-AuPd is evaluated by oxidizing ethanol in alkaline media. The optimized NP-AuPd shows remarkable electro-catalytic activity and excellent stability. The nanoporous structure not only increases the number of reaction sites and mass transfer, but it also enhances the durability of the catalyst. The developed method can be extended to the preparation of binary nanoporous thin films with controlled compositions and desired catalytic activities.

Metal air battery is superior to lithium secondary ion battery because of none danger of ignition and possibility of keeping for a long time. We think that it has many problems for development of secondary battery. However, we reported that metal air battery using expanded natural graphite sheet as cathode and galvanized plate as anode is promising device for primary battery for backup power supply and emergency one [1]. Discharge capacity of this battery is 2.1mAh/cm^2 which value is about three times than that of Bincho charcoal metal air battery which have been used science teaching material. We hope that this battery can be used a lot of applications, such as a light-emitting and smart phone charging and so on at the emergency, because DC 12 V output can be obtained in 15 cells connected in series.

Maine parts of this battery are expanded natural graphite sheet for cathode, galvanized plate for anode and electrolyte. Expanded natural graphite sheets have been using for gasket and heat radiation materials because of high thermal conductivity, high electric conductivity, physical and chemical stability, workability and so on. We can easily and cheaply get the large size with the wide of 1.3m and long of more than 100m. Galvanized plate is very cheap and physical and chemical stability, too. These materials can be kept for a long time without particular environment. We only need to prepare the electrolyte due to fabricate this battery at the emergency.

In this paper, characteristics of metal air batteries using expanded natural graphite sheet as cathode and galvanized plate as anode with various electrolyte has been investigated for a power units at the emergency. The standard electrolyte was used 10 % sodium chloride water solution absorbed to the filter paper with thickness of 0.7 mm as a separator. We attempt to use various liquid, which we can easily get at the emergency, as an electrolyte, such as normal water, sports drink, and so on. The separators, such as glass wool and various paper, were selected with the same thinking for electrolyte. The cell size was square of 25cm^2. The standard properties of the primary battery, such as discharge capacity, voltage and internal resistance, were measured.

Figure 1 shows the standard single cell structure and its apparatus. The oxygen gas as the activation material for the cathode can be get from side edge of expanded natural graphite sheet. Figure 2 shows the discharge properties of metal air batteries using electrolytes of 10 % sodium chloride water solution, tap water, sports drink, and so on, with separators of filter papers. When sports drink are used for electrolytes, discharge capacities are larger than that of using 10 % sodium chloride water solution that is standard electrolyte. Furthermore, it was found that metal air battery using electrolyte of the other solution could be working for LED light emitting.

We hope that this battery can be used at the emergency, because DC 12 V output can be obtained in 15 cells connected in series and we can easily get all battery parts at the emergency.

m.koper@lic.leidenuniv.nl

The production of hydrogen through water electrolysis using renewable electricity is a promising carbon-neutral technology. We present insights into the hydrogen evolution reaction (HER) in aqueous H_2SO_4 (0.005 to 0.5 M) on Pt(111) on Graphene/Pt(111) under ambient temperatures and pressures. Graphene was grown on Pt(111) using chemical vapor deposition (CVD) of hydrocarbons and characterized using scanning electron microscopy (SEM) and Raman spectroscopy [1].

Cyclic voltammograms (CV) and HER currents of Pt(111) in H_2SO_4 were quantitatively benchmarked to literature to ensure reproducibility and comparability of kinetic measurements [1-3]. CV sweeps (0.005 to 0.5 M, 23°C, 0.1 to 0.8 V_{RHE}) indicate that graphene overlayers are selectively permeable to H^+ ions in the electrolyte, allowing H^+ ions into the confined layer between Pt(111) and graphene while excluding SO_4^{2-} and other anions [2]. The extent of defects in graphene was quantified by integrating the anion adsorption region from CVs. The anion adsorption coverage on electrochemically pre-treated Graphene/Pt(111) (250 cycles between 0.1 to 1.2 V_{RHE} in 0.005 M H_2SO_4) increases with HER reaction time at a rate of ~$3*10^{-6}$ $mol_{anion}\ mol_{Pt}^{-1}\ s^{-1}$ while untreated Graphene/Pt(111) exhibits a slower increase of ~$5*10^{-7}$ $mol_{anion}\ mol_{Pt}^{-1}\ s^{-1}$. Though the defect generation rate is slower on untreated Graphene/Pt(111), a sudden order-of-magnitude increase in anion coverage is observed between 9 to 12 hours of HER. In contrast, no sudden increase in the anion capacity is observed on electrochemically pre-treated Graphene/Pt(111) for up to 15 hours of HER.

Initial HER currents on both pre-treated and un-treated Graphene/Pt(111) are slower than Pt(111) by 1 to 2 orders of magnitude (0.005 to 0.5 M, 23°C, -0.08 V_{RHE}). HER currents on both pre-treated and un-treated Graphene/Pt(111) increase with HER reaction time to values equal to or higher than that of Pt(111), concurrent with increasing graphene defects as probed using CV and SEM. Unchanged HER Tafel slopes and $[H^+]$ reaction orders suggest the same HER mechanism between Pt(111) and Graphene/Pt(111). We postulate that untreated graphene is mass transfer limited and HER currents transition from mass transfer limited to kinetics limited with increasing graphene defects. Li et al. computes that a graphene overlayer would weaken the hydrogen binding energy to Pt(111), shift the reaction closer to the peak of the HER volcano plot, and thus increase HER currents [6,7]. Though our results agree with prediction, we cannot negate other possible explanations for the observed increase in HER rate. These results demonstrate the promise of overlayer and confinement modifications in designing catalysts with properties closer to achieving optimum currents.

Electrochemical characterization of fiberglass membranes modified with polyelectrolytes used as the support for the electrified liquid-liquid interface.

Paulina Borgul, Sławomira Skrzypek, Łukasz Półtorak
University of Lodz, Faculty of Chemistry, Department of Inorganic and Analytical Chemistry
Tamka 12, 91-403 Lodz, Poland
paulina.borgul@chemia.uni.lodz.pl

The interface between two immiscible electrolyte solutions (ITIES) is a system which allows the control of a potential difference between two adjacent liquid phases. It can be used to explain the charge transfer reactions happening at this soft junction. The example of ITIES, also used in this work, could be an interface formed between the aqueous solution of sodium chloride (water phase) and a solution of highly hydrophobic salt (bis-(triphenylphosphoranylidene)-ammonium tetrakis-(4-chlorophenyl)-borate) dissolved in 1,2-dichloroethane (organic phase). Systems based on ITIES found a very few applications in e.g. sensing [1], redox catalysis [2], fundamental studies [3] among many other [4].

In our work, we have used three polyelectrolytes: polyethyleneimine (PEI), poly(styrene sulfonate) (PSS) and polyhexamethylene guanidine (PHMG) to create the thin polymer multilayer on a surface of fiberglass membranes. In first, the interfacial behavior of polyelectrolytes alone was studied at the unmodified liquid – liquid interface. Next, the fiberglass membrane was activated in 1M NaOH in order to assure the negative charge at its surface. Following that, the first polyelectrolyte layer – branched PEI – was deposited by simply immersing the membrane into PEI solution. The negatively charged PSS and the positively charged PHMG were then alternatively added using layer-by-layer (LBL) technique. When such membrane was used as a support for the ITIES, interesting current patterns – typical for miniaturized junctions – were recorded. AFM and SEM revealed the membrane surface morphology. Finally, the membrane sieving properties were examined. In this respect we have used a series of model quaternary ammonium cations (tetramethylammonium, tetraethylammonium, tetrapropylammonium, tetrabutylammonium). In future, our platform can find applications in liquid – liquid interface miniaturization, molecular separation and sensing.

Ultra-thin iridium layers were deposited on Ti$_2$AlC substrate from the solution containing K_3IrCl_6 and Na_2SO_4 (pH 6.2) at 70°C by using cyclic voltammetry. These novel materials were tested as the catalysts for hydrogen production – well known as an environmental friendly, green energy fuel. Namely, the hydrogen evolution reaction (HER) was investigated both in acid and alkaline electrolytes - 0.5 mol dm^{-3} H_2SO_4 and 1 mol dm^{-3} KOH. A variety of different thickness samples were characterized by physical-chemical characterization, as well as by electrochemical techniques.

Scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS) confirmed that the nucleation of Ir was not fast, indicating practically epitaxial growth of the deposit on Ti$_2$AlC substrate. The presence of cracks was detected in the thickest Ir layer (~ 260 nm) probably caused by increase of tensile strength. Metallic iridium was detected by X-ray photoelectron spectroscopy (XPS) at the surface of all samples, indicating complete reduction of iridium ions to zero valence state.

The HER was investigated by polarization and electrochemical impedance spectroscopy (EIS) measurements. Polarization curves were characterized with the low Tafel slopes of (between -10 and -20 mV dec^{-1}) up to about -0.1 A cm^{-2}, while at higher current densities the Tafel slopes increased up to ~ 60 mV dec^{-1}. The overpotential at the current density at j = -0.01 A cm^{-2} varied from 25 mV to 36 mV in acid solution, while being a slightly higher in alkaline electrolyte. These novel catalysts exhibited excellent activity, especially under industrial operating conditions of hydrogen evolution (j = -0.3 A cm-2) - the overpotentials for the best samples were ~ 70 mV only. The facts that electrodeposition is considered as cost effective synthesis way, as well as low cost and well established Ti$_2$AlC support preparation, these novel catalysts could be promising for commercial hydrogen production by water electrolysis.

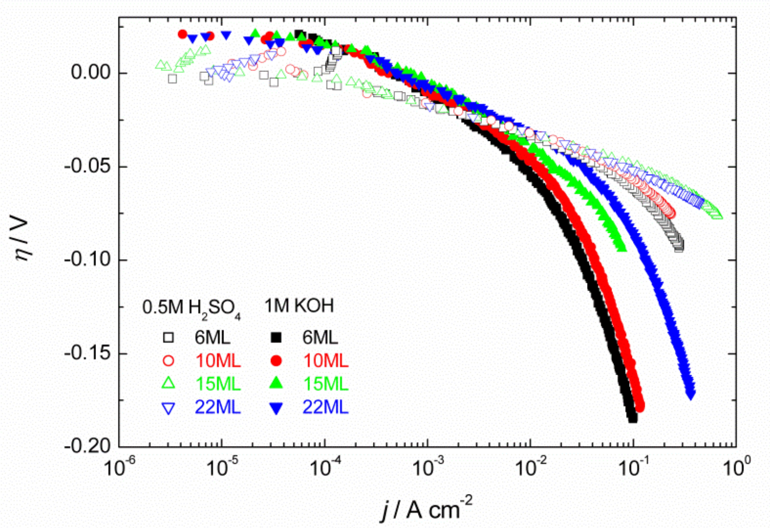

Fig1. HER polarization curves for representative Ir/Ti$_2$AlC samples in acid and alkaline electrolytes (ML-monolayer of iridium)

The structure of water in the sub-membrane region of the bilayer of DPhPC floating (fBLM) on a monolayer of 1-thio-β-D-glucose (β-Tg) modified gold nanoparticle film was studied by the surface enhanced infrared absorption spectroscopy (SEIRAS). SEIRAS employs surface enhancement of the mean square electric field of the photon which is acting on a few molecular layers above the film of gold nanoparticles. Therefore, it is uniquely suited to probe water molecules in the sub-membrane region and provides unique information concerning the structure of the hydrogen bond network of water surrounding the lipid bilayer. The IR spectra indicated that water with a strong hydrogen network is separating the membrane from the gold surface. This water is more ordered than water in the bulk. When alamethicin, a peptide forming ion channels is inserted into the membrane the network is only slightly loosened. The addition of amiloride-an ion channel blocker results in a significant decrease in the amount of water in the sub-membrane region. The remaining water has a significantly distorted hydrogen bonds network. This study provides unique information about the effect of the ion channel on water transport across the bilayer. The electrode potential has a relatively small effect on water structure in the sub-membrane region. However, the IR studies demonstrated that water is less ordered at positive transmembrane potentials. The present results provide significant insight into the nature of hydration of floating lipid bilayer on the gold electrode surface.

Solid-state batteries with Li metal anodes are emerging as a promising technology in the field of electrochemical energy storage, offering improved safety and high energy densities capable of meeting the demands of next-generation electric vehicles. Solid electrolytes based on doped, cubic $Li_7La_3Zr_2O_{12}$ (LLZO) garnets are a particularly promising class of materials for all-solid-state-batteries due to their wide electrochemical stability window and high Li-ion conductivities of ~1.0 mS cm−1 at 25ºC [1]. To realize their potential, tremendous efforts have been dedicated to improving the Li/garnet interface and increasing the critical current density at which failure takes place. With existing understanding of the surface chemistry of garnet pellets, specifically, the formation of Li2CO3 leading to increases in the Li/garnet interfacial impedance, various approaches have been developed to reduce, if not completely remove, the surface Li_2CO_3 layer [2]. In addition, maintaining uniform contact between Li metal and the solid electrolyte has also been shown to enable efficient, long-term plating and stripping of Li, as contact losses associated with morphological instabilities (e.g., vacancy accumulation and pore formation) are commonly found to be responsible for an increase in interfacial impedance and eventual cell failure [3]. Applied strategies have only managed to increase the cycle life of symmetric cells, and, until very recently, current densities above 1 mA cm-2 at 25ºC have remained inaccessible for planar LLZO membranes.

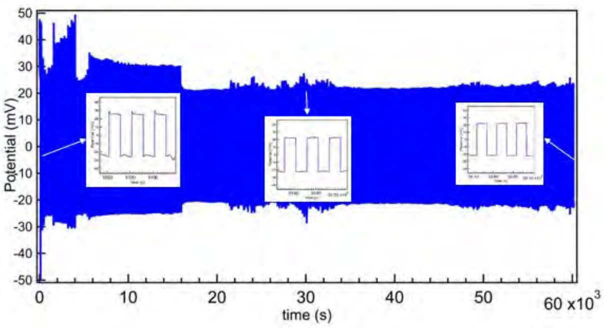

Figure 1. Galvanostatic cycling of Al-doped LLZO at 4 mA cm^{-2}. Al-doped LLZO sample exhibited stable DC cycling behavior for 18 h during 320 cycles.

Through the systematic application of our interfacial design strategy, we have demonstrated how deep understanding of the relationship between electrochemical performance of the anode-solid electrolyte interface and its structural and chemical properties can yield significant improvements in solid-state battery performance. Symmetric Li-Li coin cells were made using dense Al- and Ta-doped LLZO pellets prepared via our interface design strategy, which enabled cycling at current densities as high as 4 mA cm-2 without failure for >300 cycles with 0.5 µm Li plated/stripped per cycle. The significant improvements in performance demonstrated for both Ta- and Al-doped LLZO can be rationalized based on the combination of a conformal Li layer formed by vacuum deposition and complete formation of the ODI in the absence of any extrinsic oxide/carbonate impurities at the Li-LLZO interface. The presence of these features likely leads to a more homogeneous distribution of current density, inhibiting the nucleation of Li dendrites at so-called "hot spots," as well as the formation of a complete, self-limited reaction layer at the Li-LLZO interface. These results open up new opportunities to increase current densities in Li metal/solid electrolyte systems and approach performance limits that are dictated only by intrinsic materials properties.

Abstract

Copper (II) oxide (CuO) nanostructures were prepared on FTO using the sol-gel dip coating method. Two (2), four (4), six (6), eight (8) and ten (10) layers of dip coated films were prepared by drying each layer using a two-step method; at 110°C and 250°C for 10 and 5 min respectively. The films prepared were annealed at 550°C for 1 hr and allowed to cool down naturally to room temperature. The properties and photocatalytic performance of the films when applied towards hydrogen production were investigated. The XRD pattern of the films confirmed the tenorite phase of pure CuO. Raman spectroscopy only revealed the $1A_g$ and $2B_g$ phonon modes of CuO further confirming the purity of films produced. The photocatalytic performance of CuO films consisting of 6 layers produced the best results yielding photocurrent of -2.0 mA/cm^2 at -0.55 V vs Ag/AgCl while films with 2 layers recorded the least value of -1.1 mA/cm^2 at the same reference potential. Films prepared with 6 layers appeared to be more porous compared to others as revealed by FE-SEM studies, allowing for easier charge separation of photogenerated charge carriers, leading to the improved photocurrent observed. EIS analysis revealed the least charge transfer resistance at the CuO/electrolyte interface for films consisting of 6 layers while those with 2 yielded the highest values correlating with their photocatalytic performance. The two-step drying method for preparing CuO nanostructures have been optimized in this work, showing great promise for photocatalytic water splitting.
